There are several potential explanations for the diversity of ancient Os signatures found in these OJP peridotites. (i) Continental mantle was tectonically incorporated to the newly forming oceanic plateaux, analogous to the scenario suggested for the Kerguelen plateau mantle [4]. (ii) The OJP lithosphere may be sampling the inherent isotopic variability of the oceanic mantle as represented by abyssal peridotites, which overlaps the range reported here (extending to \( ^{187}\text{Os}/^{188}\text{Os} \) as low as 0.110 in sulfide grains from abyssal peridotites [5]). (iii) The depleted Os isotope compositions may reflect recycled heterogeneity within the upwelling plume source, as suggested recently for Hawaii [6]. Option (iii) may best explain the absence of old continental materials around the OJP, the contrasting Os isotope ratios between shallow and deep lithosphere, and the presence of recycled pyroxenite of Proterozoic age in the basal lithosphere [7]. Thus, the OJP may have been generated by mantle plume consisting of a mix of ancient, depleted, recycled Proterozoic lithosphere.
Amphibolite-facies metamorphism of the subducted slab and boninite magma genesis: An inference from the Oman ophiolite

T. ISHIKAWA1, K. NAGAISHI2 AND S. FUJISAWA3

1Kochi Institute for Core Sample Research, JAMSTEC, Kochi, Japan (t-ishik@jamstec.go.jp)
2Marine Works Japan Ltd., Kochi, Japan (nagaishi@jamstec.go.jp)
3Institute of Geoscience, Shizuoka University, Shizuoka, Japan

The Oman ophiolite contains boninite and other arc-related volcanic rocks generated after the magmatism of spreading-ridge ceased. The initiation of subduction of a young, hot oceanic lithosphere (and obduction of the future Oman ophiolite) near the spreading ridge and the resultant melting of the hydrous shallow mantle wedge represent the most favorable mechanism for the genesis of the Oman boninites. On the other hand, this ophiolite is underlain by a thin sliver of amphibolite-granulite-facies metamorphic rocks. These rocks (metamorphic sole) are believed to represent oceanic crust overridden and “ironed” by the ophiolitic lithosphere, and may be analogous to the subducted slab that contributed to producing the geochemical signature of the Oman boninites. Thus the Oman ophiolite provides a best opportunity for investigating the link between the amphibolite-facies metamorphism of the slab and the boninite magma genesis in the mantle wedge.

The amphibolites in the 230 m-thick metamorphic sole in Wadi Tayin area show significant variation in fluid-mobile element concentrations across the transect of the sole. The observed variations suggest that the amphibolites (>600°C in peak metamorphic temperature) near the contact with the overlying peridotite were equilibrated with evolved, B-Rb-K-Ba-rich fluids formed through successive fluid-rock interactions during prograde metamorphism. The estimated amphibolite-derived fluids are characterized by striking enrichments of B, Rb, K and Ba and moderate to minor enrichments of Sr, Li, Be and Pb. It is also suggested that at higher temperature (up to 700 °C), the fluids become considerably enriched in light REE and Nb in addition to the above elements. Model calculations showed that the trace element characteristics of the Oman boninites, including their U-shaped REE patterns and relatively low Ba/Rb ratios, are successfully explained by partial melting of the highly depleted mantle that had been metasomatized by the amphibolite-derived fluids. The Sr and Nd isotope compositions of the boninites and related volcanic rocks in the Oman ophiolite are also consistent with the involvement of such fluids. The compositions of the fluids liberated from the amphibolite-facies slab are likely to vary dependent on the metamorphic temperature, and the evolution and hybridization of such fluids may produced considerable variations in trace element and isotope compositions observed in the boninites.

The magmatic plumbing of the submarine volcanic chain of an oceanic island arc volcano: Long distance lateral magma transport?

O. ISHIZUKA, N. GESHI, J. ITOH, Y. KAWANABE AND T. TSUJINO

Institute of Geoscience and Geoinformation, Geological Survey of Japan/AIST (o-ishizuka@aist.go.jp)

Recent geophysical observations on basaltic composite volcanoes in Izu arc reveal the process of long distance lateral magma transport within the arc crust. Such intrusion events sometimes caused flank fissure eruption and also triggered a formation of collapsed caldera (Miyakejima 2000). To clarify a long-distance magma transport system of the basaltic volcano in volcanic arc from geological and petrological aspects, we investigated a submarine volcanic chain (Hachijo NW chain) and satellite cones nested Hachijo Nishiyama volcano, a frontal composite volcano in the northern Izu arc.

Basalts from the Hachijo NW chain generally have more primitive composition compared to those from the Nishiyama. The bulk compositional trend of Hachijo NW chain magma is controlled by crystal fractionation while plagioclase accumulation was indicated by aluminum-rich character of the Nishiyama volcano and its subaerial and submarine satellite cones other than NW chain edifices.

Trace element ratios unaffected by melting or crystal fractionation (e.g., Nb/Zr) and isotopic compositions are not significantly different between the Nishiyama and the Hachijo NW chain. This implies that the sources of magma for these volcanic systems are identical. However, Hachijo NW chain shows lower LREE/HREE and Zr/Y. These differences in trace element ratios could be ascribed to difference in degree of partial melting of the source or crustal assimilation. Assuming difference in degree of partial melting, Nishiyama magma, which is much more voluminous than Hachijo NW chain magma, should have lower degree of melting relative to Hachijo NW chain. Instead we prefer a model considering larger extent of crustal assimilation for Nishiyama magma, where assimilated crust is expected to have higher LREE/HREE and Zr/Y, but similar isotopic composition to basaltic primary magma.

Nishiyama magma is assumed to form shallow crustal magma chamber where it experienced crustal assimilation and plagioclase accumulation. Satellite cones other than NW chain can be explained by magma transport from this magma chamber in the shallow crustal level. On the other hand, Hachijo NW chain was tapped by the same primary magma as Nishiyama volcano, but experienced much less crystal fractionation and assimilation in the crust during ascent without forming shallow magma chamber. Long distance magma transport is assumed to have occurred in the lower crustal level, which is consistent with the depth of hypocenters of seismic event in 2002.
Adsorption of As(III) and As(V) onto vivianite – Evaluation as a sink for arsenic in Bengali aquifers

F.S. ISLAM1,2, M. LAWSON1, P.R. LYTHGOE1, R.A. WOGELIUS1, V. THINNAPANN1, J.R. LLOYD1, J.M. CHARNOCK1 AND D.A. POLYA1

1SEAES, University of Manchester, UK, M13 9PL
2now at Department of Land Resource Science, University of Guelph, Ontario, CANADA, N1G 2W1

Although microbially mediated reduction of Fe(III) oxy-hydroxide phases is thought to be critically implicated in the mobilisation of arsenic in shallow aquifers in Bengal (Islam et al., 2004), Cambodia (Rowland et al., 2004) and other parts of world, there is substantial evidence that mobility of arsenic in such aquifers is also controlled by the nature and distribution of secondary Fe-bearing phases. Secondary Fe-sulfides, magnetite, siderite and vivianite have all been suggested as potential arsenic sinks. Whilst there are considerable data on the adsorption and/or incorporation of arsenic into Fe-sulfides (Farquhar et al., 2002; Wolthers et al., 2005) and magnetite (Dixit and Hering, 2003; Coker et al., 2006) there is a dearth of such data for vivianite. In this study, we report the sorption behaviors of both arsenite and arsenate on vivianite under anaerobic conditions as a function of solution pH and dissolved arsenic oxidation state and concentration.

Natural well crystallised vivianite was characterised by ESEM/EDS, XRD, EPMA and BET and then mixed (1:8 wt/wt) with 1, 10 and 100 µM of As(III) or As(V) in a background electrolyte of 0.1 M NaNO₃ with pH adjusted from 3 to 11 with HNO₃ or NaOH. Solutions were purged with nitrogen and the studies were conducted under a modified atmosphere of 5% H₂ + 95% N₂ in an anaerobic cabinet at ambient temperature (T = 23 +/- 3°C) and pressure. Fe, P and As in the aqueous phase after 40 hours were measured by ICP-AES.

The adsorption of As(III) was found to be pH dependent, increasing from 10% of a 100 µM solution at pH 3 to 33 % at pH 10 and 75% at pH 11. Implications for the scavenging capacity of vivianite for As(III) in shallow reducing groundwaters in Bengal are discussed.

Fossilized microorganisms from Emperor Seamounts: Evidence for a deep sub-seafloor biosphere

M. IVARSSON AND N.G. HOLM
Dept. of Geology and Geochemistry, Stockholm University, Sweden (magnus.ivarsson@geo.su.se; nils.holm@geo.su.se)

Fossilized microorganisms have been observed in drilled samples of seafloor basalts collected during ocean Drilling Program (ODP) Leg 197. During that leg three different seamounts belonging to the Emperor Seamounts in the Pacific Ocean were drilled: Detroit (81 Ma), Nintoku (56 Ma) and Koko (48 Ma) Seamounts respectively. A wide variety of microbial-like structures were found in veins, attached to mineral surfaces and embedded in minerals like calcite, aragonite and gypsum. Morphologically, the microfossils vary a lot. Globular cell-like coccoids, sheaths, segmented filaments, twisted filaments and branched filaments were found. With ToF-SIMS (Time of Flight Secondary Ion Mass Spectrometry) fatty acids and lipids were detected in the microfossils. This is, to our knowledge, the first time such compounds have been found in association with microbial remnants from sub-seafloor environments. ToF-SIMS further showed concentrations of C₅H₄ and PO₃ in the microfossils. The biogenicity was also supported by dying the microfossils with the pigment PI (propidium iodide) that binds to dead bacteria cells and remnants of DNA. EDS-analyses showed that they contain slight amounts of elements like Si, Al, Mg, K and Na but very high amounts of carbon (~10-50 wt % C) and iron (~10-50 wt % Fe). The high iron content as well as a close association with iron oxides and deposition of iron oxides onto the filaments indicate that the microorganisms were involved in iron oxidizing reactions and that iron probably served as an energy source for the metabolism of the microorganisms.

Our observations show that all three seamounts drilled during ODP Leg 197 have been supporting a deep sub-seafloor biosphere during their volcanically active period of time when hydrothermal activity was present and fluids circulated the rocks.
Determination of production rates of cosmogenic nuclides based on data from large landslides in the Alps

S. IVY-OCHS¹, P.W. KUBIK², V. ALFIMOV¹ and H.-A. SYNAL²

¹Teilchenpyshik, ETH-Hoenggerberg CH-8093 Zurich, Switzerland
²Paul Scherrer Insitut c/o Teilchenpyshik, ETH-Hoenggerberg CH-8093 Zurich, Switzerland

We are analyzing samples from boulder and bedrock surfaces associated with large prehistoric landslides in the Alps for ¹⁰⁷Be, ²⁶Al and ³⁶Cl. In addition to determining the ages for undated landslides, we are examining cosmogenic nuclide production rates based on results from landslides with independent age constraints (for example Flims, Graubuenden Switzerland and Koefels, Tirol, Austria). We focus on ¹⁰⁷Be, ²⁶Al in crystalline regions with abundant quartz, while ³⁶Cl is used in areas underlain by calcareous rocks. Potential complications include pre-exposure, post-slide rock fall, and shielding by soil or snow. Results from several sites as well as the problems encountered will be discussed.

Independent component analysis of isotopic compositions of oceanic basalts

HIKARU IWAMORI¹ AND FRANCIS ALBARÈDE²

¹University of Tokyo (hikaru@eps.s.u-tokyo.ac.jp)
²École Normale Superieure de Lyon (albarede@ens-lyon.fr)

Isotopic variations in oceanic basalts indicate possible interactions among several distinct mantle components, such as DMM, EM, FOZO, C, HIMU, etc. Increasing number of data for various isotopic systems now allows us to systematically search the structure hidden in the multivariate compositional space by independent component analysis, ICA [1]. Principal component analysis (PCA) has been regarded to be the most efficient way to display the extreme mixing end-components. However, it has a fundamental problem: PCs are independent only when the data distribution follows the Gaussian distribution, which is not in this case. ICA is the method to deconvolute a data set into independent components that maximize the non-Gaussianity of the projected distribution of the data. Based on ICA, we have explored the isotopic compositional space of the oceanic basalts from Atlantic and South Indian Oceans, based on the data from literature [21] and GEOROC database. We show that the two independent compositional vectors/directions (referred to as independent components or ICs) are involved to create the variations with six isotopic ratios of Pb, Sr, Nd and Hf. One of the two ICs clearly divides OIBs and MORBs, while another IC distinguishes the geographical distribution including DUPAL anomaly. This feature supports that the two ICs are indeed independent. We also show that the conventional mantle end-components are not appropriate to represent the compositional space. Instead, two independent processes that create vectors parallel to DMM-FOZO or towards EM are proposed to explain the independent compositional space. Since the average composition of the oceanic basalts is similar to that of the average DMM, around which MORBs and OIBs are roughly symmetrically distributed in the IC space, we argue that these processes occur as two dominant but independent differentiation processes within the depleted mantle domain. Considering these nature, one IC is likely to be produced by recycling and stirring of MORB and its residue, while another IC is possibly created by the subduction zone processes. According to the ICs, the criterion of DUPAL anomaly is re-defined. As a result, distribution of the enriched region is modified, showing that the enriched signature disperses into the northern hemisphere.

The simulation experiments on hydrothermal formation of organic globules in carbonaceous chondrites

TAKU IWAMOTO, TADASHI YOKOYAMA AND SATORU NAKASHIMA
(tiwamoto@ess.sci.osaka-u.ac.jp)

Organic globules were found in the Tagish Lake meteorite (carbonaceous chondrite fallen in 2000). Since then, further characterizations of these globules in meteorites have been conducted. However, the formation processes of organic globules remain unclear. In order to simulate the globule formation processes, a series of hydrothermal heating experiments of an OH-bearing amino acid (threonine: Thr) have been conducted in the presence of some rocks (rhyolite, basalt).

40 ml of Thr solution with a rock piece was heated in a hydrothermal vessel at 160°C for 4 days, globules of 2 to 20 micrometers in size were observed under Scanning Electron Microscope (SEM) on the rock surface. By elemental analysis of the globules, they are found to be carbon rich substances. This result suggests that the organic globules found in Tagish Lake meteorite might be formed by organic-inorganic interactions during the aqueous alteration of the chondrite parent body.

In order to study quantitatively the globule formation processes, hydrothermal heating experiments of Thr solutions have been conducted with the silicate glass slide having smooth surfaces. SEM images of glass surfaces showed that diameters and numbers of globules increased with the heating duration and with the temperature. By image analyses, grain size distributions and mean diameters of globules have been determined. Growth rates of organic globules at different temperatures were evaluated by means of their mean diameters. Based on these results, formation of globules of about 300 nm in diameter would need several hundred years under the temperature of aqueous alteration (20°C). These results can be used to estimate temperature conditions and time scales of organic globule formation in the meteorite parent body.

Processes of biomineralization in freshwater cultured pearls

D.E. JACOB, A.L. SOLDATI AND U. WEHRMEISTER
Department of Geosciences, Johannes Gutenberg-University, D55099 Mainz, Germany. (jacobd@uni-mainz.de, soldatia@uni-mainz.de, wehrmeis@uni-mainz.de)

Freshwater cultured pearls formed by the mussel *Hyriopsis* represent excellent examples to study processes of biomineralization in molluscs. They are grown by inserting a piece of epithelial tissue from the mantle lobe into the mussel where processes identical to those forming the mussel shell occur.

Resonance Raman Spectroscopy of polished pearl cross-sections revealed that ca. 50% of the samples contain vaterite in addition to aragonite. Vaterite is the thermodynamically most unstable polymorph of CaCO$_3$ and is often discussed as a precursor phase in the mineralization of aragonite or calcite by organisms (Weiss et al., 2002). Vaterite forms relatively small areas in high quality pearls (1-1.5 mm diameter) which are spherical to irregular and always in close proximity to the center of the pearl. However, in low-quality pearls, they can be much larger, sometimes comprising the major part of the pearl, including the surface (Ma and Lee, 2006; Qiao et al., 2006).

To further study the micro-structure of the vaterite zones, cross-sections were etched with Mutvei’s solution (Schoene et al., 2005). This etching method dissolves the calcium carbonate surface with acetic acid, while the organic matrix is stabilized with glutaraldehyde and Comassie Blue colours the organic material in intensities which correspond to the concentration of the organics. SEM analyses of the etched surfaces show that growth rings transect the vaterite areas, implying that vaterite and aragonite grew simultaneously, and that vaterite may not have been an initial template for aragonite growth.

LA-ICP-MS and electron microprobe were used to quantify minor and trace elemental differences between the calcium carbonate polymorphs. Vaterite areas have about 1400 ppm Mg and 1000 ppm Na, versus around 30 ppm Mg and 1650 ppm Na found in aragonite. The Sr concentration in vaterite (250 ppm) is about half of that found in aragonite, while for Mn, Zn and Ba no significant differences were detected.

Thermodynamic assessment of the magnesium-olivine-pyroxene system using a lattice vibrational technique

M.H.G. Jacobs1, A.P. van den Berg1 and B.H.W.S. de Jong2

1Dept. Theoretical Geophysics, Faculty of Geosciences, Utrecht Univ., Budapestlaan 4, 3584CD Utrecht, The Netherlands (Jacobs@geo.uu.nl)
2Petrology Group, Faculty of Geosciences, Utrecht Univ., Budapestlaan 4, 3584CD Utrecht, The Netherlands (Bernard@geo.uu.nl)

We are currently constructing a thermodynamic database providing phase diagrams, thermophysical and therchemochemical properties for materials with a geophysical relevance, applicable in the pressure and temperature regime of the Earth’s mantle. The computational technique is based on Kieffer’s (1979) approach to model the vibrational density of states of a substance, a key property to derive the Helmholtz energy. It allows the calculation of $V_T$ and $V_A$ sound wave velocities. The developed thermodynamic framework uses model input properties related to Raman and infrared spectroscopic data. It puts tighter constraints on therodynamic properties compared to methods based on polynomial parameterisations of thermal expansivity, heat capacity and isothermal bulk modulus. Jacobs and de Jong (2005) and Jacobs et al. (2006), showed that this framework entails a description of properties free from physical anomalies for close-packed materials. In addition it discriminates, based on internal consistency, between the quality of disparate sets of experimental therchemochemical, thermophysical and phase diagram data.

The present work focuses on the application of vibrational modeling to the magnesium-olivine-pyroxene system, which constitutes over 90% of the Earth’s mantle and which is intimately linked to the magnesium-olivine system by the common phases wadsleyite, ringwoodite and perovskite. We show how our approach is used in a thermodynamic assessment of experimental data. The results, presented here, were used in a numerical model of convection in the Earth’s mantle to reveal, effects of phase transitions on the degree of layering, mineral distribution and sound wave velocities in the transition zone, around 660 km depth in the Earth.

Accretion and early differentiation history of the Earth based on extinct and long-lived chronometers

S.B. Jacobsen1, M.C. Ranen1, M.I. Petaev1, J.L. Remo1 and Q.-Z. Yin2

1Initiative for Origins, Harvard University, Cambridge, MA 02138, USA (jacobsen@neodymium.harvard.edu)
2Department of Geology, University of California at Davis, Davis, CA 95616, USA

Jacobsen and Harper (1996) showed that isotopic variations due to decay of extinct nuclides ($^{129}$I, $^{244}$Pu, $^{182}$Hf and $^{146}$Sm) could be used to study early evolution of terrestrial reservoirs and provide observational constraints on the timescale of accretion of the terrestrial planets. Measurable variations in $^{182}$W/$^{183}$W, $^{142}$Nd/$^{144}$Nd, $^{129}$Xe/$^{130}$Xe and $^{136}$Xe/$^{138}$Xe in the Earth (compared to bulk planetary values inferred from primitive meteorites) provide a preserved record of accretion, core formation, early crust, atmosphere formation and evolution. The $^{182}$Hf-$^{182}$W system is the best accretion and core-formation chronometer because it is identifiable with chemical fractionation during the accretion process itself. This system yields a mean time of Earth’s accretion and core formation of 10 Myr, with a total timescale of accretion being 30 Myr. New experimental data pertaining to the conditions that existed in the Earth’s deep mantle ($P > 100$ GPa and $T > 6000$ K) subsequent to the giant Moon-forming impact show that metal-silicate equilibrium will be rapid enough for the Hf-W chronometer to reliably record this timescale (Petaev et al. 2007). Although the $^{206}$Pb/$^{204}$Pb chronometer has been used to argue for a more protracted timescale (~100 Myr) of accretion and core formation, Yin and Jacobsen (2006) showed that these data do not require a longer time scale. Using the coupled $^{146}$Sm - $^{147}$Sm chronometer, the age of the initial silicate differentiation in the mantle source region of some of the Earth’s oldest surviving crustal rocks can be constrained to ~4.47 Ga. Attempts to use this chronometer for dating proto-crust formation at ~30 Myr are unreliable because of the uncertainties in the initial Nd isotopic composition inferred from heterogeneities in Ba and Nd isotopes in primitive meteorites (Ranen and Jacobsen 2006). The presence of a large $^{129}$Xe excess in the deep Earth is consistent with a very early formation and a short time interval for the accretion of the Earth.

δ$^{44}$Ca evolution during water-rock interaction in a carbonate aquifer

ANDREW D. JACOBSON$^1$ AND CHRIS HOLMDEN$^2$

$^1$Department of Earth and Planetary Sciences, Northwestern University, Evanston IL (adj@earth.northwestern.edu)
$^2$Saskatchewan Isotope Laboratory, Department of Geological Sciences, University of Saskatchewan, Saskatoon, Canada (chris.holmden@usask.ca)

To improve understanding of Ca isotope transport during water-rock interaction on the continents, we measured δ$^{44}$Ca values along a 236 km flow path in the Madison aquifer, South Dakota, where fluids have chemically evolved according to dolomite and anhydrite dissolution, calcite precipitation, and Ca-for-Na ion-exchange over a timescale spanning ~15 kyr. We use a reactive transport model that employs rate data constrained from major ion mass-balances to evaluate the extent to which calcite precipitation and ion-exchange fractionate Ca isotopes. Elevated δ$^{44}$Ca values during the initial and final stages of water transport may result from calcite precipitation under supersaturated conditions and Ca-for-Na ion-exchange, respectively. However, for the bulk of the flow path, δ$^{44}$Ca values evolve by mixing between dolomite and anhydrite dissolution, with no fractionation during calcite precipitation under saturated conditions. We attribute the absence of Ca isotope fractionation to the long timescale of water-rock interaction and the slow rate of calcite precipitation, which have enabled fluids to chemically and isotopically equilibrate with calcite. We therefore conclude that the equilibrium Ca isotope fractionation factor between calcite and water (Λ$_{calc-w}$) is very close to zero. We further reason that instances of $^{44}$Ca enrichment attributed to calcite precipitation must stem from kinetic isotope effects. To the extent that the Madison aquifer typifies other groundwater systems, our study suggests that groundwater δ$^{44}$Ca values can be modelled according to simple mixing theory, without the need to invoke isotope discrimination during calcite precipitation. We suggest that groundwater may play an important role in transmitting the pristine isotopic signature of Ca mineral weathering to the oceans, by way of surface–groundwater interactions in tributary networks of large rivers.

Diatom δ$^{13}$C, δ$^{15}$N, and C/N since the Last Glacial maximum in the Southern Glacial Ocean: Evidence for regional and ecological influences

H. JACOT DES COMBES$^{1,2}$, C.L. DE LA ROCHA$^1$, O. ESPER$^1$, A. ABELMANN$^1$, R. GERSONDE$^1$ AND A. SHEMESH$^2$

$^1$Alfred Wegener Institute for Marine and Polar Research, Germany (Helene.Jacot.desCombes@awi.de, Christina.De.La.Rocha@awi.de, Oliver.Esper@awi.de, Andrea.Abelmann-Gersonde@awi.de, Rainer.Gersonde@awi.de)
$^2$Department of Environmental Science & Energy Research, Weizmann Institute of Science, Israel (Aldo.Shemesh@weizmann.ac.il)

The carbon and nitrogen isotopic composition (δ$^{13}$C and δ$^{15}$N) and C/N ratio of diatom-bound organic matter is commonly used to reconstruct oceanographic processes that contribute to variations in atmospheric CO$_2$ over glacial-interglacial cycles. This organic material is presumed to be part of the diatom cell wall and the template for biomineralization, entombed upon silicification and protected from diagenesis. However, this material has not been well characterized and there is no strong sense yet for how variable its composition is between species or among members of the same species growing under different conditions. In addition, the studies that have been carried out on isotopic fractionation by diatoms have focused on the “whole cell” isotopic composition and not specifically that of the material occluded within the matrix of the silica. Some investigation of this matters would go a long way towards refinement of these proxies for nutrient utilization and primary production.

Towards this end, measurements of δ$^{13}$C, δ$^{15}$N, and C/N on diatom-bound organic matter were made over the Holocene and Last Glacial Maximum (LGM) from 3 piston cores in the Southern Ocean, one from each of the three sectors. The site in the Atlantic sector differs considerably from the other two sites by having markedly lower δ$^{13}$C, more variable δ$^{15}$N and C/N ratios, and a sedimentary diatom assemblage that is never dominated by Fragilariopsis kerguelensis. The proportion of F. kerguelensis in the samples, and to a lesser degree, the carbon content of the organic matter, have a strong influence on δ$^{13}$C. Extreme values of δ$^{13}$C, δ$^{15}$N, and C/N at the Last Glacial Maximum are also related to the abundance of resting spores of Eucampia antarctica. These results suggest that methods for the separation of specific diatom species out of opal sediments would considerably aid in the reconstruction of paleoceanographic conditions from diatom stable isotope and elemental records.
Formation of hydrozincite, Zn layered double hydroxide and Zn phyllosilicates in contaminated calcareous soils

Olivier Jacquat, Andreas Voegelin and Ruben Kretzschmar

Institute of Biogeochemistry and Pollutant Dynamics, Department of Environmental Sciences, ETH Zurich, CHN, 8092 Zürich, Switzerland (jacquat@env.ethz.ch)

The incorporation of Zn into layered mineral structures such as layered double hydroxides (LDH) or phyllosilicates may reduce its mobility and bioavailability in soils. The quantity and structure of Zn bearing layered phases forming in soils depend on soil physicochemical properties and contamination level. To date, most spectroscopic studies on the speciation of Zn considered neutral to acidic non-calcareous soils. In this study, we investigate the reactivity and speciation of Zn in contaminated soils developed from calcareous and dolomitic parent material.

Five soils developed from limestone and one developed from dolomite were sampled below power line towers made from galvanized steel that had been constructed 30 to 50 years ago. All soils have been contaminated by input of runoff water containing dissolved Zn from corrosion. The soils cover a wide range in clay content (90-450 g/kg), inorganic carbon content (10-89 g/kg), and Zn concentration (1'300 - 30'000 mg/kg). They have pH values between 6.1 and 7.5. The molecular scale speciation of Zn in the soil matrix was investigated by Zn K-edge EXAFS spectroscopy on powdered soil samples. Thin sections from two calcareous soils (1'300 and 30'000 mg kg\(^{-1}\) Zn) and the dolomitic soil (1'400 mg kg\(^{-1}\) Zn) were further studied by µ-X-ray fluorescence (µ-XRF) and µ-EXAFS spectroscopy. Principal component analysis and target testing indicated that octahedrally coordinated Zn in layered minerals and tetrahedrally or octahedrally coordinated sorbed Zn are likely candidate species. In the dolomitic soil, pure Zn-phyllosilicate was identified in Zn-rich spots. In the calcareous soil containing 30'000 mg kg\(^{-1}\) Zn, the Zn was diffusely distributed in the soil matrix with a spectrum similar to Zn-LDH. Crusts on calcite particles from the same soil were identified as hydrozincite using powder X-ray diffraction and EXAFS spectroscopy. Linear combination fits to the bulk EXAFS spectra indicate that LDH- and phyllosilicate-type precipitates account for a considerable fraction (17-53%) of the total Zn in all soils. To quantify the reactivity of Zn, the soils as well as synthetic references were fractionated using a 7-step sequential extraction procedure (SEP). Between 32-65% of the total Zn in the soils was extracted in the first two fractions (1M NH\(_4\)NO\(_3\) and 1M NH\(_4\) acetate at pH 6.0, respectively), suggesting that most Zn occurred in labile species. Zn-LDH, Zn-phyllosilicates and hydrozincite showed similar chemical reactivity with 46 to 84% of the total Zn mobilized in the first two fractions.

Solving the mystery of SNC meteorites

E. Jagoutz\(^1\), G. Dreibus\(^1\) and R. Zartman\(^2\)

\(^1\)Max Planck Institute for Chemistry, D-55020 Mainz, Germany (Emil@jagoutz.de)
\(^2\)EAPS, Massachusetts Institute of Technology, Cambridge, MA 02139, USA (rzartman@mit.edu)

Rb-Sr, Sm-Nd and U-Th-Pb isotopes have been intensively studied on SNC meteorites. There is a general consensus that these meteorites are magmatic rocks. While in terrestrial magmatic rocks the Rb-Sr system usually shows a greater melt-residue fractionation than the Sm-Nd system, it is just the reverse in the case of the SNC meteorites. While the whole rock SNC meteorites scatter along a 4.5Ga Rb-Sr reference isochron showing only a slight disturbance, the Sm-Nd isotopes for the same whole-rocks are strongly fractionated, with a considerable depletion of Nd for the shergottites and an enrichment of Nd for the nakhlites. One would expect that a magmatic fractionation would cause a strong enrichment in Rb, but only a moderate enrichment in Nd. The shergottites, however, which clearly originally crystallized from melts, show no significant enrichment in Rb but, by contrast, a strong depletion in Nd. The nakhlites, which are mafic cumulates with a residual major element chemistry, experienced a significant Nd enrichment. Model-calculations that are able to explain the Sm/Nd evolution cannot be extended to the other REE and completely fail to explain the observed Sm/Yb and La/Nd ratios. A mixing model reveals the need for three components to explain the composition of shergottites and nakhlites, but does not contribute to an understanding of a realistic magmatic process.

Recently we developed a magmatic model that consistently explains the observed petrographic and isotopic data for SNC meteorites. It is based on the premise that the basaltic shergottites, Shergotty, Zagami, and Los Angeles, have typical crustal compositions and were differentiated very early at 4.4 Ga, while nakhlites and olivine-bearing shergottites, Que, SAU, Y89, and others, derive from a nearly homogeneous mantle source [1].

Minor heterogeneities in the Sr and Pb isotopes are insufficient to argue against a common mantle source, and reported W isotopic differences might be caused by terrestrial contamination (the intrinsic W contents of the shergottites, as estimated from the W/La in these meteorites, may be unmeasurable). To explain their unusual fractionation pattern, we postulate the presence of two phosphates in the Martian mantle: xenotime and monazite. At the time of fractionation, xenotime partitions into the olivine bearing shergottites while monazite partitions into the nakhlites. This phosphate chemistry has little effect on the Rb-Sr system, strongly fractionates between the light and heavy REE. Because in such an environment the trace-elements do not follow Henry’s law, commonly employed melting models cannot be applied.
Differences between preserved vs. delaminated lower crust: Evidences from the Kohistan arc

Delamination and foundering of the lower continental crust (LCC) into the mantle are important crust forming mechanisms. However, knowledge of the composition and mineralogy of the preserved and/or delaminated LCC remains scarce. We provide a synopsis of recent research within the Kohistan arc (Pakistan). We show that hydrous and “less-hydrous” liquid lines of descent related to flux and decompression melting, respectively, produced compositionally different lower crustal rocks in the Kohistan arc. These observations allow a new model for CC formation where delaminated and preserved LCC differ in mineralogy and composition.

Within the Kohistan arc two mantle-lower crustal sections are exposed: the older Jijal section and the younger, rifting-related Chilas section. We describe lithologies of these sections and argue that fractionation mechanisms that produced them document two liquid lines of descent with largely differing initial water contents. The Jijal liquid line of descent is typical for a hydrous, high-pressure fractionation sequence (e.g. pyx, grt, Fe/Ti-oxides, amph, An-rich plag). The composition of the Jijal lower-crustal gabbroic rocks differs markedly from bulk lower crust estimates but is complementary to silica-rich rocks (tonalite, granite etc.), exposed within the Jijal section and within the so-called Kohistan Batholith.

The Chilas liquid line of descent is typical for a “less-hydrous” fractionation sequence (e.g. ol, pyx, plag, amphib). Gabbro-norite to diorite rocks are dominantly composed of plagioclase, clinopyroxene and orthopyroxene (±quartz, ±amphibole). Despite the similarity of the Chilas gabbroic rocks to typical lower crust compositions, the “less hydrous” fractionation results in massive amounts of gabbroic material and small volume of silica-rich rocks. This mass balance and their mineralogy precludes them to represent the magmatic equivalent of the upper crust.

We propose that the upper, non-sedimentary CC is dominantly formed by hydrous high-pressure fractionation with subsequent delamination of the complementary garnet-pyroxene-amphibole-rich LC cumulates. This LC The delaminated amphibole-rich lower Jijal crust has trace element content and mineralogy adequate to explain certain characteristics of OIB. In contrast, the LCC, which is preserved over geological timescales, is formed by “less-hydrous” parental melts. We suggest that the bulk crustal composition is a mixing between these two compositional end-members.

Plastic deformation of orthoenstatite and the ortho- to high-P clinoenstatite transition studied by atomistic simulation

S. JAHN1 AND R. MARTOŇÁK2

1GeoForschungszentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (jahn@gfz-potsdam.de)
2Department of Experimental Physics, Comenius University, Mlynská dolina F2, 84248 Bratislava, Slovakia

Atomistic computer simulation techniques are used to study plastic deformations of orthoenstatite, MgSiO3, at high pressure, P, and high temperature, T. The combination of molecular dynamics with metadynamics allows the direct observation of the structural changes at the atomic scale during the creation of stacking faults in the (100) planes. The respective slip deformations consist of at least four partial deformations crossing high energy intermediate structures. Although the low energy structures that may be observable experimentally suggest a dominant (100)[001] single slip system, the partial deformations also have contributions in (100)[010] direction.

Choosing conditions in the stability field of high-P clinoenstatite (T=1000 K, P=15 GPa), one sequence of plastic deformations in orthoenstatite leads to reformation of perfect orthoenstatite, whereas a second sequence results in the formation of the thermodynamically stable high-P clinoenstatite. From experiments (Lin, 2003; Kung et al., 2004) it is known that due to the high kinetic barrier of the partly reconstructive phase transition, the formation of high-P clinoenstatite is prevented at ambient T in a wide pressure range up to at least 22 GPa. We are able to identify some of the possible metastable high-P polymorphs of orthoenstatite, which lead to anomalous behavior of the elastic properties (Kung et al., 2004) and to changes in the Raman spectra (Lin, 2003).

The influence of metasomatized mantle wedge related to flat-subduction processes in extra back-arc basalts in Patagonia, Argentine

T.L.R. JALOWITZKI\(^1\), R.V. CONCEIÇÃO\(^2\) AND Y. ORIHASHI\(^3\)

\(^1\)Instituto de Geociências, UFRGS, Porto Alegre - RS, Brazil (tiago.jalowitzki@ufrgs.br)
\(^2\)Instituto de Geociências (CPGq), UFRGS, Porto Alegre - RS, Brazil (rommulo.conceicao@ufrgs.br)
\(^3\)Earthquake Research Institute, The University of Tokyo, Tokyo, Japan (oripachi@eri.u-tokyo.ac.jp)

During the Cenozoic age, there were relatively large volumes of basaltic lava eruptions in the eastern Andes along the Chile trench, South America, which generated extensive volcanic plateaus in a geotectonic environment of continental “extra” back-arc. The outcropping volcanic products in the studied area are displaced from 34ºS to 46º30’S and host ultramafic xenoliths. Twenty-three samples of volcanic basalts from 11 different localities were analyzed. These rocks are basanites-tefrites, trachybasalts and basalts of the alkaline series, with phenocrysts and/or xenocrysts of olivine, orthopyroxene and clinopyroxene. In general, REE patterns for these rocks present similar variation with an expressive enrichment in light REE in relation to the heavy REE. The multi-elemental diagram analyses allow the individualization of the basalts into two groups with distinct behaviors. Group I shows OIB-like characteristics with Th enrichment and Pb depletion, while Group II presents OIB-like characteristics with Pb, Ba and Sr enrichment, which is related to some influence of the subduction zone. Isotopic data for both group present low \(^{87}\text{Sr}/^{86}\text{Sr}\) isotopic ratios (0.7031-0.7049) and moderate \(^{143}\text{Nd}/^{144}\text{Nd}\) values (0.512689 to 0.512983) that are comparable to typically mantle basalts with OIB characteristic, according to Hart and Zindler (1989). However, Group I generally exhibit higher \(^{143}\text{Nd}/^{144}\text{Nd}\) and lower \(^{87}\text{Sr}/^{86}\text{Sr}\) isotopic ratio compared to the majority of samples from Group II. These characteristic are similar to the ones observed to Pliocene-Pleistocene post-plateau basalts studied by Gorrings and Kay (2001). However, our data suggest that some of these basalts in Group II are generated from depleted mantle wedge with some influence of the subduction event when flat-subduction of Nazca plate might be temporally occurring under the South American plate during the Miocene. Our conclusions are very close to the one reached by Stern et al. (1990) who classified the basalts in “cratonic” and “transicional” observing a geographic distribution for them. However, our basalts from both groups resemble the “cratonic” basalts of Stern et al. (1990), and we address the difference from one to the other to different contribution proportion of fluids originated from the subducting slab. We do not observe samples with “transitional” characteristic or any geographic distribution for them.

Controls on weathering rates by reaction-induced hierarchical fracturing

B. JAMTVEIT\(^1\), A. ROYNE, A. MALTHE-SORENSSEN AND J. MATHIESEN

\(^1\)(bjorn.jamtveit@geo.uio.no)

Weathering takes place through several stages that include mechanical disintegration of the rocks, and subsequent interactions between the exposed rock surface, the hydrosphere and the biosphere. Here we demonstrate how physical and chemical weathering processes are intimately coupled during weathering of basaltic intrusions (dolerites) in the Karoo Basin in South Africa. Incipient chemical weathering of the dolerites occurs around water-filled fractures originally produced by thermal contraction or by externally imposed stresses. This chemical weathering causes local expansion of the rock matrix, which generates elastic stresses. On mm to cm scales, these stresses lead to mechanical layer-by-layer spalling, producing the characteristic spheroidal weathering patterns. However, our field observations and computer simulations demonstrate that in confined environments, chemical weathering drives a much larger scale hierarchical fracturing process in which fresh dolerite undergoes a continuous domain division that effectively regenerates fresh surfaces in a self-accelerating manner. This process produces the characteristic weathering patterns seen in Karoo and a wide-range of other geological environments, and provides a first-order control on the total weathering rate.
The mechanism of oxidation and “leaching” of ilmenite during natural and experimental alteration

A. JANSSEN, T. GEISLER, C. PUTNIS AND A. PUTNIS
Institut für Mineralogie, University of Münster, 48149 Germany
(ajanssen@uni-muenster.de; tgeisler@nwz.uni-muenster.de; putnis@nwz.uni-muenster.de; putnis@nwz.uni-muenster.de)

Ilmenite (FeTiO$_3$) undergoes weathering through oxidation and removal of Fe to form an apparently continuous series of compositions from ilmenite to pseudorutile (ideally Fe$_2$Ti$_3$O$_9$), and with further weathering, to leucoxene (essentially rutile and/or anatase). We have carried out an experimental study of ilmenite alteration in autoclaves at 150°C in HCl solution, and studied the resulting products by X-ray diffraction, scanning and transmission electron microscopy, electron microprobe and Raman spectroscopy. In some experiments the solution was initially enriched in $^{18}$O and the distribution of the isotope in the alteration products mapped from the peak shift in the Raman spectra. The results indicate that the alteration proceeds in two distinct stages, each with a sharp interface between the parent phase and the product. The alteration begins at the original ilmenite crystal surface and along cracks through which the fluid can migrate. The first alteration product is pseudorutile - no phases intermediate between ilmenite and pseudorutile were detected. The textural relationship between ilmenite and pseudorutile suggests a coupled dissolution-reprecipitation mechanism rather than a solid state continuous oxidation and Fe diffusion mechanism. The second stage involves a further dissolution-reprecipitation step to form rutile. Raman spectroscopy shows that the $^{18}$O is incorporated in the rutile during the recrystallisation. Throughout the alteration process the original morphology of the ilmenite is preserved although the product is highly porous. The rutile inherits crystallographic information from the parent ilmenite, resulting in a triply-twinned rutile microstructure.

The role of crustal assimilation and fractional crystallization in the generation of a hybrid composite dikes suite in the Arabian-Nubian Shield, southwest Jordan

GHALEB JARRAR
University of Jordan, Department of Environmental and Applied Geology, P.O.Box 13633, Amman 11942, Jordan
(jarrargh@ju.edu.jo)

A suite of hybrid composite dikes from the Arabian-Nubian Shield (ANS) in southwest Jordan is investigated. The petrogenesis of these dikes is discussed on the basis of field, petrographic, geochemical and Rb-Sr isotopic data. These dikes originated from the interaction between basaltic magma and the granitic basement. This interaction ranges from brecciation and partial assimilation of the host alkali feldspar granite to almost complete assimilation of the granitic material. Field structures range from intrusive breccia (i.e. angular granite fragments in a mafic groundmass) to hybrid composite dikes. The rims are mafic (basaltic andesite) in composition with alkali feldspar ovoids (up to 1 cm in diameter); while the central parts are of trachydacitic to dacitic in composition again with alkali feldspar ovoids and xenoliths of the dike rims.

A seven points Rb/Sr isochron from one the composite dikes yields an age of 560±7 Ma and an initial $^{87}$Sr/$^{86}$Sr ratio of 0.70332±0.00004 (2σ) and MSWD value of 0.59.

Geochemical modelling using major, trace elements and isotopes suggest the generation of the hybrid composite dikes through the assimilation of 30% granitic crustal material by the basaltic magma, while the latter was undergoing fractional crystallization deep in the continental crust.
Changes in the $\delta^{15}$N of nitrate in Greenland ice: Implications for source changes over the last 500 years

JULIA C. JARVIS$^1$, MEREDITH G. HASTINGS$^2$ AND ERIC J. STEIG$^1$

$^1$Department of Earth and Space Sciences, University of Washington, Seattle, WA 98195, USA
(jjarvis@u.washington.edu)
$^2$Joint Institute for the Study of the Atmosphere and Ocean and Department of Atmospheric Sciences, University of Washington, Seattle, WA 98195, USA

Recent increases in atmospheric nitrogen oxides may have a profound effect on terrestrial and lacustrine ecosystems through increases in the deposition of nitrogen. These nitrogen oxides, emitted from both anthropogenic (e.g., fossil fuel combustion) and natural (e.g., biomass burning, lightning, and soil emissions) sources, also affect the lifetimes of greenhouse gases such as methane and carbon dioxide through atmospheric interactions with ozone and OH. Developing an understanding of natural variations in atmospheric nitrogen oxides over the Holocene will aid in the interpretation of long-term records of climate and ecosystem change. One possible source of such information is the record of nitric acid ($\text{HNO}_3$, or nitrate, $\text{NO}_3^-$), the primary sink of nitrogen oxides, obtained from ice cores in polar ice sheets.

We present isotopic measurements of nitrate ($^{15}\text{N}/^{14}\text{N}$ and $^{18}\text{O}/^{16}\text{O}$) deposited and preserved in ice at Summit, Greenland. Previous studies have suggested that the $\delta^{15}$N of nitrate in precipitation contains a source signal while the $\delta^{18}$O of nitrate contains information regarding chemical pathways of nitrate production prior to deposition. Our measurements from a 100-meter ice core, which contains approximately 300-500 years of climate information, show a large shift in $\delta^{15}$N between the top and bottom of the core. We discuss the possibility that this shift is indicative of changing sources of nitrogen oxides to the atmosphere over the industrial transition. This would imply that our ice record can be used to evaluate the contribution and extent of influence of pre-industrial sources of nitrogen oxides, providing an important constraint on the interpretation of other records of environmental change.

Trials into the effect of manganese oxide addition to composted municipal solid waste

Z. JARVIS$^1$, L. BROWN$^2$, F. WORRALL$^2$ AND C. DOWDING$^1$

$^1$Department of Engineering, University of Durham, Durham, England (zak.jarvis@durham.ac.uk; catherine.dowding@durham.ac.uk)
$^2$Department of Earth Sciences, University of Durham, Durham, England (laura.brown@durham.ac.uk; fred.worrall@durham.ac.uk)

Procedure

Trials were carried out into the effects of amending the compost-like output (CLO) from the aerobic digestion of municipal solid waste with varying levels of waste manganese oxides. It was theorised that manganese oxide could affect humification of the decomposing CLO, with potential improvements in carbon storage in the material. Carbon emission data was recorded over the five week period of the study, and $E_4/ E_6$ ratios of a sodium pyrophosphate extraction were measured from CLO samples after five weeks of composting to assess levels of humic matter. Sand was included in the study as a control amendment with the manganese oxide, which was itself a granular material coated onto sand grains.

Results

A statistically significant effect was found between manganese oxide level and carbon flux rate, with flux rate increasing with increasing manganese oxide level. The effect was not significant between all levels however. The level of sand amendment included for comparison was found to be a significant factor only in one of the two trials carried out, where flux rate increased with sand addition. The $E_4/ E_6$ ratio for the CLO extractions were found to be unaffected by the addition of manganese oxide. The absorbancies at both wavelengths (465nm and 665nm) were found to increase significantly with increasing manganese oxide level.

Conclusions

The effect of the manganese oxide was found to have an effect on the rate of flux, although the confounding nature of environmental variations means that further work would be needed to quantify this effect with greater confidence. Attributing the increase in flux rate with manganese oxide to the physical or chemical properties of the amendment is difficult with the data collected to date.

The results from the absorbance analysis suggest that while the degree of humification of the humic matter was unchanged by the presence of manganese oxide, more humic matter in total seems to have been formed.
Deciphering the record of early life in Precambrian oceans using combined microscopy and microchemistry of organic-walled microfossils.

E.J. Javaux1 AND C.P. Marshall2

1University of Liège, Department of Geology, unit of Paleobotany-Paleopalynology and Micropaleontology, Belgium
2Vibrational Spectroscopy Facility, School of Chemistry, The University of Sydney, Sydney, Australia

Organic-walled microfossils (acritarchs) can be exquisitely preserved in fine-grained siliciclastics and chert through the Proterozoic and conceivably in the Archean. These fossils record crucial steps in the early evolution and diversification of complex ecosystems, and their morphology indicates the evolution of major biological innovations. However, the taxonomy of these fossils is often impossible to resolve beyond the level of domain.

Acritarchs are conventionally interpreted as algal cysts but most probably include a larger range of organisms such as prokaryotic sheaths, heterotrophic protists or even parts of multicellular beings. The organic remains can be studied in thin sections with optical microscopy and with Raman micro-spectroscopy to prove endogenicity. They can then be isolated from the rock by gentle acid maceration to be further studied by FTIR micro-spectroscopy, SEM and TEM microscopy to reveal morphological and ultrastructural details, and biopolymer composition, permitting in some cases to determine their biological affinities by comparison with extant clades. We present how combining microscopy (light microscopy, Scanning and Transmitted Electron Microscopy) with micro-spectroscopic analyses of individual Proterozoic microfossils (FTIR and Raman micro-spectroscopy) offers further insights into the paleobiology and evolution of early microorganisms in Precambrian oceans.

Such a multidisciplinary approach offers new possibilities to investigate the record of early life on Earth and beyond.

The most probable Earth composition

M. Javoy

Lab. Isotopes Stables IPG, 75005, Paris, France

Redox and isotopic criteria for Earth primitive materials clearly select a unique chondrite family, which, whatever its conditions of formation, can be modelled simply by a mixture in variable proportions of three mineral types: silicates (enstatite with minor amounts of oligoclase and free silica), metal (Si-bearing kamacite) and sulfides of Fe, Ca and Mg (evolving to metal, oxides and silicates with increasing temperature and decreasing fS2).

The modelling of a million such mixtures results in well defined elemental correlations, which can be used efficiently to test the obtained compositions versus high pressure mineralogy and seismological data. About a quarter of them have Fe contents compatible with the Earth’s Core/Mantle ratio and mantle range of densities. Their composition is perfectly compatible with the geophysical constraints in their present state of accuracy.

They predict Lower Mantle iron derives largely from the reaction:

\[
\text{SiO}_2 + 3\text{Fe} \rightarrow \text{FeSi} + 2\text{FeO}
\]

This results in a strong correlation between bulk mantle iron content and core silicon content (Si_n = 1.5 Fe_m - 5.9).

There is also a well marked anticorrelation between silica saturation and iron content of the lower mantle (Perovskite% = 100 (1.07-0.015Fe_m%)). That is, the denser it is , the softer it is.

Finally the Lower Mantle is strongly depleted in major radioactive elements (U~7ppb).

From the presently available experimental high pressure melting experiments a primitive pyrolitic upper mantle is obtained by an average 25-40% partial melting of the original solid silicate part.

Earth envelopes' compositions hence are as follows:

Primitive Upper mantle: pyrolitic

Lower Mantle: Mg_{0.8} Fe_{0.15} Al_{0.03} Ca_{0.03} Si_{0.07} Al_{0.03} O_3

Core: 85.3% Fe, 5.7% Ni, 6% Si, 3% O.
A multiproxy approach to constrain the origin of the natural fertilisation on the Kerguelen plateau

The Kerguelen Ocean and Plateau compared Study (KEOPS) took place during the austral summer (19 Jan-13 Feb 2005, R/V “Marion-Dufresne”, 68°-78°E/ 49°-52°S sector). One of the KEOPS objectives was to determine the mechanisms responsible for the bloom occurring on the Kerguelen plateau and allocated to natural fertilisation due to island inputs.

Coupled with physical measurements, a multi-proxy investigation was carried out in order to better constrain the sources of iron, but also the water mass and particle pathways. REE concentration and Nd isotopes suggest that weathering of Heard Island brings significant amounts of iron to plateau waters (Zhang et al., in rev.), in agreement with radium isotopes (van Beek et al., in rev.) and consistent with total dissolved and particulate iron results. Th isotopes allow the quantification of particle settling velocities on and off the Kerguelen plateau and the identification of strong boundary scavenging along the south-east Kerguelen slope, likely due to the occurrence of nepheloid layers (Venchiarutti et al., subm.). Slow particle settling velocities are observed on the Kerguelen plateau, consistent with the high mineralization rates characterizing this area, deduced from the barite concentrations which were used as proxy for twilight zone mineralization of organic matter (Jacquet et al., in rev.).

This talk highlights the main results deduced from each proxy, underlining both coherences and contradictions. A synthetic and simplified scheme of the potential sources and sinks of iron over the plateau is finally discussed.

Geochemical monitoring of CO\textsubscript{2} storage: Natural analogues studies using isotopic composition of gases and travertines

E. JEANDEL\textsuperscript{1,2}, A. BATTANI\textsuperscript{1}, P. SARD\textsuperscript{2} and E. TOCQUE\textsuperscript{1}

\textsuperscript{1}Institut Français du Pétrole, 1-4, av. de Bois Préau, 92852 Rueil-Malmaison Cedex, France (Elodie.JEANDEL@ifp.fr)
\textsuperscript{2}Dept. Sciences de la Terre, bât. 504, 91405 Orsay Cedex, France (sarda@geol.u-psud.fr)

Studies of natural analogues can be used to understand long-term processes affecting CO\textsubscript{2} in geological storage, because CO\textsubscript{2} can remain trapped for geologically significant times.

Noble gases are useful tools for tracing CO\textsubscript{2} and track its leakage toward surface. They also provide information about the origin of CO\textsubscript{2}; its migration, physical processes such as diffusion, solubilization in water and residence time.

We collected gas samples from natural CO\textsubscript{2} reservoirs and surface seeps in French carbo-gaseous province: Sainte Marguerite seeps (Allier, France), Montmiral natural CO\textsubscript{2} field (Drôme, France), and in the Colorado Plateau (Green River seeps (Utah), Springerville St Johns natural CO\textsubscript{2} field (Arizona)).

The preliminary results obtained provide strong evidence for a mantle-derived magmatic source for CO\textsubscript{2} in all sampled accumulations, and show various physical processes affecting CO\textsubscript{2} during its migration.

For example, natural CO\textsubscript{2}-degassing springs near Sainte Marguerite, Allier, France show evidence of Rayleigh fractionation on argon, neon isotopes and elementary ratio of atmospheric-derived noble gases. This distillation process highlights rapid migration of CO\textsubscript{2} toward surface, consistent with small accumulation of radiogenic/nucleogenic isotopes.

The Helium concentrations range between 0.28 and 8.22 ppmv, consistent with a magma degassing at depth. Such low concentrations imply that solubilization of CO\textsubscript{2} in water occurs at shallow depth, thus CO\textsubscript{2} migration mainly occurred in the gaseous state.

Active and fossil travertines were present in all sampled areas. They represent geological record of the movement and discharge of CO\textsubscript{2} and associated fluids to the Earth’s surface. They also provide information about the origin of CO\textsubscript{2} from which they precipitate. We present here our first petrographical observations as well as isotopic results for the travertines, including $\delta^{13}$C and $\delta^{18}$O. The samples from Green River have $\delta^{13}$C values typical of thermogene carbonates and presumably associated with deep magmatic degassing. On the contrary in Montmiral, the $\delta^{13}$C values are more typical of the meteogene travertines, associated with atmosphere-derived CO\textsubscript{2}.
Nitrate reduction, sulfate reduction and sedimentary iron-isotope evolution during the Cenomanian-Turonian Oceanic Anoxic Event (OAE2)

HUGH C. JENKYNSE1, ALAN MATTHEWS2, HARILAOSSIKOS1,3 AND YIGAL EREL2

1Department of Earth Sciences, University of Oxford, Oxford, UK (hugh.jenkyns@earth.ox.ac.uk)
2Institute of Earth Sciences, Hebrew University of Jerusalem, 91904 Israel (alan@vms.huji.ac.il; yerel@vms.huji.ac.il)
3Department of Geology, Rhodes University, Grahamstown, South Africa (h.tsikos@ru.ac.za)

Organic-carbon rich shales from localities in England, Italy and Morocco, which formed during the Cenomanian-Turonian Oceanic Anoxic Event (OAE), have been studied for their total organic carbon values (TOC) together with their carbon-, nitrogen- and iron-isotope ratios. Carbon-isotope stratigraphy ($\delta^{13}C_{\text{org}}$ and $\delta^{15}N_{\text{org}}$) allows accurate recognition of the strata that record the Oceanic Anoxic Event, in some cases allowing characterization of isotopic species before, during and after the OAE. Within the black shales formed during the OAE, relatively heavy nitrogen-isotope ratios, which correlate positively with TOC, suggest nitrate reduction, extant sulfur-isotope data and molecular fossils of green sulfur bacteria signify the development of free H2S in the water column by sulfate reduction. Black shales deposited before the onset of the OAE in Italy have unusually low bulk $\delta^{57}Fe$ values, unlike those found in the black shale (Livello Bonarelli) deposited during the Oceanic Anoxic Event itself: these latter conform to the Phanerozoic norm for organic-rich sediments. Pyrite formation in the pre-OAE black shales has apparently taken place via dissimilatory iron reduction (DIR), within the sediment, a suboxic process that causes an approximately -2 % fractionation between a lithogenic Fe(III)oxide source and Fe(II)aq. In contrast, bacterial sulfate reduction (BSR), at least partly in the water column, characterized the OAE itself and was accompanied by only minor iron-isotope fractionation. This change in the manner of pyrite formation is reflected in a decrease in the average pyrite framboid diameter from ~10 \(\mu\)m to ~6.5 \(\mu\)m. A gradual, albeit irregular increase in Fe-isotope values during the OAE, as recorded in the Italian section, may demonstrate limited isotopic evolution of the dissolved iron pool, consequent upon ongoing water-column precipitation of pyrite under euxinic conditions.

An important implication of the low $\delta^{57}Fe$ values measured in this study is that they decrease the gap between the lowest values observed for Phanerozoic sediments in which DIR is indicated to exert a strong control of isotopic fractionation and the very low Fe-isotopic compositions observed for Archaean rocks.

Speciation of arsenic in the coprecipitated As(V)-Fe(III) solids

Y.F. JIA1, L. XU1 AND G.P. DEMOPOULOS2

1Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, China, 110016 (yongfeng.jia@iae.ac.cn)
2Department of Mining, Metals and Materials Engineering, McGill University, Montreal, QC, Canada, H3A2B2 (george.demopoulos@mcgill.ca)

Lime neutralization and coprecipitation with ferric iron is the common method for the removal and immobilization of arsenic from industrial mineral processing effluents. The nature of the arsenate in the coprecipitated As$^{V}$-Fe$^{III}$ solids is not fully understood though it is generally believed that arsenate is adsorbed as surface complex on ferrihydrite. In this study we used infrared spectroscopy and X-ray diffraction to characterize the coprecipitates with an attempt to shed some more light on this issue.

A suit of As$^{V}$-Fe$^{III}$ coprecipitates were synthesized by neutralization of acidic solutions of various Fe/As molar ratios to pH 4-8 using both sodium hydroxide and slaked lime as base. The synthesized samples were subjected to powder X-ray diffraction and Fourier transformed infrared analyses. Lab synthesized scorodite, poorly crystalline ferric arsenate and 2-line ferrihydrite were used as reference materials. The speciation of arsenate was determined based on the As-O stretching vibration bands located at 650-950 cm$^{-1}$ and the characteristic XRD bands of poorly crystalline ferric arsenate and ferrihydrite.

Both infrared spectroscopic and X-ray diffraction data showed that poorly crystalline ferric arsenate is the dominant arsenate phase in the As$^{V}$-Fe$^{III}$ solids coprecipitated at pH 4 using NaOH as base. At pH 8 the arsenate is present basically as adsorbed surface complex in ferrihydrite. The results are similar to the arsenate-ferrihydrite adsorption system in which poorly crystalline ferric arsenate surface precipitate is formed at acidic pH while bidentate surface complex is the major arsenate species on the surface of ferrihydrite. Crystalline yukonite (Ca$_3$Fe$_2$(AsO$_4$)$_4$(OH)$\cdot$12H$_2$O) was generated in the coprecipitated solid when the CaO neutralized system was subjected to heat treatment at 75 °C.

Geochemistry and genetic models for tin deposits in South China

SHAO-YONG JIANG, KUI-DONG ZHAO, YAO-HUI JIANG, HONG-FEI LING AND PEI NI

South Key Laboratory for Mineral Deposits Research,
Department of Earth Sciences, Nanjing University,
Nanjing 210093, P.R. China

South China is one of the most important tin producers in the world. Except for the classical granite-related magmatic-hydrothermal tin deposits, there are many other types of tin deposits in this region, such as sediment-hosted massive sulfide type and migmatitic hydrothermal-related tin deposits. In addition, A-type granite related tin deposits are also found in South China recently.

The Dachang tin deposit in Guangxi Province is the second largest tin producer in China. Although some researchers have suggested that this deposit is a skarn or replacement type associated with the Yanshanian magmatic hydrothermal event, our detailed geochemical investigation including major, trace, rare earth elements, Pb, S, Sr, Nd, B, H, O, He, and Ar isotopes have indicated a submarine exhalative-hydrothermal origin for the bedded and massive sulfide ores in the deposit.

The Yunlong tin deposit in Yunnan Province is a medium-sized tin deposit, which occurs mainly as cassiterite-quartz-tourmaline ore veins hosting in a suite of metamorphic rocks and migmatite. Previously many researchers considered this deposit as a typical granite-related tin deposit, with a blind granite body at depths or it is genetically related to a S-type granite body occurring just outside the deposit. Our recent fluid inclusions, geochemical and isotopic (H-O, S, Pb, B) studies in the deposit indicated that metamorphic hydrothermal fluids generated by dehydration of the regional Chongshan group rocks were possibly responsible for the formation of this tin deposit. Hence, we proposed that the Yunlong tin deposit belongs to a new type of tin mineralization, i.e., migmatitic-hydrothermal type.

The Yunlong tin deposit in Yunnan Province is a medium-sized tin deposit, which occurs mainly as cassiterite-quartz-tourmaline ore veins hosting in a suite of metamorphic rocks and migmatite. Previously many researchers considered this deposit as a typical granite-related tin deposit, with a blind granite body at depths or it is genetically related to a S-type granite body occurring just outside the deposit. Our recent fluid inclusions, geochemical and isotopic (H-O, S, Pb, B) studies in the deposit indicated that metamorphic hydrothermal fluids generated by dehydration of the regional Chongshan group rocks were possibly responsible for the formation of this tin deposit. Hence, we proposed that the Yunlong tin deposit belongs to a new type of tin mineralization, i.e., migmatitic-hydrothermal type.

The Furong tin deposit in Hunan Province is a newly discovered large tin deposit. Tin mineralized bodies mainly occur as veins in the crush zone of the Qitianling granite that genetically related to chlorite alteration, although less important small greisen and skarn orebodies also occurred in the contact of granite with country rocks. Our study shows that the Qitianling granite is distinctly different from common S-type tin granite in the world but rather similar to A-type granite. Tin mineralization is suggested to be related to post-emplacement chloritization of the Qitianling granite. Sn-rich mafic minerals (amphibole, biotite and titanite) in the granite released tin and other metals (e.g. Ti) into the hydrothermal fluids when these minerals were altered to chlorite. Then cassiterite and rutile precipitated together when the physical and chemical condition of Sn- and Ti-rich fluids changed. It is a special model for granite-related tin mineralization.

Geochemistry of Late Mesozoic lamprophyre dikes from the eastern North China Craton: Implications for subcontinental lithosphere evolution

YAO-HUI JIANG, SHAO-YONG JIANG, MING-LAN HOU, HONG-FEI LING, KUI-DONG ZHAO AND PEI NI

State Key Laboratory for Mineral Deposits Research,
Department of Earth Sciences, Nanjing University,
Nanjing, China (yhj186@hotmail.com)

Mineral chemical, element geochemical and Sr–Nd–Pb isotopic data have been determined for the late Mesozoic lamprophyre dikes from the Jiaodong and Liaodong Peninsulas. Together with the published data, three late Mesozoic lamprophyre belts in the northwestern Jiaodong Peninsula, also suggest that the Sulu lamprophyre belt (belt 1), Guojialing–Linglong lamprophyre belt (belt 2) and Dashiqiao–Laizhou lamprophyre belt (belt 3), respectively. These lamprophyre dikes are potassic and ultra-potassic rocks and have high MgO and compatible element contents. They are all enriched in LREE and LILE and depleted in HFSE. The belt 3 lamprophyre dikes have similar Sr–Nd–Pb isotopic compositions to the EM 2-type mantle. From the belt 3 through belt 2 to belt 1, the lamprophyre dikes show a trend towards the EM 1-type mantle in terms of Sr–Nd–Pb isotopic compositions. In addition, the Sr–Nd–Pb isotopic compositions of each lamprophyre belt show a trend towards those of MORB. Furthermore, the belt 1 lamprophyre dikes have super-chondritic Nb/Ta ratios (>17.5) whereas the belt 2 and belt 3 lamprophyre dikes show sub-chondritic Nb/Ta ratios (<17.5). All these features, together with comparison to the Late Triassic (201 Ma) Sulu mafic dikes that have similar Sr–Nd isotopic compositions to the EM 1-type mantle and also show super-chondritic Nb/Ta ratios, suggest that the eastern NCC lithospheric mantle near the Sulu Orogenic Belt was hybridized by the melt derived from the subducted Yangtze continental slab during the Triassic collision of the Yangtze Craton with NCC and then all the subcontinental lithosphere beneath the eastern NCC was metasomatized by slab-derived fluid during the late Mesozoic Palaeo-Pacific plate subduction. Detailed elemental and isotopic data, together with our recent studies on the origin of the late Jurassic (160–153 Ma) Linglong suite and Early Cretaceous (130–126 Ma) Guojialing suite in the northwestern Jiaodong Peninsula, also suggest that the Early Cretaceous lamprophyre dikes were derived from partial melting of the delaminated lithospheric mantle plus additional input from the upwelling asthenospheric mantle. Such a delamination is a consequence of the progressive slab roll-back associated with the subduction of the Palaeo-Pacific plate.

Shallow crystallization and deep magma storage: Insights from U-Th and $^{40}$Ar/$^{39}$Ar geochronology

B.R. JICHA, B.S. SINGER, C.M. JOHNSON, B.L. BEARD AND J.M. HORA

Department of Geology & Geophysics, University of Wisconsin-Madison, USA (bjicha@geology.wisc.edu; bssinger@geology.wisc.edu; clarkj@geology.wisc.edu; beardb@geology.wisc.edu; jhora@geology.wisc.edu)

Precise $^{40}$Ar/$^{39}$Ar age determinations and $^{238}$U/$^{230}$Th analyses from volcanoes atop vastly different thicknesses of crust in four subduction zones reveal new insights about the temporal and physical development of arc magmatic systems over several tens of thousands of years. Analytical advances yield $^{40}$Ar/$^{39}$Ar ages and U-Th mineral isochrons for latest Pleistocene to Holocene lavas and tephras with uncertainties of only a few thousand years. Thus, quantifying the length of time between crystallization and eruption has become more robust and crystallization-eruption intervals may be calculated over the lifetime of an individual volcano; this represents a significant advance in linking volcanic evolution to magmatic processes as compared to restricting U-Th geochronology to historical eruptions. Our most compelling discovery is that minerals (opx, cpx, mt, plag, ol), matrix glass, and whole rocks measured in dozens of basaltic to rhyolitic lava flows and pyroclastic deposits erupted over the last ~150 ka define $^{238}$U/$^{230}$Th isochrons whose age cannot be distinguished from that of the eruption. This finding indicates that the observed phenocrysts began to grow less than 1 to 2 ka prior to eruption and that processes including crystal fractionation and magma mixing—required to explain the spectrum of basaltic to rhyolitic compositions erupted at these volcanoes—took place prior to growth of the erupted crystals. The short crystal residence times are consistent with inferences from trace-element zoning and diffusion profiles in phenocrysts and $^{226}$Ra-$^{230}$Th disequilibrium data from recent eruptions at several volcanoes, each of which likely reflect exceptionally rapid transit of evolved melt through the crust, during which crystallization of the erupted phenocrysts occurs en route due to decompression.

The duration of magma storage and processing in the deep crust, although more difficult to constrain, can be tracked using initial ($^{238}$Th/$^{232}$Th) ratios in sequences of lavas and tephras erupted over $10^4$-$10^5$ year periods of volcano growth that have been precisely dated using $^{40}$Ar/$^{39}$Ar geochronology. Our large set of $^{238}$U/$^{230}$Th data suggests that the duration of deep crustal storage, differentiation and mixing of magma may vary greatly, ranging from a few thousand years to longer than 100 ka. In most cases, it appears that the deep crust buffers mafic magma flux from the mantle, which may explain our finding that long-term arc volcano growth rates are modulated to within a narrow range, despite gross differences in crustal thickness or age.

Oxygen isotope record of Devonian and Carboniferous biogenic apatite

M.M. JOACHIMSKI1, S. BREISIG1, W. BUGGISCH1 AND A.S. ALEKSEEV 2

1Institut of Geology and Mineralogy, University of Erlangen-Nuremberg, Germany (joachimski@geol.uni-erlangen.de, stephan.breisig@gmx.de; buggisch@geol.uni-erlangen.de)
2Department of Paleontology, Geological Faculty, Moscow State University, Russia (aaleks@geol.msu.ru)

Oxygen isotope ratios of conodont apatite (n=1286) were studied in order to reconstruct the palaeotemperature and ice volume history during the Devonian and Carboniferous. Oxygen isotope ratios are around 18‰ V-SMOW in the Early Devonian, increase gradually during the Pragian and Emsian, show comparatively high values around 20‰ V-SMOW in the Middle Devonian, decrease during the early Frasnian to minimum values around 18‰ V-SMOW at the Frasnian-Famennian transition, and increase again to 19‰ V-SMOW in the Famennian. The Early Carboniferous record is characterized by a first major increase to values around 21‰ V-SMOW in the middle Touraisian to earliest Viséan, high values around 21‰ V-SMOW in the Viséan and a second major increase in the Serpukhovian to maximum values around 23‰ V-SMOW. Oxygen isotope values of Pennsylvanian and Early Permian conodont apatite vary between 19 and 22‰ V-SMOW.

The $\delta^{18}$O fluctuations recorded in the Devonian are interpreted as palaeotemperature changes with the Early and Late Devonian revealing relatively warm climatic conditions, whereas the Middle Devonian is characterized by a cooler climate. The positive shifts in the oxygen isotope ratios in the Touraisian and Serpukhovian are too large to be explained solely by a change in sea water temperature and/or salinity. Instead, the positive shifts in the oxygen isotope ratios in the Touraisian and Serpukhovian points to an intensified ice build-up during the latest Mississippian. The relatively large variance in the oxygen isotope ratios of Pennsylvanian conodonts is explained by the waxing and waning of Gondwanan ice sheets.

The comparison of the conodont apatite with published brachiopod calcite $\delta^{18}$O records (taking into account the different thermodynamic oxygen isotope fractionations for apatite and calcite) reveals that $\delta^{18}$O values of apatite are in many cases significantly higher than calcite $\delta^{18}$O values. Apatite $\delta^{18}$O values translate into realistic palaeotemperatures by assuming a modern $\delta^{18}$O value for Palaeozoic sea water and do not support the idea of a secular change of the oxygen isotope composition of sea water.
Reactive fluid flow in slabs –
A metamorphic view on the origin of the slab component

TIMM JOHN

Physics of Geological Processes PGP, University of Oslo,
0316 Oslo, Norway (timm.john@fys.uio.no)

Subduction zones are the places on Earth where quantitatively the largest mass transfer rates exist and element fractionation occurs between crust and mantle. The agents, which are central to these processes, are aqueous fluids, supercritical fluids, and melts. Field evidence found in formerly subducted rocks shows that the preferential flow field of released slab fluids is highly channelized and that these fluids tend to react with parts of their wall rocks. Thereby they are able to serve as agents for mobilization and transport for most trace elements. I will describe a model for fluid flow within slabs that suggests that slab melting must not necessarily be invoked for mobilization of so-called fluid-immobile trace elements. For this model it is critical that permeabilities in the subducting slab appear to be too low and dihedral angles between fluid and relevant minerals too high to allow for pervasive porous flow, hence the fluids tend to localize while flowing. I will outline how fluid channelization controls reaction rates and element redistributions during metamorphism of the subducting plate as well as trace element composition of subduction-related fluids during flow. Channelized fluid flow predicts that most formerly subducted material will show only very limited evidence for fluid flow, consistent with the rarity of observed high fluid fluxes in subduction-related rocks. Aqueous fluid produced by dehydration reactions will not percolate through large rock volumes, but rather will be carried away from the dehydration sites by a veining network. Indeed evidence for significant aqueous-fluid fluxes have been found in high-pressure veins with adjacent selvages. In such selvages, LILE’s generally show the highest mobilities, followed by light REE’s and then heavy REE’s and HFSE’s. Equilibrium between aqueous fluid and surrounding rock will only be approached at sites of fluid production and mineral reaction. However, this fluid can be significantly modified while moving upwards through a veining network where the wallrocks are out of equilibrium with the passing fluid. In a subducting slab, such reactive fluid flow can preferentially dissolve minerals and release their trace elements. The degree of change in aqueous fluid composition will depend on the fluid composition itself, the amount of fluid–mineral surface interaction and the ratio between the kinetics of the mineral reactions and the velocity of the passing fluid. In this talk I will focus on field evidence for reactive fluid flow in localized channel networks in high-pressure metamorphic terranes and its distinct chemical signature that is a direct counterpart to that in arc magmatism.

Interplay of deformation, fluid infiltration and eclogitization

TIMM JOHN, HÅKON AUSTREIM, DANIEL W. SCHMID, LARS RÜPKE AND YURI PODLADCHIKOV

Physics of Geological Processes PGP, University of Oslo,
0316 Oslo, Norway (timm.john@fys.uio.no)

It is a common observation that during increasing metamorphic conditions dry coarse-grained rocks often fail to react because of sluggish mineral reactions. The crucial trigger mechanism to start the delayed metamorphic reactions is the infiltration of fluids. But how do fluids flow within dry rocks with very low permeability and how fast do the system react? The Kråkenes Gabbro is a partially deformed and transformed igneous body located in the Western Gneiss Region (Norway). The body is transected by a swarm of cm-wide hydrous eclogite-facies shear zones. The shear zones have cores of intensely deformed material surrounded by a dm-wide reaction halo where deformation is less obvious. The water-bearing minerals are highly concentrated in shear zones and their modal abundance progressively decreases with increasing distance to the deformation front. Fluid infiltration into the undeformed parts apparently occurred both along grain boundaries and through reactive minerals. Thereby, olivine appears to have been too reactive and thus shielded by corona formation, whereas clinopyroxene mainly reacted along its grain boundary and the magmatic plagioclase reacted to a micron-sized hydrous symplectite. It is interesting to note that these symplectites lack deformation features, indicating that they formed under static conditions. The subdomains can be regarded as tiny batch-experiments in which the fluid was rapidly supersaturated in the precipitating mineral phases, so that the replacement products inherited the chemical variations of the subdomains. In this manner magmatic zoning of plagioclase grains have been preserved. These findings imply that the kinetics of the reactions were faster than the fluid flow. From less transformed subdomains it is evident that element transfer was controlled by discrete transport pathways. At the terminations of such transport pathways the stable mineral assemblage precipitated. Real eclogite formed only if the element exchange between different subdomains was efficient, otherwise “metastable” phases formed. Obviously, the dynamic formation of porosity and permeability is crucial for the described observations, because it allows fluid access to the reaction interfaces and mass transfer even in undeformed parts. However, even though the suggested fluid pathways are wide, in cases up to several hundred microns, the final effective porosity is low. Thus, beside the deformation enhanced fluid infiltration along the shear zones effective porosities only exist while minerals react – then the newly formed mineral assemblage closes the pathways. Formation of porosities is either reaction enhanced along grain boundaries or occurs in form of porosity waves associated with mineral reactions through reactive domains.
Iron isotope compositions of 2.5 Ga banded iron formations (BIFs) from the Hamersley Basin and Transvaal Craton identify the iron sources and formation pathways during BIF genesis. $^{56}\text{Fe}$/$^{54}\text{Fe}$ ratios for magnetite reveal a strong inheritance from Fe(III) hydroxide precursors, with a peak about $\delta^{56}\text{Fe}=0$. Near-zero $\delta^{56}\text{Fe}$ values for the Fe(III) hydroxide precursors may be produced by complete or near-complete oxidation of Fe(II)$_{aq}$ derived from marine hydrothermal fluids, suggesting the existence of a significant oxidant in the upper water column at 2.5 Ga. Transformation of the Fe(III) hydroxide precursors to magnetite occurred through several diagenetic processes that produced a range of $\delta^{56}\text{Fe}$ values: 1) addition of marine hydrothermal Fe(II)$_{aq}$, 2) reduction by bacterial dissimilatory Fe(III) reduction (DIR), and 3) interaction with excess low-$\delta^{56}\text{Fe}$ Fe(II)$_{aq}$ that was produced by DIR.

The range in $\delta^{56}\text{Fe}$ values for siderite reflects a mixture of iron sources including seawater Fe(II)$_{aq}$ and Fe(II)$_{aq}$ produced by DIR. The inferred Fe sources and pathways for magnetite and siderite from adjacent bands, however, are distinct, and these minerals did not generally form in Fe isotope equilibrium. Instead, the Fe isotope variability of magnetite and siderite document fine-scale isotopic heterogeneity that reflects a strong component of diagenesis. Support for an important role of DIR in siderite formation in BIFs comes from previously published C isotope data on organic carbon and siderite, which may be explained as a mixture of C produced by bacterial and seawater sources.

Several factors likely contributed to the important role that DIR played in formation of the 2.5 Ga BIFs from the Hamersley Basin and Transvaal Craton, including high rates of ferric hydroxide formation in the upper water column, delivery of organic carbon related to photosynthesis, and low clastic input. We infer that DIR-driven Fe cycling was much more important during deposition of these BIFs than in modern marine systems. Low pyrite contents in oxide-facies BIFs suggest that bacterial sulfate reduction (BSR) was minor, and the absence of sulfide allowed preservation of magnetite and siderite; low BSR also provided a competitive advantage for DIR. When compared to BIFs that formed prior to 3.0 Ga, the Fe isotope signature for DIR is absent in the older sequences, suggesting that this metabolism may have been absent in the Early Archean. Moreover, the generally positive $\delta^{56}\text{Fe}$ values for the older BIFs suggest that oxidants were more limited, which in turn would limit DIR activity.

**Iron isotopes constrain the roles of biologic and abiologic processes in formation of banded iron formations**

$^3$Univ. Johannesburg - Auckland Park (nbeukes@uj.ac.za)

To investigate volatiles (H$_2$O, CO$_2$, S, Cl) and magma formation in subduction zones, we have analyzed olivine-hosted melt inclusions from 10 basaltic centers at varying distances from the trench in the Michoacan-Guanajuato Volcanic Field in central Mexico. Our data from these primitive basaltic cones (most contain Fo87-90 olivine) reveal the surprising result that H$_2$O contents are high (3.0-5.2 wt%) from the volcanic front to ~140 km behind the front. The high H$_2$O across the arc, combined with high S and Cl, suggest that flux of volatiles from the subducted plate has affected a broad region of the underlying mantle.

To understand the depths over which subducted slab components dehydrate beneath the arc, we have modeled the thermal structure of the mantle wedge and slab using a 2D numerical model (Manea et al., 2005). We then use phase equilibria to evaluate dehydration of subducted sediment, altered oceanic crust, and hydrated lithospheric mantle in the slab (Rupke et al., 2004). An important constraint is that volcanism has migrated towards the trench over the last 3 Ma, suggesting an increase in slab dip angle. Thus our studied cones farthest from the trench are older than those closer to the trench, and their volatile contents likely reflect mantle hydration resulting from a different slab geometry than the present-day configuration.

For the present-day slab model (13 Ma oceanic crust at trench), maximum mantle wedge temperatures beneath the volcanic front (1200-1300°C) agree with petrological calculations. The model results predict dehydration of subducted sediment and altered oceanic crust beneath the forearc, the volcanic front, and extending ~50 km behind the front. Subducted lithospheric mantle, if hydrated, would undergo dehydration beneath the arc ~50 km behind the volcanic front. In addition, chloride formed by hydration of the overlying mantle wedge would no longer be stable ~100 km behind the volcanic front. Thus the width and high magmatic H$_2$O in the Quaternary arc may be due partly to dehydration of subducted serpentinized mantle and the stability of chloride in the overlying mantle wedge.

For the present-day slab model, subducted sediment and oceanic crust dehydrate largely beneath the wide forearc during near-horizontal subduction. The main source of H$_2$O to flux the wedge beneath the volcanic front at 2-3 Ma comes from dehydration of serpentinized lithospheric mantle in the slab. Thus our results for both the present-day and 3 Ma slab configurations suggest a role for deserpentinization of the downgoing slab in magma generation beneath Mexico.

**Slab dehydration beneath central Mexico inferred from melt inclusions and geodynamic modeling**

Springtime Deposition and Emission of Mercury from Arctic Snow

K.P. Johnson1, J.D. Blum1, G.J. Keeler1 and T.A. Douglas2

11100 N University Ave, University of Michigan, Ann Arbor, MI, 48109 (kelseyjo@umich.edu, jdblum@umich.edu, jkeeler@umich.edu)
2Cold Regions Research and Engineering Laboratory, P.O. Box 35170 Fort Wainwright, Alaska 99703-0170 (Thomas.A.Douglas@erdc.usace.army.mil)

Atmospheric mercury depletion events (MDEs) provide a pathway for gaseous elemental mercury (Hg0) to be rapidly oxidized to Hg2+ and deposited to terrestrial surfaces. MDEs occur between polar sunrise and spring melt in many high-latitude locations. Projected changes in the Earth’s climate this century will alter contaminant transport pathways (Macdonald, 2005) and may enhance Hg deposition and bioavailability in high latitude ecosystems (Lindberg, 2002).

We investigated net Hg deposition by MDEs to the Arctic cryosphere near Barrow, Alaska by (1) monitoring Hg concentrations in surface snow for 18 days, (2) quantifying emission of total gaseous mercury (TGM) from snow in flux chambers and (3) applying a newly developed analytical technique to measure Hg isotopic fractionation during (photo)chemical reactions. A nine-day MDE occurred during our intensive sampling campaign.

Daily monitoring of the upper 1 cm of the snowpack at two locations showed an increase in total Hg concentration throughout the MDE to maximum levels of 147 and 237 pg/g Hg. Twice-daily sampling at one site revealed a secondary trend of night-time Hg deposition. Mercury concentration in surface snow typically rose after exposure to darkness (~12 hours), while it remained unchanged or slightly decreased after exposure to daylight (~12 hours). Within two days of MDE cessation, Hg in surface snow returned to near-baseline levels and is probably the result of both Hg0 emission and physical mixing of the snowpack (high-Hg surface layer diluted by low-Hg snow column).

Flux chambers were employed to elucidate the rate and mechanism of TGM emission from natural snow. The TGM emission pattern was typical of light and/or temperature dependent reactions: emission peaked shortly after solar noon and ceased overnight. Peak TGM emission from MDE and non-MDE snow reached > 15 ng/m²/hr and ~8 ng/m²/hr, respectively. Blocking direct UV radiation decreased TGM emission by only 25%; UVB was not wholly responsible for this flux. Hg isotopic ratios of snow samples before and after flux chamber incubation are being measured to help identify an isotope signature of Hg (photo)chemical reduction.

Modeling glyphosate and metal-glyphosate speciation at solution-mineral interfaces

CAROLINE JONSSON, JOHN LORING, PER PERSSON AND STAFFAN SJÖBERG

Department of Chemistry, Umeå University, S-90187 Umeå, Sweden (Caroline.Jonsson@chem.umu.se; John.Loring@chem.umu.se; Per.Persson@chem.umu.se; Staffan.Sjoberg@chem.umu.se)

Glyphosate (N-(phosphonomethyl)glycine, PMG, H₃L) is a widely used organophosphorous herbicide. It interacts with metal ions and mineral surfaces, which may affect its mobility, degradation and bioavailability in the environment. However, so far these interactions are far from fully understood.

This paper is a discussion on the complexation of PMG with metal ions in aqueous solution and the adsorption of PMG and Cd(II) on different mineral surfaces. EXAFS, ATR-FTIR, and XPS measurements showed that PMG adsorbs to the surfaces of goethite (α-FeOOH), aged γ-alumina (γ-Al₂O₃) and manganite (MnOOH) through one oxygen of its phosphonate group to singly-coordinated OH-surface sites.

The coadsorption of PMG and Cd(II) on the surfaces of goethite and manganite results in the formation of ternary mineral-PMG-Cd(II) surface complexes, as suggested from EXAFS results. In addition to the surface reactions in the binary Cd(II)-mineral and PMG-mineral systems, a single ternary complex with the stoichiometry ≡MeL₁Cd(OH)₁.₅ was sufficient to explain coadsorption data.

Surface complexation models consistent with the different spectroscopic results were fit to adsorption data using the 1pK reaction formalism involving charge distributions.
Sorption of arsenic under oxic and anoxic conditions: Possible origins of elevated arsenic in groundwater

JÖRGEN JÖNSSON AND DAVID M. SHERMAN

Dept. of Earth Sciences, Bristol University, Bristol, UK
(jorgen.jonsson@bristol.ac.uk; dave.sherman@bristol.ac.uk)

In Bangladesh and West Bengal, millions of people are using groundwater with elevated (> 50ppb) concentrations of arsenic. The origin of the elevated arsenic levels is still unclear. Both As(V) and As(III) are strongly sorbed to iron(III) (hydr)oxides. We have developed surface complexation models for sorption of As(III) and As(V) on goethite and ferrihydrite. These models predict that sorption should limit As concentrations to acceptable levels even when As(V) is reduced to As(III) and ferrihydrite transforms to goethite. One hypothesis for the elevated As concentrations is that sorbed As is released during bacterial reductive dissolution of Fe(III) (hydr)oxides. However, this should yield a strong correlation between dissolved Fe and As but this is not observed. The formation of secondary Fe(II) or mixed Fe(II)/Fe(III) minerals such as siderite (FeCO₃), green rust (GR) and magnetite has been suggested to reduce the aqueous concentration of Fe while leaving the concentration of As high in the Bangladesh and West Bengal aquifers. To test this hypothesis we have studied the adsorption of arsenite and arsenate to siderite, carbonate GR and magnetite as a function of pH using EXAFS and batch adsorption experiments.

EXAFS spectra show that As(V) sorbs to GR, magnetite and siderite by forming bridging bidentate inner-sphere surface complexes. The adsorption is similar to that of As(V) on Fe(III) (hydr)oxides and the adsorption decreases with increasing pH. No evidence of As(V) reduction is found. Hence, reduction of As(V) could release As(V) into solution but the formation of GR, magnetite or siderite would immediately re-adsorb the released As(V), keeping the aqueous As(V) concentration low. EXAFS spectra show that As(III) forms strong inner-sphere surface complexes on magnetite and GR, similar to that of As(V). No evidence of As(III) oxidation is found. On siderite, however, As(III) sorbs only by forming a weak outer-sphere complex and adsorbs much less strongly than to GR, magnetite or Fe(III) (hydr)oxides.

We propose that the elevated groundwater concentrations of As in West Bengal and Bangladesh result from the reduction of iron(III) (hydr)oxides to siderite in conjunction with the reduction of As(V) to As(III).

Magnesite dissolution in the presence of organic and inorganic ligands

G. JORDAN¹, O. POKROVSKY², X. GUICHET³ AND W.W. SCHMAHL¹

¹Dept. f. Geo- u. Umweltwiss., LMU, München, Germany (jordan@lmu.de)
²LMTG-OMP CNRS, Univ. P. Sabatier, Toulouse, France
³Division Géologie-Géophysique-Géochimie, IFP, Rueil-Malmaison, France

Quantitative and predictive modelling of CO₂ sequestration in deep aquifers requires precise knowledge of carbonate mineral reactivity at conditions pertinent to CO₂ storage. Whereas the effect of temperature, salinity, pH, and pCO₂ on Ca- and Mg-carbonate dissolution is extensively studied, the understanding of the influence of organic and inorganic ligands, omnipresent in deep sedimentary basins, remains very limited. Organic and inorganic molecules can exert various influences on the kinetics of growth and dissolution of crystals. The ligands can promote or inhibit growth and dissolution and can control crystal morphology.

Here, a combination of mixed-flow reactor experiments and in-situ hydrothermal atomic force microscopy experiments has been used to investigate the effect of organic (acetate, oxalate, citrate, succinate, EDTA) and inorganic (sulphate, phosphate, borate) ligands on the surface morphology of magnesium and on the molecular mechanism and kinetics of magnesite dissolution at different pH values and NaHCO₃ concentrations.

Since AFM enables to observe monolayer step motion on the surface as well as the step formation frequency by pit nucleation, the effect of ligands on the rate of detachment at specific surface sites can be determined. Thus, AFM data can be interpreted towards a determination of the consequences of adsorption at specific sites on the dissolution kinetics of magnesite in a molecular scale. Comparisons of these data with the dissolution rates of the (104) surfaces and with the dissolution rates of entire crystals (obtained by mixed-flow reactor experiments) allow one to link the molecular-scale effects to the macroscopic effects of ligands on magnesite dissolution.

At circum-neutral pH, the experiments showed a most pronounced effect in citrate- and EDTA-bearing solutions. For citrate, the modification of the reactivity of a distinct kink-site could be detected. More pronounced than the effect of organic ligands was the effect of 0.01 M NaHCO₃ (at pH around 8) which caused a general decrease in reactivity at far from equilibrium conditions. The ligands phosphate, oxalate, citrate, and EDTA were found to weaken but not to fully compensate the retardation of the reactivity generated by NaHCO₃.
Voltammetric determination of Te(IV) and Te(VI): Sorption behaviour on Fe and Mn oxides

CRISTIANE L. JOST1,2, ANDREA KOSCHINSKY1, LEANDRO M. DE CARVALHO2 AND PAULO C. DO NASCIMENTO2

1Jacobs University Bremen gGmbH, Campus Ring 8, D-28759, Bremen, Germany (cristiane.jost@gmail.com, a.koschinsky@jacobs-university.de)
2Universidade Federal de Santa Maria, 97110-970, Santa Maria-RS, Brazil (leandro.carvalho@smail.ufsm.br)

Sorption experiments by Koschinsky et al. (2004) had shown an extremely fast and effective enrichment of tetravalent tellurium (Te(IV)) on Mn and Fe oxides, but no comparable enrichment of the geochemically very similar Se(IV). This Te enrichment was related to a surface oxidation process of Te(IV) to Te(VI) on the Fe-Mn oxide surfaces, which apparently does not take place for Se(IV). In order to compare the behavior of tetravalent and hexavalent Te and Se species, which can both exist in natural waters, new sorption experiments were carried out with the hexavalent species of Te and Se.

Te(IV) was determined by differential pulse cathodic stripping voltammetry (DPCSV) using a 0.1 M HCl and 1 mg L−1 Cu2+ medium according to Ferri et al. (1998). As Te(VI) cannot be reduced electrochemically, a UV-reduction step was required after the sorption experiments and before the voltammetric analysis. For the UV-irradiation procedure, best results were obtained by using a 0.4 M HCl medium for 3 ½ h irradiation time at 90°C (Hg-high pressure lamp, 500 W).

The results of the sorption experiments indicate sorption of Te(VI) on all Mn and Fe oxides used in the experiment, however, the sorption rate was significantly lower than in the experiments with Te(IV). This supports our assumption that Te(IV) is preferentially removed from aqueous solution by Fe and Mn oxide phases compared to Te(VI) and compared to Se(IV) and Se(VI). Comparison of solid phase concentrations of Te and Se in marine oxides indicates that this different sorption behaviour leads to a significant fractionation of the two elements in the marine environment.

Trace element distributions in hydrothermal quartz: Fluid or structural control?

A-L. JOURDAN1, T.W. VENNEMANN1, J. MULLIS2, K. RAMSEYER3 AND C.J. SPIERS3

2MPI, University of Basel, Switzerland.
3Department of Geology, University of Bern, Switzerland.

Quartz is probably the most common hydrothermal vein mineral and its isotopic composition and the chemical composition of its included fluids are widely used for petrogenetic interpretations. In contrast, its own chemical composition is often close to being pure SiO2. A number of studies have, however, shown that some trace elements may enter its structure. While the factors governing such an incorporation are, as yet, not clearly understood, it is obvious that they can potentially be useful for petrogenetic interpretations.

A number of Alpine fissure quartz crystals having formed from chemically different fluids were analyzed for a range of possible trace elements (Li, Na, Mg, Al, P, K, Ca, Ti, Fe, Ge, and H) using different in situ methods (electron and ion microprobes, LA-ICP-MS, and FTIR spectroscopy) after cathodoluminescence (CL) analyses to determine the growth zones. CL bright zones were associated with high Al (up to 7000 ppm), Ge, and Li contents, these elements being strongly correlated, in particular within zones of discontinuous grown crystals. No correlation was found between Al and Na and K. The Al-Li-Ge correlation remains the same in quartz analyzed from different localities as well as along the same growth sector within any one crystal, suggesting that differences in the chemical composition of the fluids (also monitored through the oxygen isotope compositions of the quartz) do not control this correlation. However, the Li/Al ratio (i.e. compensating ion/ substituting ion) can be changed along a growth sector and within different crystals and it never appears to approach unity. While significant quantities of H (deduced from OH− absorption spectra) are also present within the quartz, with high amplitude IR-spectra corresponding to Al-Li rich zones, the H-content alone does not compensate for the charge difference between a Si4+ and (Al3+,Li+) coupled substitution. Also, while no significant differences in trace element content have been observed between the two rhombohedral faces (r and z, where z generally grows faster than r), the prismatic face (m) always has lower trace element content compared to r and z.

It can be concluded that the incorporation of trace elements into hydrothermal quartz is strongly influenced by the growth mechanism, structure, and probably by surface effects, but less so by the chemical composition of the fluid.
Considerations in dating impact craters using the $^{40}$Ar/$^{39}$Ar method: The problem of inherited $^{40}$Ar*

F. JOURDAN$^{1,2}$, P. R. RENNE$^{1,2}$ AND W. U. REIMOLD$^3$

$^1$Berkeley Geochronology Center, USA (fjordand@bgc.org)
$^2$University of California, Berkeley, USA
$^3$Museum f. Natural History, Germany

A large number of impact structures on Earth remain to be dated accurately and precisely (e.g. http://www.unb.ca/pasc/ImpactDatabase/index.html) and [1]. A very versatile and powerful chronometer is the $^{40}$Ar/$^{39}$Ar method, because of its sensitivity to thermal input, the availability of internal reliability criteria such as age plateaux and/or isochrons, and the possibility to obtain compositional parameters (i.e., Ca/K, K/Cl and $^{40}$Ar*). Apart from alteration and/or metamorphic processes that can strongly bias the measurement of the age of a sample, accurate $^{40}$Ar/$^{39}$Ar age determinations are often challenged by the presence of inherited $^{40}$Ar* (i.e., Ar not completely degassed from the target rock during the impact) in the sample.

Here, through the study of 2 impact structures (Tswaing, South Africa and Jänisjärvi, Russia) and comparison with results from 4 other structures, we study the cause and consequence of the presence of inherited $^{40}$Ar*. For example, in the case of Tswaing impact glass particles, no ages approximating the previously accepted impact age of 250 ± 104 ka [2] could be obtained, whereas the Jänisjärvi impact melt rock yielded a statistically robust global isochron age of 682 ± 4 Ma.

The main characteristic controlling the apparent age bias (for a given proportion of inherited $^{40}$Ar*) is the age difference between the impact and the target rocks. The buffer effect for a given crater structure can be predicted knowing the age of the impacted basement and having a rough estimation of the age of the crater structure itself. The occurrence of $^{40}$Ar* inherited is likely influenced by (1) the degree of polymerization (i.e., silicate structure complexity) of the target rock and presumably related to the diffusivity of Ar in the melt/glass, (2) the Ar partial pressure at grain boundaries, (3) the quantity of energy involved in the impact, and (4) the porosity of the target rocks. In addition, the degree of polymerization will control the degree of homogenization of the melt and the rate of $^{40}$Ar* diffusion in the melt. Homogenization of the inherited $^{40}$Ar* ratio at the grain scale (i.e. 150-250 µm) facilitates accurate age determination through isochron analysis, although in completely melted rocks a homogenization of atomic scale environments for inherited and radiogenic Ar eliminates the possibility to resolve the two components thermally, i.e., by step-heating.

Plagioclase lamellae in peridotite-hosted orthopyroxene

Z. JOVANOVIĆ1, E. HELLEBRAND1,2 AND J.E. SNOW3

1Max Planck Institute for Chemistry, Geochemistry Dept., Mainz, Germany (zoranj@mpch-mainz.mpg.de)
2Geology and Geophysics Dept., University of Hawaii, Honolulu, USA (ericwgh@hawaii.edu)
3University of Houston, Department of Geosciences, Houston, USA (jesnow@uh.edu)

The solubility of low-Ca orthopyroxene (opx) in calcic clinopyroxene (cpx) and vice versa is temperature dependent. During cooling, pyroxenes develop subparallel exsolution lamellae. Deviations from this canonical behaviour are very rare. Here we present results from porphyroclastic plagioclase lherzolites from the Ozren ultramafic massif (Dinaride orogenic belt) that contain plagiozise (plag), which seems to be texturally exsolved from opx.

Plag lamellae are parallel to cpx exsolution lamellae and occupy up to 10 vol-% of opx. Spacing is irregular between different porphyroclasts and within the single porphyroclast, but generally ranges between 30 and 500 μm. Some plag lamellae are interrupted by trace amounts of spinel, cpx or amphibole (very rare). In places, opx porphyroclasts are devoid of plag lamellae, but instead contain irregular plag blebs and trails. Opx have very well developed alumina concentration gradients around the Na-poor (An90) plag lamellae and blebs.

Opx-hosted plag exsolutions are very difficult to recognize, both in thin section and BSE images. They are easily overlooked and probably more widespread than commonly assumed. We have also observed them in harzburgite opx near a highly evolved gabbro dike (Central Indian Ridge). To our knowledge they have been described only in peridotites from the Ronda massif (Obata 1980). In contrast, cpx-hosted plag exsolution lamellae are apparently more widespread in peridotites (e.g. Rampone et al. 1993). Closed-pyroxene exsolution requires additional silica in form of Eskola component to produce plag (2CaAl2SiO6+2Ca0.5(-0.5)Fe0.5AlSi2O6). Plag residua is known from HP and UHP mafic rocks. However, Eskola pyroxene is not expected in silica undersaturated rocks. Alternatively, spinel exsolution from pyroxene could provide the Si to produce plag, but spinel contents are too low to balance all observed plag. A third possibility is that the peridotites were lithospheric and that heating was sufficiently fast to reach near-solidus conditions to allow for grain boundary melt migration without rehomogenizing exsolved pyroxenes.

Recent XAS investigations of Zn-impacted soils have identified Zn-phyllosilicates, Zn/Al-Layered Double Hydroxides, Zn sorbed on Mn and Fe oxides and Zn complexed to soil organic matter as the most probable chemical forms for anthropogenic Zn in soils (e.g. Kirpichtchikova et al., 2006 and reference therein). However, the long-term stability of these Zn species has been rarely investigated. This question, which is of primary importance to assess the fate of anthropogenic Zn, can be partly addressed by studying the chemical forms of Zn occurring in naturally Zn-enriched soils overlying geochemical anomalies. Such approach has already allowed us to identify chemical forms of lead and arsenic able to resist to long-term weathering (Morin et al., 2001; 2002).

In the present study, the selected soil has developed upon sulfides mineralized sandstone (Ardeche, France) and exhibit Zn concentrations (up to 500 mg/kg) similar to those found in impacted soils. Molecular-level information gained by EXAFS indicate the occurrence of two main Zn species [Zn-bearing clay minerals and Zn-sorbed Fe oxides], with varying proportions as a function of depth. In the topsoil (A0- and Bs-horizons), about 50 % of Zn is hosted by the clay minerals, whereas this proportion decreases to less than 10 % at depth (C-horizon) where no clay minerals could be detected by XRD. These results suggest that Zn-sorption onto Fe oxides represents the first-stage of weathering of the ZnS-mineralized sandstone (C-horizon). After longer weathering (A0- and Bs-horizons), Zn is progressively incorporated in neoformed clay minerals which likely represent long-term hosts for this element in soils.

Trace element SIMS investigation of multistage garnet – Constraints on partial melting processes in crustal rocks

C. JUNG1, S. JUNG1, E. HELLEBRAND2 AND E. HOFFER1

1Philipps Universität Marburg, FRG, Fachbereich Geowissenschaften (jungs@staff.uni-marburg.de)
2University of Hawaii, USA, Dept. of Geology and Geophysics (ericwgh@hawaii.edu)

The basement dominated granulite-facies part of the central Damara orogen (Namibia) hosts abundant migmatites that originated by partial melting of metapelitic or, less abundant, meta-igneous sources. A migmatitic orthogneiss shows the growth of garnet within the host gneiss (A), the leucosomes (B) and cross-cutting granite dykes (C). Based on microstructural features and microprobe data, garnet A is considered to be metamorphic and garnet B and C are considered to be anatectic and igneous, resp. Rb/Sr and Sm/Nd whole rock isotope data confirm the suggestion that the gneiss belongs to the Pre-Damara basement. Sr isotope data are heterogeneous but assigning an age of 550 Ma for the gneiss, 500 Ma for the leucosomes and 493 Ma for the dykes results in similar initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of ca. 0.730. These results suggest high-grade metamorphic conditions at ca. 550 Ma, followed by in-situ partial melting at ca. 500 Ma and intrusion of granitic dykes at ca. 493 Ma. All garnets have a $10^5$-$10^6$ CI-normalized range in REE abundances and steep LREE-depleted and HREE-enriched element patterns. Garnet from A, B, and C are zoned in Y, HREE, Sr and Ti in which garnet A shows a small core with HREE, Y, Sr and Ti enrichment and a broad rim with trace element depletion. Garnet B has a core enriched in Yb+Y but depleted in Er and Dy and an outermost rim even more depleted in these elements. Garnet C has a broad core with enrichment in Yb+Y and depletion in Er and Dy. The rim is enriched in HREE+Y. LREE (Sm, Nd) profiles are similar to HREE profiles for garnet B and C but garnet A shows the opposite of HREE zoning with a LREE-depleted core and a LREE-enriched rim. These features indicate that HREE fractionation of garnet A follows a Rayleigh fractionation scheme but Nd and Sm concentration profiles are modified by volume diffusion at high temperatures. Garnet B shows evidence for a two-step growth history (melt absent vs. melt-present?) evidenced by the marked hump between core and rim. The trace element pattern of garnet C can be explained by a combination of a Rayleigh fractionation process and a liquid diffusion controlled process. The data show that trace elements may potentially be more sensitive to chemical changes in rocks than major elements in which an accurate interpretation leads to an improved understanding of p-T paths of metamorphism and melting.

High-precision Lu-Hf garnet ages from granulite-facies migmatites (Damara orogen, Namibia)

S. JUNG1 AND E.E. SCHERER2

1Fachbereich Geowissenschaften, Philipps Universität Marburg, FRG (jungs@staff.uni-marburg.de)
2Institut für Mineralogie, Universität Münster, FRG (escherer@uni-muenster.de)

The basement dominated granulite-facies part of the central Damara orogen (Namibia) hosts abundant migmatites formed by partial melting of metapelitic sources during intrusion of hot granitic melts. Centimeter-sized garnet is a common product of incongruent melting reactions and has been dated with the Sm-Nd and U-Pb methods. In addition, the U-Pb ages of matrix monazite have also been determined for the majority of the samples. In general, Sm-Nd garnet whole rock ages are precise (better than 1%) and agree with the Pb-Pb ages of the garnets, although the latter are relatively imprecise (2-8%) due to low $^{206}\text{Pb}/^{204}\text{Pb}$ ratios. Collectively, the Pb-Pb garnet data define an age of 540±40 Ma, whereas the Sm-Nd garnet-whole rock ages range from 530±3 Ma to 506±2 Ma. These age estimates agree with previous Sm-Nd grt-WR ages and U-Pb monazite ages from elsewhere in the orogen and are interpreted to constrain the time span of high-grade metamorphism and melting. To better resolve the relationship between high grade metamorphism and melting and garnet growth, and to improve upon the precisions of the Sm-Nd and Pb-Pb age determinations, garnets were dated with the Lu-Hf technique. All garnets display similar Lu-Hf isotope systematics, with high Lu (16-40 ppm) and high Hf (0.9-1.5 ppm) contents, moderately high $^{176}\text{Lu}/^{177}\text{Hf}$ ratios (1.7-7.3), and radiogenic $^{176}\text{Hf}/^{177}\text{Hf}$ ratios (0.30059-0.35467). Due to these characteristics, the internal isochron ages are precise (0.2-1.0%), and range from 531±1 Ma to 514±5 Ma. For all samples, the Lu-Hf grt-WR ages are similar to—or lower than—the U-Pb monazite ages and are also similar to (with one exception) the Sm-Nd grt-WR ages from the same sample. The similarity among Lu-Hf and Sm-Nd grt-WR ages, Pb-Pb garnet ages, and U-Pb monazite ages imply relatively fast cooling rates immediately after the peak of regional metamorphism, which was probably related to fast uplift of the basement-dominated part of the orogen.
Geochemical and isotope geochemical investigations on Palaeozoic sedimentary rocks

ANKE JURISCH1, BERNHARD M. KROOSS1 AND BIRGIT PLESEN2

1Institute of Geology and Geochemistry of Petroleum and Coal, RWTH Aachen University, Lochnerstr. 4-20, 52056 Aachen, Germany (jurisch@lek.rwth-aachen.de)
2GeoForschungs Zentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (birgit@gfz-potsdam.de)

Palaeozoic natural gas reservoirs in the Central European Basin (CEB) regionally contain high percentages of molecular nitrogen (N2). The highest nitrogen contents are found within Rotliegend reservoirs of the North East German Basin (NEGB) where thick, highly mature Palaeozoic sedimentary sequences are present.

The release of molecular nitrogen from coals and sedimentary rocks with low contents of dispersed organic matter was investigated by means of non-isothermal open system pyrolysis, elemental analysis and stable isotope mass spectrometry. The principal goal was to explore the contents, isotopic composition (δ15N) and the speciation of nitrogen in organic and inorganic constituents of these sequences.

Total nitrogen contents of Namurian shales from four deep wells (4400 - 7000 m) in NE Germany ranged from ~500 to ~2700 ppm. Between 50 and 100 % of this nitrogen is inorganic and fixed as ammonium. Although there is a clear facies trend from marine sediments in the lower part to paralic and terrestrial sediments in the upper part of the Carboniferous sequence, the corresponding δ15Nfix values are within a narrow range (+1 to +3.5‰) along the entire profile while the isotopic composition of the thermally liberated nitrogen was consistently lighter (by 3-5‰). Low nitrogen contents (as low as 460 ppm) and high δ15N values (up to +5.6‰) in one well in the basin centre suggest a significant release of nitrogen (as NH3 and/or N2) associated with 15N enrichment in the residual nitrogen.

Open-system non-isothermal pyrolysis has revealed the presence of inorganic nitrogen species with relatively low thermal stability in marine Namurian A shales. Inorganic nitrogen components in the paralic Namurian B facies show a higher thermal stability range while nitrogen in kerogen and coals is fixed in very refractory compounds decomposing in the 700 – 1200°C temperature range. The presence of significant amounts of inorganic nitrogen is also reflected in the high N/Corg (atomic) ratios (up to 0.108) of the Palaeozoic shales. Thus the on-line isotope analysis indicates the presence of precursor pools with different thermal stability and nitrogen isotopic composition.

The combination of laboratory data, field data and numerical simulations is expected to further constrain the time, temperature and fluid flow conditions and result in an improved understanding of this complex issue.

Pit lakes in Kemerovo region, Russia: Geochemical composition and ecological risk

N.V. JURKEVICH AND S.B. BORTNIKOVA

Trofimuk Institute of Petroleum Geology and Geophysics
SB RAS

The open pit mining and processing of polymetallic ores in XVIII-XX centuries resulted in rise of pits with high-sulfides wastes in all over the world and Russia particularly. The pit lakes arise after pits flooding with atmospheric and underground water and are characterized by low pH, high metal and SO42- concentrations. Unfortunately investigations on pit lakes composition, development and transformation haven’t been carried out adequately in our country. The several pit lakes situated in the Salair ore field (Kemerovo region) are examined in this paper.

Results of the field researches in 2005-2006 and following analytical works allowed to ascertain the composition of water and bottom sediments in pit lakes situated in three ore deposits: Aleksandrovskoe, II Mine, III Mine. Slow interaction between water and oxidized ore bodies in the pit walls resulted in formation of acid solutions (pH=3-5) with high mineralization (5-8 g/l) and metals (Fe-up to 350 mg/l, Zn - to 100 mg/l, Cu, Cd and Pb - to 10 mg/l) and metalloids (concentration of arsenic is up to 0.3 mg/l). The concentrations of concerned elements considerably exceed the background and maximum allowable values with the greatest portion of Cu, Zn, Cd species is most toxic free ion.

The geochemical anomalies of various elements (Ti, Mn, V, Cu, Zn, Cd, Pb, As, Sb, Ag, Te) appear in the pit lake bottom sediments which are mainly in very soluble forms and of high mobility.

The data obtained point out not only an ecological risk but also indicate it is possible to extract the ore elements from these objects for the second time. But currently superficial lakes with transparent water and bottom sediments lacking in vegetation are very popular pleasure resorts for Salair’s natives. The detailed research of circulation of toxic elements will be conducted in the system «pit wall – bottom sediments – water – biota» which is essential to forecast the subsequent changes in pit lakes and find the methods of improvement of these objects.
Magmatic transport of nitrogen, hydrogen and carbon constituents from reduced planetary interiors

A.A. KADIK1 and Yu.A. LITVIN2

1 V.I. Vernadsky Institute of Geochemistry and Analytical Chemistry, RAS (kadik@geoeki.ru)
2 Institute of Experimental Mineralogy, RAS, Chernogolovka, Russia (litvin@iem.ac.ru)

In theories of the Earth’s formation, the composition of gases extracted by primary planetary magmas is accounted for the large-scale melting of the early mantle in the presence of the metallic Fe phase. The melting should have been accompanied by the formation of volatile compounds, which composition was controlled by the interaction of N, H and C with silicate and metallic melts.

In a series of experiments in the system Fe-bearing melt + molten Fe rich metallic phase (0.1-12 % Si + H2 carried out at 4 GPa and 1520-1600°C and log fO2 (oxygen fugacity) = -5 below 1W, we have characterised the nature (oxidised versus reduced) and quantified the abundance of C, H and N-compound dissolved in an iron bearing silicate melt. The speciation of components dissolved in the glass has been determined by Infrared and Raman spectroscopy.

The solubility of Si in liquid metal increases with decreasing fO2 from 0.1-0.55 wt % at ΔlogfO2(IW)= -2-3 to 10-12 wt % at ΔlogfO2(IW)= -4-5. Carbon content in iron-rich globules to be fixed between 3 and 6 wt %. The amount of H (as H2O, OH, H2, CH4) and C (as CO2, CO3, CH4, Si-C) dissolved in the glasses was measured by ion microprobe and by CNH analysis. Hydrogen content decreases with decreasing fO2 from 0.3-0.4 wt % at ΔlogfO2(IW)= -2-3 to 0.1-0.2 wt % at ΔlogfO2(IW)= -4-5 as a result of decreasing of H2O in melt. Carbon content increases with decreasing fO2 from 0.2-0.5 wt % at ΔlogfO2(IW)= -2-3 to 1-2 wt % at ΔlogfO2(IW)= -4-5 as a result of increasing of CH4. The nitrogen solubility (as N2, N+) reaches 2-3 wt % at ΔlogfO2(IW)= -2-4.)

In the light of experimental data we argue that magma in reduced environment in area of the Fe-Si alloy stability could form melts containing dissolved both oxidized, and reduced components of hydrogen and carbon species. We assume that core growth took place under reduced conditions imposed by the pristines terrestrial materials and was accompanied by the emission of CH4, H2, N2 and NH3 and minor H2O into the atmosphere.

Support: RFBR grant 05-0564391t, ESD RAS project 7-1.2.

Colloid formation in aerated Fe(II) containing water: Effect of phosphate, silicate and Ca on morphology and structure

R. KAEGL1, A. VOEGELIN2, D. FOLINI3 and S.J. HUG1

1 Eawag, Dübendorf (rafael.kaegi@eawag.ch; stephan.hug@eawag.ch)
2 ETH Zurich (voegelin@env.ethz.ch)
3 Empa, Dübendorf (doris.folini@empa.ch)

The biogeochemical cycling of nutrients and pollutants is strongly influence by the formation and presence of colloids. In this study we focused on the microscopic analysis of colloids formed due to iron oxidation and hydrolysis in synthetic carbonate-buffered groundwater (pH 7, 2-30 mg/L Fe(II)). We investigated the influence of phosphate (2-20 mg/L P), silicate (2-20 mg/L Si), and Ca (2.5 mM Ca- or 8 mM Na-bicarbonate) on colloid formation. The morphology, chemistry and crystallography of the colloids were characterized using HR-TEM (high resolution transmission electron microscopy), TEM-EDX (energy dispersive x-ray analysis) and SAED (selected area electron diffraction).

When Fe(II) is added to a Na-bicarbonate-buffered water, idiomorphic lepidocrocite (Lp) crystallizes, as confirmed by SAED. Individual sheet-like crystals are between 100 - 200 nm long and a few nm thick. These crystals agglomerate to ‘spherical’ entities with a diameter of up to 500 nm. Several of these ‘spherical’ entities aggregate again to fractal-like aggregates.

At high Si/Fe ratio, the crystallization of Lp is suppressed and ferrihydrite (Fh) forms instead. The Fh crystals are platelets of ~5 nm showing lattice fringes in HR-TEM images. The individual Fh agglomerate to spheres of ~200 nm and form fractal-like aggregates. SAED images of aggregates show two distinct rings at distances of 0.15 and 0.25 nm, indicative of 2-line Fh.

At high P/Fe ratios, a Fe-phosphate (Fe-P) forms. The Fe-P appears as spherical particles of ~100 nm in diameter, but no primary crystals can be observed. However in the SAED pattern, a faint ring at a distance of ~0.29 nm is observed, in agreement with XRD patterns from amorphous Fe-P references.

At lower Si/Fe or P/Fe ratios, depletion of Si or P due to precipitation of Fh or Fe-P results in the subsequent formation of Lp. The presence of Ca in solutions containing Si and P enhances Fe(III)-colloid coagulation due to a reduction of the electrostatic repulsion. Based on our microscopic investigations, it is not clear, yet, whether Ca is also directly incorporated into the colloid structures.

Despite the varying chemistry, the morphologies of all colloids are very similar. The formation can be described with the following three steps: 1. rapid formation of primary particles (Fh, Lp, Fe-P), 2. formation of ‘spherical’ entities and 3. agglomeration to fractal-like aggregates.

3 Empa, Dübendorf (doris.folini@empa.ch)
Melt-rock reaction and late-stage melting in peridotite xenoliths from Marsabit (Kenya)

Benjamin Kaeser1, Angelika Kalt1, Thomas Pettke2 and Thomas Ludwig3

1IGH, Université de Neuchâtel, Rue Emile-Argand 11, CH-2009 Neuchâtel, Switzerland (v1bkaeser@staffmail.ed.ac.uk; angelika.kalt@unine.ch)
2Institut für Geologie, Universität Bern, Baltzerstrasse 1-3, CH-3012 Bern, Switzerland (thomas.pettke@geo.unibe.ch)
3Mineralogisches Institut, Universität Heidelberg, Im Neuenheimer Feld 236, D-69120 Heidelberg, Germany (tl@min.uni-heidelberg.de)

Mantle metasomatism is widespread in mantle rock suites worldwide, highlighting the importance of melt- and fluid-rock reaction in the Earth’s upper mantle. Styles of metasomatism can be very complex and include a wide variety of mineralogical and geochemical signatures, reflecting both, the nature of the initial metasomatising agent (carbonate or silicate systems, melt or fluid) and its evolution through reaction with the pre-existing mantle rock. Here, we present a study on variably metasomatised peridotite mantle xenoliths (from Marsabit, Kenya) that aims to constrain either of the above parameters by integrating results from textural and in-situ (LA-ICPMS, SIMS) geochemical analysis.

The investigated xenoliths are cpx-bearing cryptically metasomatised harzburgite (LREE, Li, B, U, and Th enrichment of cpx) and modally metasomatised cpx-free harzburgite and dunite. Metasomatic phases include amphibole, plagioclase, apatite, graphite and opx. Transitional samples show that metasomatism led to replacement of cpx by amphibole. Further, in all modally metasomatised xenoliths melt pockets (silicate glass containing silicate and oxide microlites and carbonates) occur in close textural relationship with the earlier metasomatic phases. Textural, major and trace element compositions and results from thermobarometry and fO2 calculations indicate that the mineralogy and compositions reflect complex interplay between melt-rock reaction processes, trace element fractionation, pre-existing mantle heterogeneity and effects of changing P, T and fO2 during one single metasomatising event. The metasomatising agent was a SiO2-Na2O-CO2-H2O-rich liquid (possibly a fluid). The unusual style of metasomatism (composition of amphibole, presence of graphite, formation of opx) reflects low P-T conditions (ca. 750-850°C at <1.5 GPa) in the wall rock during impregnation and locally low fO2. The latter allowed the precipitation of graphite from CO2. The Si-rich fluid possibly derived from alkaline basic melts by melt-rock reaction during Tertiary-Quaternary magmatism. Melt pockets formed during late melting of the earlier phases (mainly amphibole) shortly before or during xenolith transport in the host magma and was triggered by CO2-rich fluid infiltration.

Uraniferous carbonate rocks from Mt. Kithaeron, central Greece

F.-C. Kafandaris1, A. Godelitsas1, D. Kostopoulos1, S. Xanthos2, E. Chatzitheodoridis3 and E. Baltatzis1

1University of Athens, Faculty of Geology and Geoenvironment, Athens, Greece (agodel@geol.uoa.gr)
2Aristotle University of Thessaloniki, School of Electrical and Computer Engineering, Thessaloniki, Greece
3National Technical University of Athens, School of Mining and Metallurgical Engineering, Athens, Greece

The average abundance of U in carbonate sedimentary rocks is 2.2 ppm. Sandstones and shales contain 0.5 ppm and 3.5 ppm respectively while the typical U concentration in seawater is 3.2 ppb (Krauskopf and Bird 1994). Uranium in the oceans follows anoxic pathways and it is mainly removed from the water due to chemical processes taking place at the interface of organic-rich sediments. Uranium is therefore correlated to organic carbon whereas the diagenetic cycle of the element may include reduction of U(VI) to U(IV) related to sulfate bio-reduction (Mo et al. 1973, Klinkhammer and Palmer 1991). The concentration of U in marine carbonates from SE Europe and the eastern Mediterranean is reported to be in the region ca. 1 – 7 ppm. Here we present the occurrence of carbonate rocks, limestones and dolomitic limestones with variable organic content, from Mt. Kithaeron (central Greece) containing unusually elevated U concentrations up to ca. 56 ppm. We also present a relationship between the U content and radioactivity (see Figure below).

They are typical Alpine (Neotethyan) sediments, of likely Triassic age (according to existing paleontological data) belonging to the SubPelagonian zone of the internal Hellenides. The rocks were investigated using a combination of microscopic, spectroscopic and wet-chemical techniques. Our study revealed that U is probably associated to the non-carbonate part of the rocks (organic matter, Fe- and Mn-oxides, phosphates, etc.).

²CSIC, Institut de Ciències de la Terra 'Jaume Almera', Lluís Solé i Sabaris s/n, 08028 Barcelona, Spain

We have quantified the timescales of magma mixing and residence before eruption by modelling compositional gradients of multiple elements (Fe, Mg, Mn, Ca) in several olivine crystals from the different lava flows that erupted during December 1991, January 1992 and March 1992 at Mt. Etna. Three different olivine populations were identified based on core crystal compositions (Fo70, Fo78, Fo80-82) and these are interpreted as open system involving mixing between three different components (magmas or crystal sources). The difference in core compositions contrasts with the common composition of most rims at Fo70-72 indicating that all crystals share their late magmatic histories. The zoning patterns of these olivine types are: (i) a dominant population of reversely zoned or unzoned crystals with cores at Fo70 and rims at Fo72-74, (ii) a less abundant, normally zoned crystal population with cores at Fo80-82 and rims Fo72-74 (occasionally Fo78), (iii) a subordinate population with crystal cores at Fo75-78, an intermediate zone of Fo80, and rims at Fo74. These types of zoning indicate two distinct mixing events. An early episode between the two high Fo magmas (e.g., cores at Fo78 and Fo80-82) followed by the remixing of this with a more differentiated magma with Fo70 crystals. The results of modelling the chemical gradients indicate that the early mixing event occurred about 100 - 200 days prior to eruption. Crystals showing evidence of this older mixing event are mainly represented in the December 1991 rocks and their proportions decrease in the latter eruptions. In contrast, the times since the last mixing episode with the more differentiated magma are present in all studied rocks, and are in general shorter. They increase from a few days or weeks for the December 1991 products to a few months for the March 1992 deposits. This sequence of events and time scales may be explained by arrival of an already mixed magma to a shallower reservoir containing the differentiated magma. The observation that the times since this last mixing event increase with eruption sequence indicates ageing of the crystals in this shallow reservoir which was simply being emptied after an initial recharge of mixed, mafic melt that may have triggered the eruption. This single recharge was apparently sufficient to sustain the eruptive activity during the December 1991 to March 1992 eruptions.

Aerobic and anaerobic microbial ecosystem recorded in the Steep Rock Group, Ontario, Canada

T. KAKEGAWA AND M. HAIKAWA

Graduate School of Science, Tohoku University, Sendai, Japan (kakegawa@mail.tains.tohoku.ac.jp)

The Steep Rock Group is mainly composed of ca. 3.0 Ga submarine volcanic and sedimentary rocks. Thick carbonate unite, containing stromatolite, is the well-known characteristic of this group. The stromatolite is overlain by other carbonate, black cherts, black shales and carbonaceous massive sulfides, although most outcrops were mined out.

Carbon isotope compositions of kerogen in the examined samples range from -37 to -23 ‰. The heaviest carbon isotope composition is found in the stromatolite sample. SEM observation indicate that kerogen in stromatolite samples often contain micro-crystals of Mn and Fe oxides. Such Mn and Fe oxides were most likely formed during diagenesis using dissolved oxygen in shallow water and have distinct characteristics compared to the secondary Mn and Fe oxides formed by Phanerozoic weathering. These mineral and isotopic characteristics suggest the aerobic microbial activities during the formation of stromatolite. The lightest carbon isotope composition was found in black shale samples, suggesting the activity of methanotrophs during the black shale sedimentation.

Micro-scale sulfur isotope compositions of pyrite were also determined by the laser microprobe system. Sulfur isotope compositions of pyrite in black shales and massive sulfides range from -8 to -5 ‰. Such isotope compositions, small range and pyrite texture suggest that microbial sulfate reduction in stratified ocean water followed by syngenetic pyrite precipitation from deep euxinic ocean water. Those all data indicate that variety of microbial ecosystem, corresponded to the paleo-water depth, existed in the 3.0 Ga Steep Rock oceans.
Li, Be, B and $\delta^{11}$B values from the peralkaline Ilimaussaq intrusion and its country rocks (South Greenland)

Melanie Kaliwoda 1, Rainer Altherr 2 and Gregor Markl 1

1 Universität Tübingen, Institut für Geowissenschaften, Germany
2 Universität Heidelberg, Mineralogisches Institut, Germany; melanie.kaliwoda@uni-tuebingen.de

The Ilimaussaq intrusion is characterized by four progressively more fractionated magmatic pulses: (1) augite syenite, (2) peralkaline granite and (3+4) agpaitic nepheline syenites. The peralkaline granite is interpreted as a contaminated equivalent of the augite syenite. Evidence for late-stage hydrothermal activity is present as veins penetrating all units. The intrusion is partly hosted by supracrustals, partly by the Proterozoic Julianehåb granite.

Li, Be and B contents, as well as $\delta^{11}$B ratios have been measured with SIMS (secondary ion mass spectrometry) in all important primary and secondary minerals from the different rock types of the Ilimaussaq intrusion and the Julianehåb granite to understand the behaviour of the light elements during differentiation of an alkaline magmatic system. The main Li carrier in the system is Na-rich amphibole, with a maximum Li content of 6000 µg/g in the foyaites and naujaites, but with only 50 µg/g in the early Ca-rich amphiboles of the augite syenites. The highest Be contents occur in late-stage hydrothermal aenigmatite (500 µg/g), followed by nepheline (16-100 µg/g) and sodalite (15-60 µg/g). The main B carrier of the rocks is sodalite with maximum contents of 120 µg/g. $\delta^{11}$B measured in most amphiboles is about –20 ‰ and displays closed-system behaviour in the inner part of the Ilimaussaq intrusive rocks, but rises in the augite syenites from –20 to –7 ‰ towards the contact with the Julianehåb granite. The highest Be contents occur in late-stage hydrothermal aenigmatite (500 µg/g), followed by nepheline (16-100 µg/g) and sodalite (15-60 µg/g). The main B carrier of the rocks is sodalite with maximum contents of 120 µg/g.

Melt inclusions from the Barberton Greenstone Belt, South Africa

A. Kallio 1, L. Danyushevsky 2 and T. Ireland 1

1 Research School of Earth Sciences, Australian National University, Canberra, Australia (antti.kallio@anu.edu.au)
2 CODES, University of Tasmania, Hobart, Australia

Melt inclusions from komatiites in Archean Greenstone Belts can increase our understanding of the origin of ultramafic magmas. However, the question of whether old inclusions preserve original magmatic compositions has to be answered first. To address this problem, we have studied melt inclusions from the southwestern part of the Barberton Greenstone Belt with visual heating experiments. Our sample is a partially serpenetised olivine cumulate with olivine relics of Fo93-94 composition.

Unheated inclusions show a variety of petrographic textures. Inclusions range from mostly glassy to crystalline. The morphology of the inclusion edges varies from smooth edges to many irregular protrusions at the edges. The origin of these different morphologies is not yet fully understood.

Inclusions that were visually inspected during heating behave similarly. Melting starts at 800-900°C. A vapour bubble forms and gets smaller with increasing heating indicating that the system is closed. At a peak experimental temperature of 1360°C a small bubble is still present, and the melt is in the olivine-only field. Inclusions were not heated to a higher temperature to avoid H2 loss during experiments. After initial experiments, subsequent inclusions were quickly heated to a temperature of 1360°C, held for 30s and quenched to try to preserve olivine rim compositions and volatile contents. The relative proportions of the bubble and inclusions sizes are approximately constant, except for a few selected altered looking inclusions where a large expanded bubble is observed.

FeO content of reheated inclusions shows a negative correlation with Fo-content of host olivine, which is indicative of re-equilibration during cooling (Danyushevsky et al., 2000). Major element compositions of inclusions have been recalculated to correct for Fe-loss. Inclusions larger than 35 microns and with ‘normal’ bubble sizes show coherent major element trends. Smaller inclusions have lower MgO outside the main trend, probably caused by poor quenching.

Compositional profiles have been analysed across the olivine rims around several inclusions in order to constrain the cooling history of the individual olivine grains (Danyushevsky et al., 2002).

We will present major, trace and volatile (H2O, Cl, S) contents of the melt inclusions and their host olivine phenocrysts and use them to estimate the composition and temperature of the parental melt and the conditions of its evolution.

Cell enumeration in extremely nutrient-poor sediments

JENS KALLMEYER1,*, STEVEN D’HONDT1 AND THE KNOX-02RR SHIPBOARD SCIENTIFIC PARTY

1NASA Astrobiology Institute, Graduate School of
Oceanography, University of Rhode Island, South Ferry Road, Narragansett, RI 02882, USA,
present address: GeoForschungsZentrum Potsdam, Section 4.3 Telegrafenberg, B 221, 14473 Potsdam, Germany,
Tel: *49-(0)331-288-1787 (kallm@gfz-potsdam.de)

This expedition explored extraordinarily slowly accumulated sediments of the South Pacific mid-ocean gyre, farther from continents and productive oceanic zones than any other site on Earth. It provided an opportunity to study the nature of life in the most oxidized and food-limited sediments of Earth’s ocean. These sediments are relatively rich in cosmic debris and a direct terrestrial analogue for slowly accumulating energy-poor sedimentary environments on other planetary bodies (e.g. wet subsurface sediments of Mars).

So far most cell enumerations have been carried out in shelf sediments which contain variable but significant amounts of organic matter. Such sediments usually have cell abundances that range from 10^6 to 10^10 cells cm^-3 at the surface and decrease with depth to about 10^5 cm^-3 around 100 to 1000 mbsf. The sediments retrieved during this cruise have much less organic matter and also lower cell numbers. Due to the low cell abundances, ranging from 10^6 cm^-3 at the surface to 10^3 cm^-3 at 10 mbsf, it is necessary to extract the cells from the sediment and concentrate them prior to counting, using novel technique (KALLMEYER, subm.). The sediment is treated with a mixture of different detergents, solvents and complexing agents, followed by separating the cells from the sediment particles by density centrifugation. The cell extracts are then filtered and stained with SYBR Green I®, a highly dsDNA specific stain.

The cell counts show that there is a microbial community in these sediments despite the fact that there is basically no organic matter available. The cell abundances are the lowest ever encountered in the marine environment. These very low cell counts imply that current estimates of subsaeal floor biomass are far too high, because the abundance of cells in this extensive habitat is approximately three orders of magnitude lower than current estimates of average cell concentrations in subsaeal floor sediments.

Establishing high precision trace element maps of the main dust source areas of eastern and south-central Australia

BALZ S. KAMBER1, HAMISH A. MCGOWAN2, SAMUEL K. MARX2 AND LYNDA M. PETHERICK2

1Department of Earth Sciences, Laurentian University, Sudbury, Canada (bkamber@laurentian.ca)
2School of Geography, Planning and Architecture, The University of Queensland, Brisbane, Australia (h.mcgowan, s.marx, and l.petherick@uq.edu.au)

Continental-scale geochemical mapping relies on precise and accurate chemical analyses of surface samples. Eggins et al. (1997) demonstrated that appropriate analytical protocols can yield high precision (typically better than 1-2% rsd) and accurate trace element data for >40 elements by inductively-coupled-plasma mass spectrometry (ICP-MS).

Here we present such a high-precision geochemical dataset (40 trace elements) for the source areas of dust that is transported across the Eastern Australian seaboard. These source areas (river floodplains, palaeo-lakebeds, dunes, playas) have generally similar relative trace element abundances, typical of upper continental crust. However, the new ICP-MS data document geochemical provinces on the sub-catchment scale. The geochemical provinciality is largely inherited from the main erosion source lithologies and translates into provenance resolution of ca. 50 x 50 km.

When modern far-travelled (up to 4,000 km) mineral dust of known provenance (from ground observation) is compared to the surface geochemical map, we find excellent agreement with the source area for many elements (McGowan et al., 2005). Mismatching elements are those affected by: (i) density sorting (Zr, Hf, HREE); (ii) reprecipitation (Be, Sr) and (iii) air pollution (first and second order transition metals, Ti and Pb). Comparison of 210Pb activity between known source areas and far-travelled dust demonstrates clearly that the enrichment in metals like Pb, Zn and Cu happens during atmospheric transport through the coastal East Australian pollutant plumes (Marx et al., 2005).

For the purpose of dust provenancing, for which Zr, Hf and HREE are unsuitable, it is sufficient to digest surface sediments in closed beakers at 130°C. However, we also demonstrate that only high-P digestion at 200°C yields complete sets of accurate data for all elements. This factor will severely increase the effort and cost of any rigorous surface geochemical mapping project.

Dynamics of zero-valent sulfur species, including polysulfides, in Wadden Sea tidal flat pools

A. KAMYSHNY, JR. AND T.G. FERDELMAN
Max Planck Institute for Marine Microbiology, D-28359 Bremen (akamyshn@mpi-bremen.de; tferdelm@mpi-bremen.de)

Zero-valent sulfur (ZVS) species (rhombic elemental sulfur, colloidal elemental sulfur, inorganic polysulfides (S\textsubscript{n+2}\textsuperscript{2-}) and polythionates (S\textsubscript{n}O\textsubscript{2}\textsuperscript{2-})) play an important role in a variety of environmentally, geochemically and biogeochemically important processes. Polysulfides are known to decompose halogenated pollutants by reductive dehalogenation pathway. They are the important reactants in pyrite formation and sulfuration of sedimentary organic matter during early diagenesis. ZVS compounds are also important bacterial substrates. In natural aquatic systems ZVS species can be produced by microbial as well as by chemical pathways.

ZVS species dynamics in tidal flat pools of Wadden Sea (North Sea) was studied. Concentrations of solid sulfur, colloidal sulfur and distribution of inorganic polysulfide species were detected in different pools as a function of time after detachment of the pool from the sea.

Every sample was analysed by the protocol that consists of 4 procedures: 1) detection of individual inorganic polysulfides by rapid single-phase derivatization with methyl trifluoromethanesulfonate followed by HPLC-UV detection of dimethylpolysulfanes [1]; 2) detection of colloidal elemental sulfur, polysulfide and polythionate ZVS by reaction with hydrogen cyanide followed by HPLC-UV detection of thiocyanate; 3) pre-treatment with zinc chloride solution followed by chloroform extraction and HPLC-UV detection of elemental sulfur; 4) analysis of individual polythionates by HPLC-UV. Detection limit of each procedure was ≤2 µM.

Maximum sulfide concentration detected in the pools was 273 µM. During the initial 2 hours of pool detachment from the sea the main ZVS pools were colloidal sulfur and polysulfides. Dispersed solid sulfur concentrations reached significant values only 5 hours after pool detachment. Maximum concentration of colloidal sulfur detected in the pools was 73 µM and total ZVS >100 µM. Polythionates with n=4-6 were not observed in any of the analysed samples.

Individual polysulfides with chain lengths of 4-6 sulfur atoms were quantitatively detected for the first time in marine waters. Polysulfides concentrations were found to be lower than the predicted ones by calculations based on thermodynamic values. Maximum detected sum of S\textsubscript{4}\textsuperscript{2-}, S\textsubscript{5}\textsuperscript{2-} and S\textsubscript{6}\textsuperscript{2-} concentrations was 5.9 µM.

A deep mantle reservoir inferred from isotope signatures of Kimberlites

ICHIRO KANEOKA
Earthquake Research Institute, University of Tokyo,
Bunkyo-ku, Tokyo 113-0032, Japan (ikaneoka@aol.com)

Based on radiogenic isotopes, depleted (DM) and enriched (EMI, EM2) mantle reservoirs together with the other one (HIMU) have been generally accepted. However, existence of BSE-like (non- or less fractionated and least degassed) mantle reservoir is a matter of debate.

Although much caution is required to get reliable data of Kimberlites, their isotope data bear characteristic features. Based on Sr-Nd isotopic systematics, Kimberlites have been classified into Group I and II (Smith, 1983). In the Sr-Nd isotope diagram, Group I Kimberlites cluster close to the value of BSE, whereas Group II Kimberlites in the enriched area. Pb isotope systematics show similar systematics. The latter can be explained by incorporation of recycled materials and their distribution is limited. Hence I concentrate my discussion on Group I Kimberlites. Based on HF isotopes of Greenland kimberlites, Bizzarro et al. (2002) suggested the existence of a hidden reservoir, since Kimberlite data systematically lie below the Nd-HF isotope mantle array. While HF isotope data themselves also cluster close to the BSE value, Sr, Nd and Pb isotope systematics of Kimberlites have often been attributed to the mixing of components between the asthenosphere and lithosphere. However, our \textsuperscript{3}He/\textsuperscript{4}He and Ne isotopic studies of Greenland and Russian Kimberlites have revealed the occurrence of Lohi-type noble gas isotope signatures in their magmas and suggest their deep mantle origin (Tachibana et al., 2006; Sumino et al., 2006).

Noble gas isotope signatures are similar to those of Lohi-type OIBs. However, solid isotope epsilon data of Kimberlites with different time and space cluster much more tightly than those of OIBs and they are close to BSE. To produce such a feature, mixing among two or more multiple components operated with the same degree even in different time and space is unlikely. Accordingly, such a feature would be attributed to the properties of kimberlite magma source itself. Thus, isotope signatures of Kimberlites suggest possible existence of a deep mantle reservoir which is close to BSE and less fractionated and less degassed than the other mantle reservoirs. However, HF isotope signatures might require an additional component to explain the trend of kimberlites.

Localization of hydrocarbon contamination by measuring microbially induced changes of soil magnetic properties

A. KAPPLER¹, K. PORSCH¹, M.-L. RIJAL² AND E. APPEL²

¹Geomicrobiology, Center for Applied Geosciences, Sigwartstrasse 10, 72076 Tuebingen, Germany
(andreas.kappler@uni-tuebingen.de; katharina.porsch@uni-tuebingen.de)
²Geophysics, Center for Applied Geosciences, Sigwartstrasse 10, 72076 Tuebingen, Germany
(moti-lal.rijal@uni-tuebingen.de; erwin.appel@uni-tuebingen.de)

Soil contamination by crude oil and other hydrocarbons represents a severe, global environmental problem, but often the location and extent of contamination is not known. Hydrocarbons, or their degradation products, can stimulate iron-metabolizing microorganisms, leading to the formation or dissolution of (magnetic) iron minerals and an associated change of soil magnetic properties. Therefore, the screening of soil magnetic properties has the potential to serve as an efficient and inexpensive tool to localize and assess hydrocarbon contamination.

In order to identify the influence of different biogeochemical factors on the microbially influenced changes of soil magnetic properties after hydrocarbon contamination, oil spills were simulated in laboratory batch experiments. The parameters tested in these experiments included soils with different geological bedrocks, type and amount of added hydrocarbon, and microbiological parameters (sterile, autochthonous or added micro-organisms). In order to follow the changes of the soil magnetic properties, the magnetic susceptibility of the samples was measured weekly.

First results show that changes in the magnetic mineralogy are caused by microbial activity, as sterile samples showed no changes. In the microbially active set-ups, depending on the water content the magnetic susceptibility increased or decreased up to 10% in comparison to the initial magnetic susceptibility within a few weeks. In one iron-rich soil even a decrease of the magnetic susceptibility of ~40% was observed. The amount and type of the hydrocarbon source did not have an influence on the changes in magnetic susceptibility. However, DGGE fingerprints of different set-ups, performed at the end of the experiment, revealed that the amount and type of the hydrocarbon source influenced the microbial communities.

These first results show that the magnetic susceptibility changes in the presence of hydrocarbons and that this change is microbially induced. This suggests that the screening of soil magnetic properties can be applied to localize and assess hydrocarbon contamination. In order to understand the biogeochemical processes better, the change of the iron mineralogy will be followed by Mössbauer spectroscopy in future batch experiments. Furthermore, iron-metabolizing microorganisms will be isolated and identified.

Effects of calcium fluxes on authigenic carbonate formation at mud volcanoes off Costa Rica

D. KARACA, C. HENSEN AND K. WALLMANN

IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany
(dkaraca@ifm-geomar.de; chensen@ifm-geomar.de; kwallmann@ifm-geomar.de)

The Costa Rican forearc is characterized by active fluid venting related to mud diapirism and volcanism. Our study aims at thoroughly investigating the major parameters controlling authigenic carbonate formation such as fluid composition and advection rate. These efforts will help further our understanding of turnover rates at mud volcanoes and better constrain the use of authigenic carbonates as archives for past fluid flow. Pore water profiles of four sites on the southern Costa Rica margin show that all fluids are low in chloride and methane rich. Fluids of Quepos Slide and Culebra Fault are enriched in calcium, barium and bromine. In contrast, fluids of Mounds 11 and 12 are low in calcium. We present results of a numerical reactive-transport model used to quantify the effects of calcium fluxes and fluid flow rates on carbonate precipitation and methane discharge. At active vent locations of Mounds 11 and 12, 98% of the methane is released into the bottom waters due to exceptionally high advection rates (100-200 cm a⁻¹); corresponding to a low efficiency of AOM. This causes a reduced alkalinity production and hence a lower degree of authigenic carbonates formation. In comparison, moderate flow rates (0.1- 40cm a⁻¹) at Culebra Fault and Quepos Slide lead to reduced methane output (7% - 40%) from the sediment. Here, higher efficiency of AOM and Ca fluxes increase the calcium carbonate precipitation rates. Thus, higher Ca fluxes from below induce more precipitation of calcium carbonate. Further steps are in progress to better constrain the impact of calcium enriched fluids on carbonate precipitation by application of systematically simulating variations of fluid flow rate and Ca²⁺ concentrations in the ascending fluids.
Trace element contents of Jurassic coals from eastern Taurides, Turkey

REYHAN KARA GÜLBAY AND SADETTIN KORKMAZ
Karadeniz Technical University, Department of Geological Engineering, Trabzon/Turkey (kara@ktu.edu.tr; korkmaz@ktu.edu.tr)

In this study, trace element and organic matter-trace element relation between Jurassic coals exposing in three different fields in the eastern Taurides were examined and their enrichment levels with respect to upper crust values were computed and the coal characteristics were also compared with those from USA and other parts of the world.

In comparison to the Feke and Kızılınç coals, Pb, Zn, Ag and Hg element contents of the Gedikli coals are considerably high; Ni, As and Ge contents are moderately high and Cr, Cu, Co, Cd, Sb, Ga and Sn contents are slightly high. The element concentrations are very similar to those of other fields. In the Gedikli coals, Sr content is extremely low and Ba content is slightly low with respect to other fields. Re, Mo, U, V and B element concentrations are different for each of three fields.

The major element contents of the Feke, Gedikli and Kızılınç coals were correlated with average values of coals from USA and other parts of the world and Fe, K, Mg and Na concentrations were found to be similar. Ti and Al contents of the world and USA coals are higher while Ca and Mn concentrations are lower. Considering trace element contents of the world and USA coals, Ba is considerably high, Cu and Zr are moderately high and Ga, Rb and Sc elements are slightly high. In comparison to world and USA coals, Sr content of the Feke and Kızılınç coals are very high while those of the Gedikli coals are lower.

For major and trace elements, factors of enrichment with respect to upper crust values were also computed. Among the major elements, Ti and K are depleted in the Feke field and Na is depleted in the Kızılınç field while other elements are enriched. The highest enrichment levels were calculated for Ca and Sr. Except for Se and Rb, all other trace elements are enriched with respect to upper crust. Re has the highest enrichment level followed by Ge, B, Sb, Cd, U, As, Te and Mo. Se and Rb show the lowest enrichment level in all the fields and, Th , Ba, Ge, Sc, Cs, Hf, Nb, Zn and Li generally have lower enrichment levels in the studied fields.

The behaviour of strontium and zinc during ageing of Fe(III) hydroxide

O.N. KARASEVA1, L.Z. LAKSHANTANOv1,2 AND L.I. IVANOVA1

1Institute of Experimental Mineralogy RAS, 142432, Chernogolovka, Russia (olga@iem.ac.ru)
2NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen Ø, Denmark

Oxides and hydroxides of Fe(III) are common components of soil environment and can have a significant role in toxic metal mobility and retention. Sorption of many elements, among them heavy and Earth metals, on Fe hydroxides is fairly well understood. However, little is known about the influence of ageing and transformation of Fe hydroxides on the ions sorbed from solution. The alteration of the ferric hydroxide specific surface area during crystallization and the dynamics of interaction between Zn and Sr with Fe hydroxide were investigated experimentally at 25°C using a combination of potentiometric acid-base titration and metal uptake experiments.

The maximum decrease in Fe hydroxide surface area was observed during first day. Assuming similarity of the acid-base properties of hematite and Fe hydroxide surfaces, the specific surface area of Fe hydroxide was determined as a function of ageing time. The specific surface area determined after one hour, one and ten days following the initial precipitation are 570, 450 and 420 m²/g.

We observed a significant difference in the behaviour of strontium and zinc during Fe hydroxide crystallization. Solubility of Sr increases while the hydroxide surface area and consequently, the surface site density, decreases. While increasing ageing time from 2 hours to 10 days, Sr adsorption decreases by ~15%. The fundamental reason leading to reduction of Sr concentration in the solution is the adsorption at the surface of ferric hydroxide. In the case of zinc, even at low pH, sorption on the ferric hydroxide exceeds 40% and increases during mineral crystallization. This demonstrates the predominance of Zn coprecipitation with Fe hydroxide. Such a mechanism effectively decreases mobility because incorporated cations are only remobilized by a change in chemical conditions significant enough to force dissolution of the host mineral.
Combining riverine and satellite data for monitoring the climate effect on the carbon cycle in NE Iceland

M.I. KARDJILOV1, S.R. GISLASON2 and G. GISLADOTTIR3

1Department of Geology and Geography, University of Iceland, Askja, Sturlugata 7, IS-101 Reykjavik, Iceland (marin@hi.is, ggisla@hi.is)
2Institute of Earth Sciences, University of Iceland, Askja, Sturlugata 7, IS-101 Reykjavik, Iceland (sigrg@raunvis.hi.is)

The objective of this study is to measure and compare the CO2 sequestration rates of vegetation and weathering of rocks in 8 (glacial and direct runoff) river catchments in NE Iceland over the years 1998-2003. Furthermore to test if increase in CO2 fixation of vegetation translates into more CO2 fixation over the years 1998-2003. Furthermore to test if increase in CO2 fixation of vegetation translates into more CO2 fixation over the years 1998-2003. The study period includes 3 of the warmest measured years in Iceland and the world. The 8 river catchments are mostly basaltic, they differ in age (from present to 15 Myr), elevation, temperature, runoff, glacier- and vegetation cover (from desert to woodland) and they are unpolluted.

Riverine discharge was continuously monitored but river carbon concentrations were measured at the end of each of 50 expeditions. Dissolved inorganic carbon flux (DIC), particulate organic carbon flux (POC), dissolved organic carbon flux (DOC) were calculated from correlations between the concentrations and the discharge at the time of sampling for each catchment (Kardjilov et al. 2006a, 2006b). Satellite remotely sensed gross primary production (GPP) and net primary production (NPP) are based on MODIS GPP and NPP products.

DIC, POC and DOC fluxes of the glacial feed rivers are depend on temperature, while for the direct runoff rivers they are precipitation dependent. The gross primary production of the vegetation is temperature dependent for all of the river catchments, while the net primary production of the vegetation shows fluctuations. There is a strong feedback between the vegetation NPP fixation of carbon and the riverine fluxes in the coldest catchments indicating that the effect of climate change for the carbon cycle is more severe for the coldest, driest and least vegetated catchments.

Petrogenesis of the most-recent Quaternary volcanism with implications for post-collisional lithospheric thinning of Eastern Turkey, Erzincan

O. KARSLI1, B. CHEN2, I. UYSAL1, J.R. WUBRANS3, F. AYDIN1 and R. KANDEMIR1

1Karadeniz Technical University, Trabzon-Turkey
2Peking University, Beijing-China
3Vrije University, Amsterdam-Netherlands

Geochemical and Sr, Nd and Pb isotope data are presented for a representative suite of the Quaternary Erzincan Volcanics (QEV) along the North Anatolian Fault Zone in order to understand the origin of the most recent volcanism in Eastern Turkey. Unspiked K-Ar and 40Ar/39Ar dating of lavas from the QEVs yielded ages of 102 ± 2 to 1060 ± 78.9 ka. The QEVs range from high-K low silica trachyandesite to rhyolite in composition, with rhyolite volumetrically the most abundant. All rocks show high K-calc-alkaline affinity, a geochemical signature common to many post-collisional magmas. They display the following geochemical signatures: (i) enrichment in large ion lithophile elements (LILE) (Rb, Ba, K, Th), light rare-earth elements (LREE) (La/Yb)CN=3-33), and depletion in high field strength elements (HFSE) (Ta, Nb, Hf, Sm, Y, Yb), (ii) pronounced negative Nb and Ti anomalies, and (iii) small negative Eu anomalies in andesite to dacitic and significant Eu anomalies in rhyolite samples. These rocks have homogeneous and relatively low 87Sr/86Sr =0.70404-0.70587 and slightly depleted Nd isotopic compositions (εNd from -0.9 to 2.8), with significantly varied Mg# ranging from 1.7 to 53. However, Pb isotopic compositions [206Pb/204Pb] = 18.90-19.02, [207Pb/204Pb] = 15.64-15.70, [208Pb/204Pb] = 38.91-39.97) reveal a profound enriched source signature (EM II), which implies that some portion of metasomatized lithospheric mantle could have contributed to their genesis. Compositional and textural disequilibrium and the negatively correlated of Sr and Nd isotopic ratios suggest that mixing of basic and acid magmas played an important role in magma genesis. A possible scenario for the genesis of these volcanic rocks is: basaltic magma formed as a result of partial melting of a subcontinental lithospheric mantle (SCLM) source responding to a possible upwelling of astenospheric mantle; underplating of these high-temperature basaltic magmas sparked melting of a juvenile lower continental crust producing rhyolitic melts; then magma mixing between basaltic and the rhyolitic magmas followed. Fractional crystallization (FC) coupled with contamination by upper continental crust could have played an important role in the evolution of mixed magma. Modelling based on Sr and Nd isotope data suggest that less than 10% of an isotopically depleted basic magma, which was chemically enriched in LILEs and LREEs due to metasomatism by fluids released from a subducting slab, was involved in the generation, but a juvenile lower continental crustal reservoir contributed about 90% of the source material for the QEVs.
Geochemistry of the Neoproterozoic Ikorongo Group of clastic sedimentary rocks, NE Tanzania: Implications for provenance, tectonic setting and upper crust composition

C. KASANZU
University of Dar es Salaam, Department of Geology, Box 35052, Tanzania (kcharls16@yahoo.com)

Geochemical data are presented for the Neoproterozoic clastic sedimentary rocks from the Ikorongo Group in northern Tanzania in an attempt to constrain their provenance, tectonic setting and infer the composition of the Neoproterozoic exposed upper crust of the Tanzania craton. The Neoproterozoic Ikorongo Group is comprised of shales, siltstones and sandstones lying unconformably on the late Archaean Nyanzian Supergroup of the Tanzania Craton. The REE patterns of the Ikorongo mudrocks show fractionated REE patterns ((La/Yb)CN = 7.41-38.30), relatively flat HREE ((Gd/Yb)CN = 1.42-5.16) and negative Eu anomalies (Eu/Eu* = 0.71 on average) which characteristics are similar to the average post-Archaean Australian Shale (PAAS). The La-Th-Sc systematic together with the PAAS-like REE patterns and trace element ratios of La/Sc (2.02-13.84), Co/Th (0.09-1.58), Cr/Th (1.39-18.24), and Th/Sc (1.39-18.24), indicate that the source area was dominated by a mixture of mafic and felsic rocks. The geochemical considerations and palaeocurrent studies suggest that the provenance of the Ikorongo group include high-Mg andesites, dacites, rhyolites and granitoids from the Neoarchaean Musoma-Mara greenstone belt of the Nyanzian Supergroup. Major and trace element tectonic setting discrimination diagrams suggest a continental setting for the Ikorongo Group.

In situ boron isotope analysis in foraminifera: Implications for palaeo-pH predictions

S.A. KASEMANN¹ AND D.N. SCHMIDT²
¹Grant Institute of Earth Science, University of Edinburgh, Edinburgh, UK (simone.kasemann@ed.ac.uk)
²Department of Earth Science, University of Bristol, Bristol, UK (d.schmidt@bristol.ac.uk)

The most significant consequences of the current increase in atmospheric CO₂ are future global warming and ocean acidification; oceanic pH is predicted to drop ~ 0.3 pH units over the next 250 years. To understand the link between ocean pH and ecosystem response an accurate determination of past pH is critical. Foraminiferal tests are a key component of marine carbonate and their boron isotope composition is a widely used proxy to reconstruct oceanic pH and hence past atmospheric CO₂ concentrations. To assess the robustness of the proxy and the precision of the pH and pCO₂ reconstructions we need to understand the factors that influence the incorporation of boron into foraminiferal calcite.

In this study we used in-situ and high-spatial resolution secondary ionization mass spectrometry (SIMS) to investigate the nature and extent of boron isotope variation within the tests of a number of planktonic foraminifera specimens from sediment traps and sea surface sediment samples (e.g. G. sacculifer, G. ruber, G. truncatulinoides, G. tumida and G. menardii). The sediment traps have a biweekly resolution and hence allow assessment of seasonal variability in boron isotopes. They cover bloom phases of this species, i.e. optimal environmental conditions, and also times when the species are rare and tiny, representing suboptimal environmental conditions. Furthermore, these traps were deployed for several years and hence allow assessment of inter-annual variability.

Distinct chamber and chamber-wall layer analyses within individual tests showed consistent average B-isotope values of G. truncatulinoides tests over a size range from 460 to 670 μm. In contrast, there was a significant change in the B-isotope ratio from chamber to chamber within a specimen with lower values in the last chambers of the specimen and higher values in the older part of the test. The highest B-isotope composition and concentration are found in the earlier chambers, whereas the gametogenetic crust has lower B-isotope values. The B-isotope changes within a specimen of G. ruber are in agreement with predicted values based on model calculations by Zeebe et al [2003]. Due to the spatial resolved analyses, it is possible to discriminate between the processes influencing the B-isotopic fractionation and to improve the palaeo-pH reconstruction.

Secular variation of halogen concentrations in Yugama crater lake water, Kusatsu-Sirane Volcano

Y. KASHIYAMA1, Y. MURAMATSU1 and T. OHBA2

1Dept. of Chemistry, Gakushuin University, Tokyo, Japan
(elliptical84@yahoo.co.jp, yasuyuki.muramatsu@gakushuin.ac.jp)
2Volcanic Fruid Research Center, Tokyo Institute of Technology (ohba@ksvo.titech.ac.jp)

Mt. Kusatsu-Sirane is an active volcano located along the volcanic front on Honshu Island, Japan. Crater lake water in Yugama, located at the top of Kusatsu-Sirane volcano, contains high concentration of chloride. It was observed that variation of chloride concentration in Yugama water reflected the volcanic activity (Ohba et al., 2000). However, there are limited data on other halogens. In this study, concentrations of I and Br in Yugama water were determined to know their levels and their relationships to chloride.

54 water samples, which were collected from Yugama lake during 1988-2006 were used in this study. Some other samples collected surroundings of Yugama were also used. Concentrations of I and Br were measured by ICP/MS.

Concentration ranges of I, Br and Cl in Yugama water samples collected during this period were 0.3-6ppm, 2-9ppm and 1500-3500ppm, respectively (data for Cl; Ohba et al., 2000). It is interesting to note that concentration of I in Yugama water is about 100 times higher than that of sea water. Secular variations of I and Br are similar to that of Cl. The concentrations of these three elements increased markedly during 1989-1992, with a special reference to I, which increased about 10 times. Relationships between the halogen concentrations and the volcanic activity (e.g. frequency of earthquakes) of Mt. Kusatsu-Sirane were observed, although the timing of I increase was 1-2 years later than that of Cl and Br.

In this area, there are some hot springs which are supposed to be originated from the same source as Yugama water. Variations of their halogen concentrations and also I/Cl ratios were found to be wide in those samples, while their Br/Cl ratios were relatively constant.

Figure 1: Secular variation of halogen concentrations in Yugama water

Reconstruction of the past biogeochemical cycles based on compound-specific N and C isotopic analyses of sedimentary porphyrins

Y. KASHIYAMA1,2, N.O. OGAWA2, Y. CHIKARAISHI2, S. NOMOTO3, R. TADA1, H. KITAZATO2, N. OHKOUCHI2

1Department of Earth & Planetary Science, University of Tokyo, Japan; (chiro@jamstec.go.jp)
2Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, Japan
3Department of Chemistry, University of Tsukuba, Japan

Porphyrrins are thought to have derived from biomolecules such as chlorophylls and heme, among which eoxophyllo-erythroetoporphyrins (DPEP) and its analogues are structurally related to chloropigments. These compounds thus preserve stable isotopic compositions of N and C of structotrophs of the past environment. We have developed methods for precise determinations of N and C isotopic compositions of individual sedimentary porphyrins and maleimides, which include isolation and purification of individual alkyloporphyrins and porphyrins acids by dual-step HPLC preparation (Kashiyama et al., 2007a). We have analyzed various alkyloporphyrins and porphyrin acids from organic-rich Miocene sediments of the paleo-Japan Sea (Onnagawa Formation) as well as Cretaceous black shales (Livello Selli and Livello Bonarelli, Italy) deposited in the western Tethys during the Ocean Anoxic Events (OAEs). The N isotopic composition of DPEP, which should have derived in chlorophylls in general, ranged from -6.9 to -3.6‰ (n=7) in the Miocene shale and -6.6 to -3.9‰ (n=5) in the OAE black shales, indicating that the N2 fixation was a major process for N assimilation hence the dominance of diazotrophic cyanobacteria in primary production in these paleo-oceans. Furthermore, DPEP were relatively enriched in 13C in both environments (-17.9 to -15.6‰ in the Miocene shale and -20.5 to -17.9‰ in the OAE black shales), which suggests relatively small carbon isotopic fractionation during photosynthesis and supports significant contribution of cyanobacteria-derived chloropigments. We also determined isotopic compositions of source-specific porphyrins such as 17-nor-DPEP (derived from chlorophyll-c), 8-nor-DPEP (possibly derived from divinylchlorophyll; Kashiyama et al., 2007b) as well as DPEP with extended alky side chains and their equivalents among porphyrin acids (derived from bacteriochlorophyll c, d, and e; analyzed as maleimides). The latter two porphyrins had variable and rather unique isotopic compositions compared to DPEP. Such an approach should allow reconstruction of community structures of phototrophs and associated biogeochemical processes associated with the photosynthesis in the past oceans.

The Barents Ecogeochemistry Project – Ecogeochanical Mapping of 1,500,000 km² in NE-Europe

G. KASHULINA¹, R. SALMINEN², V. CHEKUSHIN³, I. BOGATYREV³, M. TENHOLA², AND H. NISKAVAARA²

¹Polar Alpine Botanical Garden Institute KSC RAS, Fersman st. 18 a, Apatity 184200, Russia (kashulina@aprec.ru)
²Geological Survey of Finland, PB 96, 02151 Espoo, Finland
³S/C Mineral, Veselnaya 6, St.Petersburg 199106, Russia

Scientists from Russia, Finland and Norway have jointly carried out a geochemical research and survey project in NW-Russia, Finland and NE-Norway. An important aim of the Barents project was to define the anthropogenic influence in relation to the natural variations of geochemical baseline over a large area containing both several world’s largest industrial emitters and Europe’s most pristine wilderness areas.

Terrestrial moss, the upper organic soil layer, the soil C-horizon and stream water samples were collected in 2000-2001 from 1085 sites in Russia and 288 sites in Finland.

Both total and aqua regia extractable element concentrations were determined from <2 mm fraction of minerogenic samples. Total element concentrations were measured in the plant and organic soil samples. Concentrations of more than 50 elements were determined from the samples.

The maps showing the distribution of 48 elements were shown in the Atlas. The geochemical patterns of minerogenic C-horizon are strongly controlled by element distribution in the bedrock. Some new metallogenic provinces were found in the area. Stream water data are mainly controlled by geological formations and structures both for major and trace elements. Anthropogenic activity is well reflected by anomalies in moss and organic soil layer near major industrial centres. Since the project area covers different bioclimatic zones from arctic tundra to subboreal forest, respective latitude dependence is visible on many elements distribution for moss and the organic soil layer.

Parallel to multimedia sampling and analysis, a qualitative visual estimate of the state of the ecosystem was performed for each studied site. Although this area is the most pristine in Europe, only 20% of the studied sites had no visual signs of human impact.

The replacement of calcium carbonate by hydroxyapatite

ARGYRIOS KASIOPTAS, CHRISTINA PERDIKOURI, CHRISTINE PUTNIS AND ANDREW PUTNIS

Institut für Mineralogie, University of Münster, Germany (akasiop@uni-muenster.de)

The replacement of calcium carbonate by apatite is an important process in the growth of diagenetic apatite and also in biomimetic materials chemistry where apatite-replaced coral is being developed as a bone implant material. In the latter case the material properties depend on being able to pseudomorph the fine-structure of the coral. We have investigated the mechanism and the kinetics of the replacement of aragonite by apatite using the cuttlebone of Sepia officinalis, commonly known as the cuttlefish. The cuttlebone has an open chamber-like architecture with plate-like pillars (~5 microns thick) supporting parallel thin sheets, constructed from aragonite in association with an organic framework. Our samples, collected from various beaches in NSW Australia, have been thoroughly sun-dried and bleached. Scanning electron microscopy was used to characterise the morphology of the cuttlebone and aragonite was verified by X-ray powder diffraction. The amount of remaining organic component was determined after acid-dissolution.

Experiments were carried out using cut pieces of the cuttlebone sealed in autoclaves with (NH₄)₂HPO₄ solutions of varying concentration over a range of temperatures up to 170°C. The aragonite was completely converted to hydroxyapatite which was verified by X-ray powder diffraction and IR spectroscopy. Scanning electron microscopy showed that the fine-structure of the cuttlefish bone was maintained after the replacement process. The process of replacement is described in terms of a coupled dissolution-reprecipitation mechanism.

To determine the activation energy of the replacement mechanism, hydrothermal experiments were carried out over a range of lower temperatures to partially replace the aragonite, and the quantities of each phase determined by Rietveld analysis of powder X-ray diffraction patterns.

Atomic Force Microscopy was used to study the reaction of organic and inorganic calcium carbonate surfaces with (NH₄)₂HPO₄ solutions in situ in a fluid cell at room temperature to attempt to directly observe the dissolution and reprecipitation process.
Hydrogen generation at clay minerals of sandstone cements

A. KASSAHUN¹, M. HOFFMANN¹ and N. HOTH²

¹Groundwater Research Institute Dresden, Meraner Strasse 10, 01217 Dresden, Germany (akassahun@gfi-dresden.de)
²TU BA Freiberg, Dep. of Drilling and Fluid Mining

Hydrogen availability is crucial for the activity of anaerobic chemolithoautotrophs. These microbes are able to tolerate extreme environmental conditions, prevailing in e.g. hydrothermal vent systems, deep aquifers, underground mines and mine residues. If microbial or hydrothermal H₂ supply is lacking, mineral - water reactions could sustain anaerobic chemolithoautotrophic metabolism. In sandstones, iron rich clay minerals of the cements are suspected to be the most reactive minerals in respect to H₂ formation, since water reduction is commonly related to oxidation of mineral bound ferrous iron.

Methods

Rock samples from the Westfäl C sandstone formation (2,800 m depth) were analyzed for their cement minerals using XRD and sequential extractions. Milled rock samples and iron rich chlorite samples were reacted in headspace vials with a pH=3.5 buffer solution for 30 days. The headspaces were analyzed for H₂ by gas chromatography. Non-sterile and sterile test systems were used. Additional tests with Westfäl C sandstone rock samples and groundwater were performed at 90 bar and 40°C in a high pressure reactor (CO₂/Ar gas phase) for 5 months. The gas phase was sampled regularly for GC analysis of H₂.

Results

In all test systems, hydrogen generation was observed at levels of 100 to 500 nmol H₂ / g sample. Test systems unfavourable for autochthonous microbial activity (sterile mineral tests, low pressure rock sample tests) contained higher H₂ concentrations than test systems that favour autochthonous autotrophic metabolism (non-sterile mineral tests, high pressure rock sample tests). In addition, H₂ levels declined with time, indicating microbial H₂ consumption during the tests by autochthonous autotrophs. The figure shows H₂ concentrations over time in sterile and non-sterile Fe-chlorite - water interaction tests. Dissolved hydrogen concentrations in the test systems (10-60 µmol / L) clearly exceeded literature reported environmental H₂ levels of e.g. sulphate reducing or methanogenic aquifers and of basaltic ground waters. Generated H₂ concentrations are comparable to calculated H₂ fluid concentrations of midocean ridge basalt.

Geochemistry of barium in sediments of the western Black Sea

S. KASTEN¹, K. BOGUS¹, M. JONES², C. MÄRZ³, K. PFEIFER¹ AND R. SEIFERT⁴

¹Alfred Wegener Institute for Polar and Marine Research, Am Handelshafen 12, 27570 Bremerhaven, Germany (Sabine.Kasten@awi.de, Kerstin.Pfeifer@awi.de)
²DFG Research Center Ocean Margins RCOM, Postfach 330440, 28334 Bremen, Germany
³University of Bremen, Department of Earth Sciences, Postfach 330440, 28334 Bremen, Germany (cmaerz@uni-bremen.de)
⁴Institute of Biogeochemistry and Marine Chemistry, University of Hamburg, Bundesstrasse 55, 20146 Hamburg, Germany (seifert@geowiss.uni-hamburg.de)

During two cruises with RV POSEIDON and RV METEOR to the western Black Sea (west of Crimean Peninsula) in 2004 and 2007, respectively, sediment cores were taken along a transect from 500 to 1700 m water depth. Pore water and solid phase investigations aimed at unraveling the geochemical behaviour of barium in this anoxic water column and sedimentary environment. In particular, our study focussed on the following questions: (1) In which way does the anoxic water column of the Black Sea control the flux of particulate barium phases to the seafloor?, (2) Does barite form in the anoxic water column and - if so - is the amount of barite reaching the sediment surface dependent on water depth as reported for oxic marine depositional environments?, (3) Can barium/barite be used as a sedimentary tracer of past productivity in the Black Sea?, (4) How is barium redistributed post-depositionally at the sulfate/methane transition (SMT) which is typically located around 2 m sediment depth?, (5) Can we use diagenetic barite to trace the downward migration of the SMT which occurred in the Black Sea deposits since the transition from the last glacial freshwater lake situation to the Holocene anoxic marine period? Understanding the geochemistry of barium in sediments underlying anoxic water bodies – like is the case in the Black Sea – will significantly contribute to improving interpretations of fossil sedimentary records laid down under oxygen-depleted water column conditions, like below or within oxygen minimum zones or during Cretaceous Oceanic Anoxic Events.
Nucleation and growth of the (Mn,Ca)CO₃ solid solution in double diffusion systems

D. KATSIKOPOULOS, Á. FERNÁNDEZ-GONZÁLEZ, AND M. PRIETO

Department of Geology, University of Oviedo, Spain

Introduction

Nucleation and growth of the (Mn,Ca)CO₃ solid solution was studied under conditions of double diffusion in silica hydrogel at 25°C. Three sets of experiments were carried out in U-shaped tubes of different lengths using Na₂CO₃, and MnCl₂-CaCl₂ aqueous solutions.

Results and Discussion

Using the excess Gibbs energy function of McBeath et al., 1998, two wide miscibility gaps were calculated. Experimental results show that nucleation takes place under nonequilibrium conditions when a specific value of high supersaturation β(x) is reached. Under these conditions, preferential partitioning of Mn in the solid phase has been observed. The fact that measured manganese mole fractions [X(Mn,ss)] are not restricted to the equilibrium miscibility range, can be attributed to kinetic factors. Moreover, since there is no agreement in bibliography upon the mixing properties of this solid solution, the miscibility limits at equilibrium are still under discussion.

Figure 1: Equilibrium values and experimental results plotted on a Roozeboom diagram.

Compositional profiles of crystals are characterized by alternations of Mn-rich and Ca-rich regions from core to rim, resulting in oscillatory zoning. Crystal morphologies are highly dependent on the Mn²⁺/Ca²⁺ ratio of initial aqueous solution. Even low concentrations of Mn²⁺ are capable of eliminating the {10-14} rhombohedron, by favoring the growth of rounded blocky crystals, spheres, and spherulites.

The observed reaction paths corresponding to the growth process could be used to explain crystallization behaviour and Mn/Ca distribution coefficients in natural systems.

High resolution geochemical analyses of organic-rich shale and carbonate through 350 m of the ABDP-9 core through the > 2,500 Ma Mt. McRae, Mt. Sylvia, and Wittenoom formations in the Hamersley Basin of northwestern Australia record changes in both the oxidation state of the surface ocean and in atmospheric composition. Carbonate δ¹³C compositions through the strata vary systematically with lithofacies between 0 and -10‰, suggesting a strong carbon isotope gradient in Neoarchean seawater. High resolution sulfur-33 abundance data was obtained through a modified bulk powder EA combustion technique monitoring m/z 48, 49 and 50 on the SO analyte (Baublys et al., 2004). Based on observations from SO analyses, we have additionally measured many samples by standard SF₆ techniques. We observe wide variations in δ¹³C, δ¹⁸S, Δ³³S and Δ³⁶S through the stratigraphic record with specific correlations between δ¹⁸S/Δ³³S and of Δ³³S/Δ³⁶S that are temporally resolved. In the upper Mt. McRae Formation we see a change to negative δ¹⁸S with positive Δ³³S that is interpreted to capture activation of the oxidative sulfur cycle, for perhaps the first time in Earth history. In the lower Mt. McRae the δ¹⁸S/Δ³³S and the Δ³³S/Δ³⁶S relationships are different, and we interpret this as a change in atmospheric source reactions. The data suggest that oxygenation of the surface ocean preceded that of the atmosphere by 50 million years or more. Correlation of the time series sulfur isotope signals in northwestern Australia with equivalent strata from South Africa suggests that changes in the exogenic sulfur cycle recorded in marine sediments may have been global in scope, and linked to atmospheric evolution.

Records of A-type and I-type plutonism from the northern Aravalli craton, NW India: Age, petrogenesis and regional tectonic implications

P. KAUR1, N. CHAUDHRI1, I. RACZEK2, A. KRÖNER3, M. OKRUSCH4 AND A.W. HOFMANN2

1Centre of Advanced Study in Geology, Panjab University, Chandigarh-160 014, India (param.geol@gmail.com; naveen.geol@gmail.com)
2Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (raczek@mpch-mainz.mpg.de; hofmann@mpch-mainz.mpg.de)
3Institut für Geowissenschaften, Universität Mainz, 55099 Mainz, Germany (kroener@uni-mainz.de)
4Mineralogisches Institut, Universität Würzburg, 97074 Würzburg, Germany (okrusch@uni-wuerzburg.de)

The northernmost segment of the Aravalli craton in NW India records two significant, discrete granitoid emplacement events at ca. 1711-1660 Ma and ca. 1822 Ma. The most unusual feature of 1711-1660 Ma plutonism is the occurrence of almost pure albite, classifying these rocks as alkali-feldspar granites. The individual plutons are predominantly composed of hastingsite or annite-bearing microcline-albite granites. The albite granites, which represent the subordinate facies, contain actinolite and magnesio-ferrohornblende or clinopyroxene. They are further characterised by low K2O (~0.5 wt%) and high Na2O (~7.0 wt%) abundances, whereas the microcline-albite granites show normal concentrations of alkali elements. The occurrence of virtually pure albite in these rocks has been attributed to varying extents of albitisation from moderately albitised microcline-albite granite to completely albitised albite granite. These granitoids are ferroan, metaluminous, typical within-plate A-type granites, and are derived from high-temperature melts (850-900°C). Initial ε(Nd) values range from -1.3 to -6.2 and correspond to mean crustal residence ages of 2.5 to 2.1 Ga. The geochemical and geochronological data for the A-type granitoids, and their comparisons with other correlative events documented in rocks farther south and southeast, signify a widespread and prominent rift-related regime during the late Palaeoproterozoic in the Aravalli craton. The 1822 Ma older plutonism, different from that of the A-type granitoids, is recorded by foliated biotite-bearing peraluminous, calc-alkaline, I-type monzogranites, which carry signatures of continental-arc setting. These rocks exhibit a restricted range of initial Nd values between -4.8 and -5.1 which correspond to a mean crustal residence age of 2.5 Ga. The lack of petrological and geochronological information for the 1822 Ma magmatism in the adjoining areas limits the scope of regional correlation of such an event.

Upscaling reaction rate laws in geochemical reactive transport using pore-scale network models

DMITRI KAVETSKI1, CATHERINE PETERS1, MICHAEL CELIA1 AND BRENT LINDQUIST2

1Department of Civil and Environmental Engineering, Princeton University, Princeton, NJ 08542, USA (cap@princeton.edu)
2Department of Applied Mathematics and Statistics, SUNY at Stony Brook, Stony Brook, NY USA (lindquis@ams.sunysb.edu)

Reliable predictions of reactive transport in geological porous media are important in carbon geosequestration studies and other engineering applications, including aquifer remediation and nuclear waste disposal. Given the size of geological systems to be used for CO2 geosequestration (in excess of 100’s of km²) and the long time horizon for predictions (10²-10³ years), explicit resolution of system heterogeneities at the micro-scale (i.e., the pore scale) is infeasible. Consequently, practical geochemical reactive transport models invariably operate at the continuum scale, in turn requiring various assumptions of homogeneity over averaging volumes far exceeding pore and grain sizes. However, sub-grid heterogeneities can undermine the macro-scale model accuracy, e.g., mineral weathering rates predicted from lab-scale data can overpredict observed field-scale rates by several orders of magnitude. This study focuses on reaction rate laws describing acid-driven mineral dissolution and examine whether reaction rates applicable at the pore-scale are applicable at the larger continuum scale. We use a pore-scale advection/diffusion/reaction model that includes kinetic precipitation/dissolution of anorthite/kaolinite clays and simulates the inflow of acidic CO2-rich brine under high-pressure conditions relevant to carbon geosequestration. The 4 mm³ pore network structure was estimated using X-ray computed tomography of sandstone cores, while the statistical distribution of reactive minerals was estimated using back-scatter electron imaging and energy-dispersive X-ray spectroscopy. The cores are from the Viking formation in the Alberta sedimentary basin (Canada), which is a potential site for CO2 storage.

We investigate whether the averaged concentrations of species and the mineral dissolution rates in the distributed pore network can be adequately approximated using a lumped model with volume-averaged parameters. For the anorthite/kaolinite system, the discrepancy between the pore-scale simulation and its lumped approximation increases with the acidity of the inflow brine and the heterogeneity of the reactive mineral distribution. The scaling effect can be reduced by replacing the volume-averaged mineral surface areas in the lumped model with “effective” reactive area parameters (calibrated a posteriori) that implicitly compensate for variations in active reactive areas due to sub-grid heterogeneities in the mineral distribution and reaction rates.
Rare earth element geochemistry of Kestelek (Bursa) borate deposit, West Anatolian, Turkey

O. KAVRAZLI1 and S. KOC2

1Ankara University Engineering Faculty Department of Geological Engineering Tandogan, Ankara, Turkey (ozgekavrazli@yahoo.com)
2Ankara University Engineering Faculty Department of Geological Engineering Tandogan, Ankara, Turkey (koc@eng.ankara.edu.tr)

In this study, rare earth element geochemistry of the Kestelek borate deposit, one of the Western Anatolian borate deposits, is investigated. The known borate deposits of the Turkey were deposited in the lacustrine environment during Miocene when the volcanic activity occurred since Tertiary to Quaternary. All of the Turkish borate deposits are classified as volcanic related deposits. Rare earth element analyses of borate (colemanite) samples with different depth and textural compositions which are collected from the three different ore zones of Kestelek borat deposit are evaluated. In this situation upper crust normalized distribution diagrams of rare earth elements are made to determine physicochemical conditions and original relations of the Kestelek borate occurrence environment. Borate samples present two different groups at REE distribution diagrams which are made one by one for three different ore zones in Kestelek borate deposit. At the REE distribution diagrams, two different grouping of the curves signs that at least there are two different precipitation regimes. REE are generally constant at environment conditions which supply occurring straight lines. Second group curves, show clear anomalies, present negative Ce and positive Eu anomalies that exhibit hydrothermal source and precipitation regime with high oxygen fugacity ($f_{O_2}$). Some samples show middle rare earth element enrichment. MREE enrichment is characterized at hot naturel fluids and acid leaching. At the same time, mid-acidic source originated REE components show positive Eu and MREE enrichment. According to REE analyses results of borate samples belong to the three different ore zones, positive Eu anomalies and ranges of borate samples (where La/Lu > 1) sign mid-acidic and high temperature conditions.

Petrological and geochemical constraints on origin of St. Helena HIMU basalts

H. KAWABATA, T. HANYU, Q. CHANG, AND Y. TATSUMI

Institute for Research on Earth Evolution (IFREE), Japan
Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan (hiroshik@jamstec.go.jp)

Alkali basalts on St. Helena Island are characterized by elevated $^{206}Pb/^{204}Pb (>20.5)$ and $^{187}Os/^{188}Os$, coupled with depleted Sr and Nd isotopic signature. As a result they are representative of a mantle component referred as HIMU. In order to evaluate magmatic processes and source compositions of HIMU basalts, a detailed petrological and geochemical study was conducted on the shield building lava flows and dikes of the island.

The basalts show continuous compositional variation, which correlate well with petrographical features, such as modal abundance and crystal size of olivine and clinopyroxene phenocrysts. The compositional and petrographical diversity for alkali basalts can be explained by fractional crystallization of olivine and clinopyroxene at shallow depth (~1kb), and by subsequent changes in melt/crystal ratios when magma batches were extracted from a partially crystallized magma chamber.

Primary magma compositions for St. Helena basalts estimated by simulating the reverse path of fractional crystallization, show constant TiO$_2$/Al$_2$O$_3$, Yb/Tb, and highly incompatible element ratios, suggesting a homogeneous mantle source for these magmas. Examination using both pMELTS software (Ghiorso et al., 2002) and compiled data from high-pressure experimental studies for mafic rocks suggests that the primary magma can be in equilibrium with clinopyroxene and/or garnet at >ca. 2 GPa. This is the depth of the lithosphere/asthenosphere boundary beneath the island. It should be stressed that Ca and Al-rich eclogite or pyroxenite on silica-deficient in nature, not lherzolite, could be the mantle source for St. Helena basalt magmas. In order to form the source, contribution from recycled crustal material is necessary. This hypothesis is consistent with high $^{187}Os/^{188}Os$ of St. Helena basalts.

The primary magmas are characterized by low (Rb, Ba, Th, U)/Nb and Th/U ratios, and the absence of positive Sr and Eu anomalies. Together, these suggest that upper gabbroic portions of the less altered oceanic crust, rather than the lower plagioclase-rich cumulate gabbro, was recycled and involved in the mantle source of St. Helena basalt magmas.
Pressure solution deformation of Shimanto accretionary complex: Its mass transfer and temperature dependent feature

KUNIYO KAWABATA AND HIDEMI TANAKA
Department of Earth and Planetary Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan (kuniyo@eps.s.u-tokyo.ac.jp)

Pressure solution (PS) is an important mechanism for mass transfer and for release of accumulated strain energy, which was formed through successive processes of dissolution, material transport and deposition. Pressure solution seams (PSS) has been observed in accretionary complexes of subduction zone, which would causes mass transfer. We evaluated mass transfer by PS as calculating volume change, and investigated relationship between intensity of PS and temperature, using microscopic observations, chemical analyses and paleotemperature. Studied samples are natural deformed shales associated with two distinct types of deformation, that is shear-dominated type (type S) and compaction-dominated type (type C). The PSS density is used as a quantitative index of PS intensity.

We obtained three results as following. (1) Ti concentrated within PSS for both type, implying that Ti is less soluble than other elements during PS deformation. (2) Positive correlation existed between PSS density and TiO₂ for both types and whose inclination of correlations are parallel to each other, indicating that TiO₂ concentration associated with development of PSS are always stable despite the different deformation types. (3) Positive relationship was figured out between PSS density and paleotemperature, implying that development of PSS depend on temperature.

From the former two results, volume change (ΔV) was calculated on the basis of compositional change of Ti using PSS density (γ) as,

\[ \Delta V = -2.4 \cdot \gamma \left( 2.4 \cdot \gamma + 1 \right) \]

From the last result (3), we estimated activation energies for each type by assuming duration of PS. Activation energies (type S: 18 kJ/mol, type C: 45 kJ/mol) are estimated to be lower than previous results (e.g. Schutjens, 1991) and dissimilar between two types. Possible reasons for the low values and the variation would be related to grain comminutions.

Previously reported δD values of H₂ gas (δD₂) in high temperature hydrothermal fluid (>300°C) ranged from -400‰ to -300‰ [1]. It has been thought that those δD values result from hydrogen isotope equilibrium between H₂ and H₂O, which makes δD₂ value -400‰ to -300‰ around 300°C to 400°C [1, 2].

In contrast, we discovered uniquely deuterium-depleted H₂ molecules (δD₂ = -800‰ to -700‰) in high temperature hydrothermal fluid at Southern Mariana Trough (SMT) arc and backarc systems in the western Pacific. The δD₂ in the SMT hydrothermal systems are so light that the fractionation during the hydrogen isotope equilibrium cannot explain these values at measured fluid temperature [2]. Assuming that the hydrogen isotope equilibrium is negligible in the SMT hydrothermal systems, we should consider kinetic isotope fractionations during some potential H₂ production processes in order to investigate an origin of such light H₂ in the SMT.

Degassing of H₂ from mantle would induce heavy δD values due to extremely high temperature, at which kinetic isotope fractionations are generally too weak to make such light δD value. Serpentinitization of ultramafic rocks has been thought as a major H₂ source in hydrothermal systems, while serpentine rock has not been collected in the SMT. Volcanic rock in the SMT is rather acidic than general MORs so that H₂ production by serpentinization may be little in the SMT hydrothermal systems.

On the other hand, it has been reported that chemical reaction between H₂O and crushed rock, caused by fault activity, enables to make large amounts of light H₂ (-770‰ to -470‰) [3, 4, 5]. Similar chemical reactions are expected to occur at low temperature by fracturings in plate subduction zones, close to the SMT hydrothermal systems, which is a possible origin to explain the uniquely deuterium-depleted H₂ discovered in this study.

Endolithic aspartic acid as an proxy of fluctuations in the growth of coral skeleton

HODAKA KAWAHATA1,2, LALLAN P. GUPTA2 AND ATSUSHI SUZUKI2

1Graduate School of Frontier Sciences and Ocean Research Institute, University of Tokyo, 1-15-1 Minamidai, Tokyo 164-8639, Japan (kawahata@ori.u-tokyo.ac.jp)
2Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 1-1 Higashi, Tsukuba 305-8567, Japan (gupta@jamstec.go.jp; a.suzuki@aist.go.jp)

Coral skeleton has been widely investigated for monitoring past fluctuations in marine environments. Although stable carbon isotope ($\delta^{13}C$) data appear to record coral metabolism, their interpretations differ from place to place and are sometimes controversial, because of the influence by carbon isotopic composition of dissolved inorganic carbon in seawater. Association of an organic matrix with biological carbonates has been reported in many previous studies. With the help of high-resolution micro-sampling of coral skeleton and advanced technique for amino acid (AA) quantification in low-volume sample, we indicate that aspartic acid (Asp) in coral skeleton varies with distinct seasonal pattern, and is useful in understanding why corals calcify faster in summer than in winter. Since Asp containing organic matrix in the coral skeleton is synthesized by the coral, changes in mole concentration of Asp relative to other AAs of the skeleton make it a potential indicator for monitoring fluctuations in coral physiology in the past.

Kornerupine sensu stricto associated with mafic and ultramafic rocks in the Lützow-Holm Complex at Akarui Point, East Antarctica: What is the source of boron?

T. KAWAKAMI1, E.S. GREW2, Y. MOTOYOSHI3, C.K. SHEarer4, T. IKEDA3, P.V. BURGER4 AND I. KUSACHI6

6Department of Earth Sciences, Okayama University, Japan (kusachi@cc.okayama-u.ac.jp)

Prof. W. Schreyer had a long-standing interest in the MgO-Al2O3-B2O3-SiO2-H2O system, which includes kornerupine, a borosilicate rarely found in mafic or ultramafic settings. We report a new occurrence in two ruby corundum-plagioclase lenses at the same structural level as boudinaged ultrabasic rocks in hornblende gneisses and amphibolite. Ion microprobe analyses of kornerupine give 13-59 ppm Be, 181-302 ppm Li, and 5466-6812 ppm B, corresponding to 0.38-0.47 B per 21.5 O; associated sapphirine also contains B (588-889 ppm). Peak metamorphic conditions are estimated to be 770-790°C and 7.7-9.8 kbar. Kornerupine encloses tourmaline and plagioclase, which suggests the prograde reaction: tourmaline (1) + plagioclase (>An34) + sapphire + spinel $\rightarrow$ kornerupine + corundum (ruby) + plagioclase (<An82) + fluid or melt. Kornerupine later reacted with H2O-CO2 fluid in cracks: kornerupine + plagioclase + (Na, K, $\pm$Si) $\rightarrow$ tourmaline (2) + biotite + corundum (sapphire) + magnetite + andalusite + (Ca). Secondary tourmaline differs from the included tourmaline in having less Ti and higher Na/(Na+Ca+K). There are two possible scenarios for introducing B into the lenses: (i) infiltration of boron-bearing aqueous fluids released by prograde breakdown of muscovite in associated metasedimentary rocks, and (ii) hydrothermal alteration of mafic and ultramafic rocks by seawater prior to peak metamorphism. The latter scenario is consistent with the suggestion (Hiroi et al. 1991) that Akarui Point could be part of an ophiolite complex.

Introduction

Shock-metamorphosed plagioclase in meteorite and impact crater have been less studied in spite of importance of planetary sciences, up to date. In this study, cathodoluminescence (CL) of the shock-induced synthetic plagioclase has been measured to clarify an effect of shock-metamorphism.

Sample and Methods

The unshocked synthetic plagioclase (Andesine-An40) and experimentally shocked samples at 20, 30 and 40 GPa (by rail gun experiment) as well as natural plagioclase (An50) from Ries Crater, Germany (occurred in suevite at shock stage IV<40 GPa) were selected for the CL measurements.

Result and Discussion

Synthetic plagioclase exhibits four CL peaks: (1) UV peaks at 330 nm related to defect center, (2) blue peaks at around 420 nm assigned to Mn²⁺ center and (4) red peaks at 740 nm assigned to Fe³⁺ center (Fig. 1). Peak positions of blue and yellow peaks respectively shift from 420 to 380 nm and 560 to 630 nm and intensity of all peaks decrease as function of the increasing shock pressure. This indicates that shock wave can cause a change of crystal field and emission processes leading to peak shift and decrease of intensity. These effects by impact shock are also observed in natural plagioclase samples from Ries Crater except for peak shift of yellow peak, which might be at least partly responsible for heating effect at natural shock event.

Gas chemistry of a hydrothermal plume at 8°18’S on the Mid-Atlantic Ridge

R. KEIR¹, O. SCHMALE², R. SEIFERT³, S. WEBER³ AND J. SÜLTENFUB⁴

¹IFM-GEOMAR, Kiel, Germany (rkeir@ifm-geomar.de)

⁴Universität Bremen, Bremen, Germany (suelten@uni-bremen.de)

Plate tectonic processes play an important role in the hydrothermal venting of gases such as helium, methane and hydrogen on mid-ocean ridges. While spreading rate (magma supply) primarily determines the rate of mantle helium degassing, venting of methane and hydrogen may be enhanced by extensional tectonics of slow spreading ridges, through the serpentinization of uplifted ultra-mafic rocks. Here we report the deep-water distribution of these gases in the region of a recently discovered hydrothermal vent at 8°17.9’S, 13°30.4’W. The measurements were carried out on Meteor cruises 62/5 and 68/1 in December 2004 and May 2006, as part of the German Priority Program 1144. The vent, a powerful, “odorless” black smoker inside a 2-meter deep crater, is located at the northern end of a narrow ridge within the MAR segment between the Ascension and Bode Verde fracture zones. The methane plume was detectable as far as 12 km from the vent, but the ³He signal was relatively weak, with clear anomalies only within a 2 km² area surrounding the site at the end of the ridge. ³He/⁴He, hydrogen and methane were observed to be well correlated near the plume, with molar ratios of H₂/CH₄ ≈ 15 and CH₄/³He ≈ 4 × 10⁻⁸. The latter is one of the highest CH₄/³He ratios observed in hydrothermal plumes. Measurement of hydrogen and methane in the vent fluid yielded a H₂/CH₄ ratio of 8:1, which is lower than the ratio observed in the plume. The distribution of methane in the region varied temporally, but during the first week of December 2004, it appeared that the plume trended mainly WSW from the vent. LADCP measurements (Stöber, 2005) indicated that currents at the plume depth during the ebb phase of the TPX0.5 tidal model were also in this direction. Excess methane inventories in 3 sections normal to the plume axis appeared to be about 12 to 14 mol m⁻². As the the current velocity at this time typically was about 5 cm s⁻¹, it appears that the methane source was about 0.7 mol s⁻¹. From the plume ratios above, it appears that the ³He and H₂ sources were about 2 nmol s⁻¹ and 10 mol s⁻¹ respectively. We also use the distribution of these tracers to estimate rates of methane oxidation in the region and of plume dispersion according to a Gaussian model.

Geochemistry and petrogenetic significance of natrocarbonatites at Oldoinyo Lengai, Tanzania

J. KELLER¹, A. ZAITSEV² AND D.J. KLAUDIUS¹

¹Mineralogisch-Geochemisches Institut der Universität, D-79104 Freiburg, Germany
(Joerg.Keller@minpet.uni-freiburg.de, Jurgis.Klaudius@minpet.uni-freiburg.de)
²Department of Mineralogy, St. Petersburg State University, University Emb. 7/9, St. Petersburg, 199034, Russia (a.zaitsev@nhm.ac.uk)

Oldoinyo Lengai, Tanzania, is the only active carbonatite volcano on Earth. However, Oldoinyo Lengai carbonatites are unique in most aspects of their petrological and geochemical characteristics and are distinguished from pre-modern carbonatites elsewhere as extremely alkali-rich natrocarbonatites, with Na₂O+K₂O generally >40wt%. No magmatic calciocarbonatites have been found at Lengai (Zaitsev and Keller, 2006). We present and discuss the composition and chemical variation of natrocarbonatites sampled in regular intervals from 1988 to 2006. Oldoinyo Lengai is a young, upper Quaternary volcano, and natrocarbonatites represent only the very recent stage of its evolution. Silicate lavas and pyroclastics constitute far more than 90% of the cone.

All silicate lavas of Oldoinyo Lengai show a high degree of peralkalinity and are highly evolved (low Mg, Ni, Cr etc). Prominent examples in the Recent evolution are the unusual wollastonite-combeite nephelinites (Klaudius and Keller, 2006). Bulk geochemical composition, trace element systematics and Sr, Nd, and Pb isotopic ratios suggest a liquid immiscible separation of natrocarbonatite from combeite-wollastonite-bearing nephelinites. Primitive olivine melilolites in the vicinity of Oldoinyo Lengai are the only candidates for primary mantle-melt compositions (Keller et al. 2006). Geochemistry and isotope systematics reveal different lineages. The spread in Sr, Nd, and Pb isotopic ratios of olivine melilolites, phonolites, combeite-wollastonite nephelinites and natrocarbonatites is explained as mixing line between HIMU and EM1-like mantle components. Liquid immiscible separation of natrocarbonatite melts is interpreted to occur a very shallow level within the volcano.

Constraints from Earth’s heat budget on mantle dynamics

LOUISE H. KELLOGG¹ AND SYLVAINÉ FERRACHAT²

¹Department of Geology, University of California, 1 Shields Avenue, Davis, CA 95616 USA (kellogg@geology.ucdavis.edu)
²Institut f. Atmosphäre und Klima, Universitätstrasse 16, CHN O 16.2, Zürich, CH-8092 Switzerland (sylvaine.ferrachat@env.ethz.ch)

One of the largest challenges in modeling mantle convection is the need to reconcile the global heat budget with the time and spatial scale of geochemical heterogeneity observed in mid-ocean ridge basalts (MORB) and oceanic island basalts (OIB). Most models include at least one reservoir that is enriched in radiogenic elements relative to the mid-ocean ridge basalt (MORB) source, as this appears to be required to account for most current estimates of the Earth’s heat budget. This reservoir would also be responsible for the geochemical signature in some ocean island basalts (OIBs) like Hawaii, but must be rarely sampled at the surface. Our current knowledge of the mass- and heat-budget for the bulk silicate Earth from geochemical, cosmochemical and geodynamical observations and constraints enables us to quantify the radiogenic heat enrichment required to balance the heat budget. The current work has two parts. First, without assuming a specific model for the structure of the reservoir, we determine the inherent trade-off between heat production rate and mass of the reservoir. Using these constraints, we then investigate the dynamical inferences of the heat budget, assuming that the additional heat is produced within a deep layer situated initially above the core-mantle boundary. We carry out dynamical models of layered convection using four different fixed reservoir volumes, corresponding to deep layers of thicknesses 150, 500, 1000, and 1600 km, respectively, and including both temperature-dependent viscosity and an intrinsic viscosity jump between upper and lower mantle. We then assess the viability of these cases against some of the multiple criteria that must be satisfied by any model of mantle convection: stability of the deep layer through time, topography of the interface, effective density profile, intrinsic chemical density and a positive heat flux at the core-mantle boundary.
Insights into crustal anatexis from zircon-garnet REE behaviour

N.M. KELLY, S.L. HARLEY AND R.W. HINTON
School of Geosciences, University of Edinburgh, Kings Buildings, Edinburgh, EH9 3JW, United Kingdom

Studies of the REE behaviour of zircon and garnet during high-grade metamorphism and anatexis have shown that the compositions of these minerals are sensitive to fluctuations in coexisting melt compositions and therefore to the timing of individual mineral growth relative to melt evolution. Zircon-garnet REE distribution behaviour is therefore critical to not only dating partial melting, but also to the assessment of the effects of melt generation, migration, drainage and recharge in migmatites within the deep crust.

A detailed study has been carried out on superbly exposed pelitic migmatites from the Brattstrand Bluffs, Prydz Bay, east Antarctica. The pelites underwent biotite-controlled vapour-absent partial melting at metamorphic conditions of ~6 kbar and ~860°C. Melting resulted in production of semi-restitic to restitic Sil-Spl-Grt melanosome and segregation of quartzofeldspathic leucosome with variable abundances of entrained residue. Transport of partial melts occurred on a range of scales, from a few centimetres to beyond 100m. Field observations suggest that some melt was still mobile during deformation associated with post-peak decompression.

Zircon, which is concentrated both within restitic melanosome and along contacts between leucosome and melanosome, was analysed in-situ along with garnet for REE and other key trace and major element data. Zircon and garnet REE patterns and partitioning data suggest that growth of new zircon on corroded detrital grains occurred in equilibrium with peritectic garnet in the melanosome. Similar REE evidence indicates that zircon present in larger melt accumulations and veins most likely grew at the site of melting before being extracted, to variable degrees, along with the melt. Integration of our field and thin section observations with mineral REE data leads to the general conclusion that zircon growth in migmatitic granulites predominantly occurs early in the progression of partial melting, at close to peak conditions. In contrast late zircon growth during post-peak decompression and cooling is limited.

Tracing the lost arcs: Granitic zircon as a geodynamic indicator?

A.I.S. KEMP1, C.J. HAWKESWORTH2, W.J. COLLINS1 AND T. SHIMURA3
1School of Earth and Environmental Sciences, James Cook University, Townsville, 4811, Australia (tony.kemp@jcu.edu.au, bill.collins@jcu.edu.au)
2Department of Earth Sciences, University of Bristol, Bristol, BS8 1 RJ, UK (c.j.hawkesworth@bristol.ac.uk)
3Department of Geology, Faculty of Science, Niigata University, Japan (smr@gs.niigata-u.ac.jp)

Subduction-related magmatism has long been acribed a central role in the generation of Earth’s continental crust, based in part on modern arc analogues. Yet, radiogenic isotope evidence implies that much of the present-day continental mass formed early in Earth history, and attempts to understand the geodynamic drivers are hampered by fragmentary preservation of ancient geological terranes. Recent studies have exploited the detrital zircon archive to chart the growth of crustal segments and even to infer Hadean subduction [1], but whether zircon-derived isotope information can reliably diagnose tectonic setting remains unknown.

We address this issue with reference to two case studies of areas formed in subduction-related settings, the Paleozoic Tasman Orogenic Belt of Eastern Australia, and the Cenozoic Hidaka Metamorphic Belt of Hokkaido, Japan. The Tasmanides preserve the record of 300 Myrs of accretionary tectonic processes outboard of the eastern Gondwana cratonic margin. Geological evidence argues that the voluminous and diverse granites of the Tasmanides formed behind a long-lived, retreating subduction system that was punctuated by episodic contraction. Isotopic data confirms the involvement of multiple source materials in granite genesis, the nature and proportion of which changed with time. The Hidaka belt comprises a remarkably complete arc sequence that encompasses upper mantle to shallow crustal depths. Formed in a trench-proximal position adjacent to the Eurasian margin, the Hidaka belt evolved from a continental arc to oceanic back arc realm with the opening of the Japan Sea at 25 Ma, prior to exhumation during collision between the Japan and Kuril arcs. Granitic rocks are abundant at all crustal levels.

We examine the micro-isotopic (U-Th-Pb, 18O/16O, Lu-Hf) systematics of granite-hosted zircon from both areas to deconvolve the magma sources as a function of tectonic evolution, and for the Hidaka, crustal depth. The goal is to capture the ‘signature’ of crustal growth and reworking in these arc settings from a zircon perspective, and thus to place the zircon record into a geodynamic context. We will explore the extent to which this signature manifests in isotope arrays generated from old zircons, and discuss the implications for the tectonic mode of crustal growth in ancient orogens.

Piccaninny, WA, and Matt Wilson, NT: Two possible complex impact craters in Australia

THOMAS KENKMANN, MICHAEL POELCHAU
Museum für Naturkunde – Mineralogie, Humboldt-Universität
Berlin, Invalidenstrasse 43, 10115 Berlin Germany
(thomas.kenkmann@museum.hu-berlin.de; michael.poelchau@museum.hu-berlin.de)

We present results of field analysis, microscopy, and remote sensing mapping of two circular structures in Australia of which the meteorite impact origin is not yet confirmed.

**Piccaninny, Western Australia (17°25’S, 128°26’E, 7.5 km diameter):** The circular structure (Beere 1983; Shoemaker and Shoemaker, 1985) forms a plateau in the Purnululu National Park that is built up by Devonian conglomerates and sandstones. It is framed by beehive-like domes and the Piccaninny Gorge, both make the access to the elevated plain difficult. The structure is defined by a centerward dipping circular monocline (5-15° dip), a very gentle ring syncline, and a weak central rise with a stratigraphic uplift of 40-50 m. The distinct regional cleavage pattern outside the plateau displays a systematic deflection towards the center of the structure. On the plateau the vertical cleavage planes are reactivated as faults. These fault zones typically contain comminuted decimeter-wide gouge zones and meter-wide process zones in which anastomosing subsidiary fault networks occur. Some of the interconnected shear zones resemble breccia dikes. Strata are offset by faults. Minor strata tilting and the apparent lack of shock features suggest a considerable amount of erosion (>2 km) of the possible impact crater.

**Matt Wilson, Northern Territory (15°30’S; 131°10’50”E):** The outline of this possible impact crater is elliptical (4.5 x 6.5 km) with the long axis trending NE-SW. It has been formed in Mesoproterozoic rocks and consists of a crater rim monocline, a ring syncline and a central uplift 1.5 km across. The structure is described in detail by Sweet et al., 2005, who also present microstructures indicative for shock. The central uplift of the structure shows an imbrication of thrust slices in a bilateral arrangement. Such a pattern is known from other craters like Upheaval Dome or Spider (Scherler et al., 2006). The NE-SW trending symmetry axis is delineated by major faults. The fault pattern, preferred NE strata dipping in the central uplift, and the elliptical crater outline may indicate an oblique impact from NE.

Acknowledgements: We would like to thank DFG for funding this project (KE 732-11/1).

Cenozoic topographic and climatic change in the western U.S. from a paleosol carbonate record in Montana and Idaho

MALINDA L. KENT-CORSON1, ANDREAS MULCH2 AND C. PAGE CHAMBERLAIN3

1Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305-2115 (malkc@stanford.edu)
2Institut fur Geologie, Leibniz Universitat Hannover, Callinstr. 30, 30167 Hannover, Germany (mulch@geowi.uni-hannover.de)
3Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305-2115 (chamb@pangea.stanford.edu)

Oxygen, carbon, and strontium isotope records from a Paleocene to Pliocene paleosol carbonate stratigraphy in southwestern Montana and eastern Idaho show evidence that significant changes in topography occurred between ~50 and 47 Ma. δ18O values of calcite decrease by 7-10‰, while δ13C increases by ~3‰, and strontium shifts to more radiogenic values. These changes reflect a reorganization of drainages with an increase in elevation of 2.5-3.5 km. This rise in elevation is roughly contemporaneous with the emplacement of the nearby Challis Volcanics, and the formation of metamorphic core complexes in the hinterland of the Sevier thrust belt. Moreover, when compared to previous oxygen isotopic studies that show oxygen isotopic shifts of similar magnitude occurring later (in the late Eocene to early Oligocene in northeastern Nevada, and late Oligocene to Miocene in southern Nevada), the results of this study add to a growing body of evidence for a spatial and temporal migration of high surface elevations from north to south in the Great Basin of the western United States. This surface uplift history supports tectonic models calling for north to south removal of the Farallon slab or delamination of the mantle lithosphere. Superimposed on this tectonic framework we find a high-resolution climate record with evidence of rapid Cenozoic climate fluctuations. Oxygen and carbon isotopes show major climate fluctuations at the Eocene-Oligocene boundary, and pulses of Pliocene cooling and Pleistocene warming. This adds to a growing body of literature that shows spatial variability in how global climatic changes are expressed in the terrestrial record. Understanding the larger tectonic framework is essential to making interpretation of climate based on these isotopic records.

Th/Nb evolution of the Archean mantle

R. KERRICH1 AND A. POLAT2

1University of Saskatchewan, Saskatoon, SK, Canada (robert.kerrich@usask.ca)
2University of Windsor, Windsor, ON, Canada (polat@uwindsor.ca)

Values of Nb/Th in komatiites and basalts have been used as proxies for extraction of continental crust from the mantle. Ratios of 8-16 for ~ 2.7 Ga Yilgarn komatiites and basalts were interpreted either as large scale extraction of the continental crust early in Earth history, or extensive extraction of crust from small mantle domains, where bulk Archean crust has Nb/Th=2 [1]. In an alternative model, the ratio evolved from near primitive mantle values of 8 in the early Archean to MORB like values of 19, reflecting progressive crustal extraction. A new compilation of high precision data for komatiites of the Superior Province gives a range of 7-11 at 3 Ga but 7-21 at 2.7 Ga. Associated basalts span 5-13. These results are interpreted as large scale extraction of continental crust, as TTG, from melting of oceanic crust in convergent margins post 3 Ga, and recycling of the high Nb/Th residue into the mantle source of plumes from which the komatiites and basalts later erupted.

In the Neoarchean Wawa subprovince, oceanic plateau basalts are characterized by near-flat REE patterns, and Nb/U and Nb/Th ratios generally greater than primitive mantle values, consistent with positive εNd values. They are associated with komatiites, the association being interpreted as an ocean plateau sequence erupted from a mantle plume. High Nb/U and Nb/Th ratios of plateau tholeiitic basalts are interpreted as a complementary reservoir to arc magmatism (low Nb/U and Nb/Th), hundreds of millions of years prior to recycling of oceanic lithosphere through a subduction zone (high Nb/U, Nb/Th), and its incorporation into a mantle plume from which 2.7 Ga plateau tholeiites erupted.

Geochemistry of quaternary lavas from the Main Ethiopian Rift – Constraints on continental breakup and rifting

F. KERSTEN, J.A. PFÄNDER AND R. GLOAGUEN
Institut für Geologie, TU Freiberg, Germany (franziska.kersten@student.tu-freiberg.de)

The Main Ethiopian Rift (MER) is part of the Afro-Arabian Rift System and is located within a transitional zone between continental and oceanic rifting. A bimodal suite of samples from eight volcanic centres within the rift-valley (Ayelu, Dofan, Hertali, Fantale, Kone, Bosetti, Gedemsa and Aluto, from NE to SW) have been analysed on their major and trace element as well as isotopic composition to constrain the spatial distribution and temporal evolution of their magma sources. This may provide insights on the mantle processes that are likely to control continental breakup and rifting within such a transition zone. Furthermore, the magma distribution within the lithosphere potentially controls their heat budget and thus their strength, which directly affects continental breakup and rifting.

Trace element patterns show a great similarity for samples within as well as between individual volcanic centres, suggesting a fairly homogeneous mantle source over the entire sampled range. REE patterns display steep slopes with La/Yb ratios between 5.7 and 14.7 in basalts, reflecting low degrees of partial melting of an enriched mantle source. Trace element patterns of evolved rocks from all locations indicate substantial olivine, clinopyroxene and plagioclase fractionation, which is confirmed by petrographical observations. Negative Sr anomalies, however, are insufficiently explained by fractional crystallisation and require additional processes such as crustal assimilation. The large amount of crystal fractionation observed indicates a long-term residence of primary magmas within the lithosphere and thus most likely considerable heating.

The $^{87}\text{Sr}/^{86}\text{Sr}$ values range from 0.70354 (Hertali) to 0.70493 (Fantale), $^{143}\text{Nd}/^{144}\text{Nd}$ ratios vary between 0.512741 (Aluto) and 0.512944 (Hertali). An overall correlation between Nd (and Sr) isotope ratios and latitude exists, with increasing $\varepsilon_{\text{Nd}}$ values towards the northeast, which might reflect a slightly higher influence of a MORB source mantle close to the triple junction as was also suggested from geophysical data (Keranen et al., 2004). Beside the first order geographical correlation, a relatively wide spread within the isotopic ratios is observed for some volcanic centres. This supports the hypothesis of crustal assimilation during magma ascent and crystal fractionation.

Coastal uplift, sea level changes and active tectonics of the southeastern Black Sea: Evidences from Quaternary marine terraces, Trabzon coast, NE Turkey

S. KESKIN, O. BEKTAS AND Y. EYÜBOĞLU
Karadeniz Technical University, Department of Geological Engineering, 61080, Trabzon, Turkey (keskin@ktu.edu.tr)

The data obtained from landsat imagery, airphotos, geological and geophysical records show that there are three distinctive lineaments in the vicinity of Trabzon, trending northeast-southwest (NE-SW), northwest-southeast (NW-SE) and east-west (E-W), analogous to North Anatolian Fault (NAF) and Northeast Anatolian Fault (NEAF) systems. According to current seismic data, the faults, which have three distinctive directions, show active properties. As a result of these, Boztepe, Erdogdu, Fatih (NE-SW directions), Yenimahalle and Faroz faults (NW-SW directions), forming the fault system of the Trabzon coast section, cut and raised the Quaternary marine terraces to the surface. In order to be able to reveal the motion rates and activity of these faults, field surveying, geomorphological studying, airphoto interpretation and geochronological measurements of seven different marine terraces on the Trabzon coast of the southeastern part of Black Sea was carried out. According to available data, the Holocene and Pleistocene marine terraces, at elevations ranging from 1-3 m to 4-300 m, are the result of the interaction between regional scale uplift and subsidence, interglacial sea level changes, and local fault movement. The mollusca shells, collected from these terraces at elevations ranging between 1-3 m (H), 4-14 m (T-1), 22-34 m (T-2), 60-80 m (T-3), were dated by ESR method. The ESR results showed that the ages of H, T-1, T-2 and, T-3 are 5.141 ± 0.294 ka, 124.8±26.0 ka, 292.5±49.8 ka and 407.998 ± 67.475 ka, respectively. The terraces were correlated to the OIS 1, 5e, 9, 11, which correspond to the 5.141 ka, 124.8±26.0 ka, 292.5±49.8 ka and 407.9 ka highstands of the paleo-sea-level curve. Considering the new ESR results, subsidence rate of the East Black Sea Basin and the abrupt drowning of the Black Sea self at 7150 years ago, mean uplift rates of the Holocene and Pleistocene marine terraces are ranging from 0.5 to 1.4 mm/year. The average motion rates of the faults, forming the fault system of the Trabzon coast section, are 0.5-1.4 mm/year while this rate is 16-25 mm/year for NAF and 9 mm / year for NEAF. This indicates that the motion rates of the faults decrease towards the plate. As a result of these mean uplift rates, the recurrent of the maximum earthquake (M=7) is predicted to be a few thousands years.

Potential environmental issues of CO₂ storage in saline aquifers: Geochemical results from the Frio Brine pilot tests, Texas, USA

Y.K. KHARAKA¹, J.J. THORDSEN¹, S.D. HOVORKA², D.R. COLE³, T.J. PHELPS³ AND T.D. BULLEN¹

¹USGS, Menlo Park, CA, USA (ykharaka@usgs.gov)

³ORNL, Oak Ridge, TN, USA (coledr@ornl.gov)

Deep saline aquifers in sedimentary basins provide advantageous locations close to major anthropogenic sources of CO₂ and large potential capacity for the storage of huge volumes of this greenhouse gas. To investigate the potential for the long-term storage of CO₂ in such aquifers, 1600 t and 300 t of CO₂ were injected, respectively, into the “C” and “Blue” sandstone sections of the Frio Formation, a regional reservoir in the U.S. Gulf Coast. Fluid samples obtained before CO₂ injection from the injection well and an observation well 30 m updip showed a Na-Ca-Cl-type brine with ~100,000 mg/L TDS at saturation with CH₄ at reservoir conditions, but CO₂ was low at 0.3% of total gas. Following CO₂ breakthrough, ~50 h after injection, samples showed sharp drops in pH (from 6.5 to as low as 3.7 with in-line probe), major increases in alkalinity (from 100 to up to 3200 mg/L as HCO₃⁻) and Fe ++ (from 30 to 1200 mg/L) and Feoxyhydroxides caused by low pH values (~3.0 initially) of the brine in contact with the injected supercritical CO₂.

These geochemical parameters, together with perfluorocarbons (PFTs) and other tracer gases, proved powerful tools for tracking the migration of the injected CO₂ in the injection sandstones and into the overlying Frio “B”, composed of a 4-m-thick sandstone bed and separated from the “C” by ~15 m of shale and siltstone beds. Data on brine and gas compositions of samples obtained from the Frio “B” 6 mo after injection show significant CO₂ (2.9 % compared with 0.3% CO₂ in gas) migration into the overlying “B” sandstone. Except for two PFT tracer gases, which could be explained by desorption, results of samples collected 15 months after injection show no additional CO₂ migration into the “B” sandstone. The presence of injected CO₂ in Frio “B” has important environmental implications as it shows initial leakage through the remedial cement behind the well casing or migration through the shale and siltstone beds. Environmental impacts could be major if large volumes of buoyant and reactive CO₂ and/or brine with mobilized metals and organic migrated into overlying potable groundwater resources. Sampling and geochemical analyses of fluids in deep monitoring zones together with geophysical imaging, if properly carried out, are potential early detection methodologies that could trigger remediation action should leakage of CO₂ and/or brine take place.

Hydrochemical and isotopical tracers in groundwaters from coastal zone of the Primorye, Far East of Russia

N.A.KHARITONOVA AND G.A.CHELNOKOV
Far East Geological Institute, Russian Academy of Sciences, Vladivostok, Russia (office@fegi.ru)

The deep saline and brackish waters in coastal zone of the Primorye region have been studied in this investigation. Razdol’noe manifestation of deep brackish waters is located in coastal zone of the Primorye region (Far East of Russia) and it was discovered with drilling during geothermal exploration in 1992. Wells are situated in the mouth of Razdol’naia River, about 25 km from seashore. Wells disclose two different types of cold (13°C) waters: Ca-Na-Cl and Na-HCO₃.

Aquifer with Ca-Na-Cl type water occurs in Miocene sedimentary rocks at 30-130 m depth and has TDS 4.5–13.7 g/l. Ratio of major ions Ca/Mg (1.3); Ca/SO₄ (2.1) and Na/Cl (0.4), Cl/SO₄ (0.98) are close to seawater ratios. Aquifer with Na-HCO₃ type water occurs in Mesozoic sedimentary rocks at 130-500 m depth, has lower TDS - 2.5–6.0 g/l, and is being used by local spa and bottled as well. Numerous tectonic fractures are spread across the study area and located under the cap of the Miocene – Quaternary sediments in southeast and east trends. The width of the fault zone is not less then 100-150 m.

Na-HCO₃ water has prominent hydraulic continuity with upper saline water aquifer, and is enriched by B (9.37 mg/l), F (6.00 mg/l), Li (up to 1.50 mg/l), Sr (up to 0.7 mg/l), Br (0.25 mg/l) and has low contents of I (0.002). Ratio of Ca/Mg is 1.1; Ca/SO₄ ~57.5; Na/Cl −10.1 and Cl/Br is 364.2 (much higher than in seawater). Positive correlations between Sr and Ca, Na, Mg, Cl, Fe and B (r=1.00); Ca-Mg (r=0.99), SiO₂-Al (r=1.00), K-Cl (r=0.81) and negative correlation between SiO₂ and major cations (Ca, Na, K) and F (r=1.0) are observed for both types of water. δ¹⁸O and δ2H isotopic ratios show that brackish water has a meteoric origin. The main recharge zone of this aquifer occurs in the north where the sediment complex outcrops.

Received data indicate that saline waters are result of mixing of ancient seawater with infiltrate waters and brackish water has a meteoric origin and mineralization is forming as a result of water-rock interaction. Mass balance calculation and bedrock investigations proves that the albite dissolution, with or without deep-seated mantle origin of CO₂, is a dominant factor controlling the chemical composition of groundwater.
Charateristics of syn-collision magmatism, NW Iran

M. KHEIRKHAH1, M.B. ALLEN2 AND M. EMAMI1
1Geological Survey of Iran, Azadi Square, Meraj Ave, Tehran, Iran
2Department of Earth Sciences, Durham University, Durham, DH1 3LE, UK

Quaternary lavas from the NW Iran are related to the ongoing Arabia-Eurasia collision, which represents continued plate convergence after the end of north-dipping subduction of the Neo-Tethyan ocean at ~35 Ma. The lavas are erupted across the Turkish-Iranian plateau, which ceased crustal thickening before the establishment of a number of volcanic centres within Iran and eastern Turkey, such as Ararat and Tendurek, beginning at ~10 Ma. Local active tectonics involve right-lateral strike-slip faults and pull-apart basins, but there is no simple spatial relation between the basins and volcanic centres. Here we report geochemical and Sm-Nd/Rb-Sr data for 20 samples from a ~200 km long, N-S traverse through the main volcanic centres. Samples are transitional alkali/tholeiitic basalts and basaltic andesites. Samples fall between two end-member compositions, a “depleted”, low Nb, low LILE type with 143Nd/144Nd ~0.51290 and an “enriched”, high Nb, high LILE type with 143Nd/144Nd ~0.51265. Depleted compositions occur in the north and enriched compositions in the south. Therefore enrichment decreases with distance from the Arabia-Eurasia suture to the south of the study area. There is petrographic evidence for greater crustal contamination in the southern samples, but this is not reflected in major and trace element compositions. A previous model for similar compositional variation in Anatolian syn-collision magmatism has invoked slab-breakoff beneath the plateau (Keskin, 2003). An alternative explanation is that the degree of melting decreases southwards towards the suture, because of the reduced thickness of mantle wedge above the Tethyan ocean slab.

The impact of Fe isotope fractionation by plants on the isotopic signature of soils

M. KICZKA1,2, J.G. WIEDERHOLD1,2, S.M. KRAEMER3, B. BOURDON4 AND R. KRETZSCHMAR5
1Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (kiczka@env.ethz.ch; wiederhold@env.ethz.ch; kretzschmar@env.ethz.ch)
2Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, Switzerland (bourdon@erdw.ethz.ch)
3Department of Environmental Geosciences, University of Vienna, Austria (stephan.kraemer@univie.ac.at)

Plants play an important role in the biogeochemical cycling of iron. Enhanced mineral dissolution by root exudates, Fe uptake by plants, and decomposition of Fe-containing plant material significantly influence the speciation of Fe in soils. We investigated stable Fe isotope fractionation during the cycling of Fe from rock/soil to plants and to soil organic matter in an alpine glacier forefield (Damma glacier, Central Alps, Switzerland). Its rather uniform lithology (Aare granite) and the well-defined soil formation chronosequence (max. 150 years) provide a well-constrained natural setting for our studies. Fresh granite rock and its main Fe-bearing minerals (biotite, magnetite), soil samples, soil organic matter and various plant species were analyzed for their Fe isotopic composition. Plant species under investigation acquire Fe either by Fe(III) reduction (strategy I) or by exudation of siderophores and uptake of Fe(III)-siderophore complexes (strategy II). Iron isotope ratios were measured by MC-ICPMS (Nu Plasma) using a standard-sample bracketing method (IRM-014). The reproducibility of samples was generally better than ±0.15‰ (2SD) in δ⁵⁷Fe.

While unaltered granite samples exhibit a heavy isotopic composition (0.3-0.4‰ in δ⁵⁷FeIRMM-14), biomass of strategy I plants shows an enrichment of the light isotope of up to ~2‰. A clear trend of increasingly lighter composition from roots to stems, leaves and flowers indicates strong fractionation during Fe translocation within strategy I plants. Average δ⁵⁷Fe values for whole plants, obtained from Fe elemental and isotope mass balance, are up to 0.8‰ lower than for the lightest and most labile mineral of the granite (biotite: 0.2‰ in δ⁵⁷FeIRMM-14), demonstrating a significant fractionation already during uptake. Variations in δ⁵⁷FeIRMM-14 of grasses (mainly strategy II) did not exceed ~0.3‰ and minimum values are around -0.8‰. Nevertheless, the average isotopic composition of the aboveground biomass of grasses is still ~0.4‰ lighter than biotite. This characteristic enrichment in light Fe isotopes in the plant biomass is also reflected in the isotopic signature of organic matter and soils. Organic-rich horizons exhibit up to 0.2‰ lower δ⁵⁷Fe values than mineral-dominated horizons. The distinct isotopic composition of Fe associated with organic matter and mineral phases in soils implies that Fe isotopes can be used to assess the impact of plants on the Fe cycle in soils.
Long-term changes in water chemistry of crater lakes of Kusatsu-Shirane volcano, Japan

Y. KIKAWADA, A. INOUE, K. IKEHATA AND T. OI
Faculty of Science and Technology, Sophia University, Tokyo, Japan (y-kikawa@sophia.ac.jp; inoue-a@sophia.ac.jp; t-ooi@sophia.ac.jp)

Kusatsu-Shirane volcano is located at central Japan and has three crater lakes named Yugama, Mizugama and Karagama on its summit. Yugama, the largest and the most acidic (around pH 1) among the three, is well known as an active crater lake. Volcanic fluids are discharged constantly into Yugama from its bottom, and thus chemistry of Yugama water reflects the volcanic activity of Kusatsu-Shirane volcano. Therefore many researchers have studied its water chemistry as an indicator of the volcanic activity of the volcano. To the contrary, very few researchers note the other two crater lakes, because their acidity (around pH 3) is lower than that of Yugama, and volcanic fluids directly discharged into them have not been observed. Those two are thus recognized as non-active crater lakes at present. Recently, two crater lakes, because their acidity (around pH 3) is lower than that of Yugama, and volcanic fluids directly discharged into them have not been observed. Those two are thus recognized as non-active crater lakes at present. Recently, however, we have grasped some evidence that their water chemistries also reflect the volcanic activity of Kusatsu-Shirane volcano. In this study, we have discussed the long-term changes in water chemistry of the crater lakes of Kusatsu-Shirane volcano accompanying its volcanic activity.

Five phreatic eruptions had occurred at the edge of Yugama in 1982-83. A remarkable increase in concentrations of dissolved components of Yugama water was observed after the eruptions, which has been considered to be due to the influx of highly-concentrated fluids into Yugama water. Secular change in water chemistry of Mizugama resembles that of Yugama, although the absolute concentrations of the former are much lower than those of the latter. A similar trend in secular change is also observed for Karagama and Yumiiike, a marsh embracing the old crater beside the pyroclastic corn. It was thus possible that the same fluid that was discharged into Yugama was also supplied to the other lakes during the eruptions. In addition, the concentration of the chloride ion had increased in Mizugama, Karagama and Yumiiike waters immediately after the 1982-83 eruptions. Since the influx of the chloride ion generally suggests the existence of volatiles from the magma, those observations must be an evidence that their water chemistry reflects the volcanic activity. On the other hand, such as increase in the concentration of the chloride ion after the eruptions had not been observed in Yugama. This may be interpreted as follows. The influx of the volatiles could not change the water chemistry of Yugama because its water always kept high salinity, and consequently was insensitive to the influx of the volatiles unlike the other lakes. Thus, the waters of Mizugama, Karagama and Yumiiike may be more sensitive indicators for the volcanic activity of Kusatsu-Shirane volcano compared with Yugama.

Particle size effects on heavy metal distribution, speciation, and correlations in mine wastes

C.S. KIM1 AND J.J. RYTUBA2
1Department of Chemistry, Chapman University, Orange, CA USA (cskim@chapman.edu)
2U.S. Geological Survey, Menlo Park, CA USA

Centuries of mining have left a legacy of metal-contaminated mine wastes across the world’s mineralized regions. These wastes often contain highly elevated levels of many hazardous metals in addition to the primary ore metal. Characterizing trends in metal concentrations, metal speciation (the dominant chemical form of the metal), and correlations between metals as a function of particle size can provide insight into the mechanical and chemical processes that distribute metals in the environment and impact their availability to living organisms. A combination of physical size separations, bulk chemical analyses, X-ray spectroscopic methods, and empirical leach tests aids the identification of such trends as well as the pathways that control metal transport from mine impacted sites.

Samples of both mine wastes and background soil samples from mine sites throughout California were collected and weighed prior to particle size separation using stainless steel sieves to generate 11 size-specific fractions (from >2830 μm down to <20 μm). Each fraction was weighed and analyzed using ICP-MS to determine the bulk concentrations of a standard suite of 48 elements. Results of elemental concentrations as a function of particle size were plotted and categorized based on their size-dependent behavior, resulting in groupings of elements that share similar trends and therefore possible geochemical associations.

Bulk and microspectroscopic methods were then applied to selected size fractions of mine wastes, utilizing X-ray fluorescence (XRF), extended X-ray absorption fine structure (EXAFS) spectroscopy, and X-ray diffraction (XRD) to assess the speciation, distribution, and correlation of metals of interest. The microspectroscopic methods in particular can allow the analysis of samples previously inaccessible by bulk spectroscopic techniques due to sample concentration limitations.

Results from bulk concentration analyses demonstrate that many heavy metals are concentrated in the finer grain size fractions, sometimes by over an order of magnitude, increasing their mobility and potential availability by ingestion or inhalation. However, changes in metal speciation corresponding to preferential weathering of more soluble phases may offset the potential toxicity of such metals in fine-grained fractions; this is tested through selective leach extractions. Consistent correlations between certain metals, such as iron and arsenic, were identified and further investigated with XRF, where specific As:Fe ratios could be associated with discrete phases. Such species appeared to increase in diversity with decreasing particle size, suggesting secondary mineralization or sorption processes.
Biosorption of heavy metals by using *Pseudomonas* sp. MF254A, bacterial strain isolated from the oil contaminated soil

**INSU KIM, MINHEE LEE AND AEJUNG CHOI**

Department of Environmental Geosciences, Pukyong National University, Daeyoungdong, Namgu, Busan, 608-737, Korea

**Experimental method**

Batch experiments were performed to investigate the heavy metal removal efficiency of biosorption by using a bacterial strain which was identified as *Pseudomonas* sp. MF254A. *Pseudomonas* sp. MF254A was isolated from the oil contaminated soil at a military site in Korea. For the experiments, the initial concentration of heavy metals such as As, Cd, Cr, Cu, Pb, and Zn in the distilled water was titrated as 5 mg/L. The freeze-dried biosorbent (Pseudo-monas sp. MF254A) was added to the solution and the reaction mixture was shaken on an rotary shaker at 125 rpm for 120 min (30 °C). The mixture was centrifuged and its supernatant was analyzed on ICP/MS for residual metal concentration. Various amounts of biosorbent (from 0.01 g to 3 g) were applied for the batch experiment to investigate the sorption efficiency of the biosorbent. The effect of pH on the biosorption capacity of the bacterial biomass for Pb, Cd, and Cu was investigated in the pH range of 1.0 – 12.0 by using 50 ml solutions containing 5 mg/L of metal ions.

**Results and discussion**

From the results of experiments, for Pb, Cd, and Cr, more than 98 % of initial metal ions in the solution was removed with 3 g of biosorbent. For Cu and Zn, the removal efficiency was 99 % and 91 % using 3 g of biosorbent, respectively. At pH value between 3.0 and 5.0, removal efficiencies of Pb, Cd, and Cu on biosorption were 95 ~ 99 %.

**Conclusion**

From the batch experiments, it was investigated that the bacterial strain, *Pseudomonas* sp. MF254A is a suitable biosorbent to remove heavy metals from the aqueous solution.

---

Spatio-temporal variations of winter CO₂ and CH₄ fluxes along a Alaska pipeline

**YONGWON KIM¹, HIROYUKI ENOMOTO², SHIZUKA KIMURA² AND GAKU KADOSAKI³**

¹International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, USA (kimyw@iarc.uaf.edu)
²Kitami Institute of Technology, Hokkaido, Japan (enomoto@mail.kitami-it.ac.jp; mcv06005@std.kitami-it.ac.jp)
³Earth Observation Research Center, Japan Aerospace Exploration Agency, Japan (kadosaki.gaku@jaxa.jp)

**Research Aims**

The purposes of researches are to estimate 1) how much winter fluxes of CO₂ and CH₄ along a trans-Alaska pipeline (total ca. 1000 km), 2) what are influencing factors in determining winter CO₂ and CH₄ estimates, and 3) what is implication in carbon budget as a region scale.

In order to conduct these purposes, we carried out winter transect observation during January 2005, Feburary to March 2006, and Feburary 2007.

**Discussion of results**

The spatio-temporal variation of winter CO₂ and CH₄ fluxes showed in Figure 1. Winter CO₂ fluxes in boreal forest are higher than those in tundra; on the other hands, winter CH₄ is no variation at a time and space.

**Figure 1.** Spatio-temporal variation of winter CO₂ and CH₄ fluxes along a trans-Alaska pipeline

In special, winter CH₄ flux trends to emit through the snowpack to the atmosphere along a latitudinal transect. Kim *et al.* (2007) demonstrated that winter CH₄ emitted to the vascular plants at top of tussock in snow-covered boreal forest. The area of tussock in Northern Hemisphere is 6.5X10¹³ m²; Whalen and Reeburgh, 1992). The average winter fluxes of CO₂ and CH₄ were 0.51±0.03 gCO₂-C/m²/day (average ± SE) and 2.7±0.3 mgCH₄-C/m²/day, respectively. Therefore, the winter CH₄ emission should not be overlooked in estimations of the regional/global carbon budget.

Metal reduction and formation of nanometer-sized magnetites by facultative iron-reducing bacteria isolated from inter-tidal flat sediments

**YUMI KIM**, **YUL ROH**, **JONGMIN OH**, **BYUNGGNO PARK**, **HEEDONG JANG**, **YONGJAE SUH** and **SANGHOON LEE**

1Chonnam National University, Gwangju, Korea (yumddalki@hotmail.com),
2Korea Institute of Geoscience & Mineral Resources, Daejeon, Korea,
3Catholic University, Gyonggi, Korea

Although microbe-metal interactions play important roles in the metal geochemistry and organic matter degradation in the tidal flat sediments, studies of microbial metal reduction and iron biomineralization are beginning to be studied. The objectives of this study were to explore Fe(III) and metal reduction by the facultative metal-reducing bacteria isolated from the inter-tidal flat sediments, Southwestern coast of Korea as well as to examine microbial reduction of Fe(III) oxide hydroxides and biomineralization of Fe iron oxides by fermentation processes. Taxonomic characterization of the strains isolated from inter-tidal flat sediments indicated that they belong to genus of *Shewanella* sp. The bacteria were able to reduce FeCl₃, Fe(III)-citrate, FeOOH and metals including As(V) and Se(V) using short chain fatty acids as the electron donors. The Fe(III)-reducing bacteria were capable of reducing both akaganeite and ferrihydrite during glucose fermentation. By comparison of iron minerals formed by *Shewanella* sp.during reduction of the iron oxyhydroxides at room temperature, it was shown that *Shewanella* sp. formed 2~3 nm-sized magnetite (Fe₃O₄) particles by akaganeite reduction, whereas the bacterium formed mainly X-ray amorphous iron oxides by ferrihydrite reduction. These results suggest that microbial reduction of metals and formation of nm-sized magnetites by fermentation processes at near ambient temperatures may influence the biogeochemical cycles of carbon and metals in subsurface environments. Knowledge concerning such bio-solid state processes may be important in the synthesis and production of nm-sized ferromagnetic materials.

Using copper isotopes to distinguish biotic and abiotic effects on acid mine drainage

**BRYN E. KIMBALL**, **SUSAN L. BRANTLEY** and **RYAN MATHUR**

1Department of Geosciences, Pennsylvania State University, University Park, Pennsylvania, 16801, USA (bek151@psu.edu)
2Earth and Environmental Systems Institute, Department of Geosciences, Pennsylvania State University, University Park, Pennsylvania, 16801, USA (brantley@essc.psu.edu)
3Department of Geology, Juniata College, Huntingdon, Pennsylvania, 16652, USA (mathur@juniata.edu)

Recent experiments have shown that abiotic leaching of chalcopyrite causes greater Cu isotope fractionation between original mineral (Cu₉₉ico) and leachate Cu (Cu₉₉aq) (Δ₉₉aq-min = δ⁶⁵Cu₉₉aq - δ⁶⁵Cu₉₉ico = 0.92-1.63 ± 0.23‰) than in the presence of *Acidithiobacillus ferrooxidans* (Δ₉₉aq-min = 0.10-0.53 ± 0.23‰), a known Fe- and S-oxidizing Proteobacterium. Additional mineral-free experiments show that Cu associated with *A. ferrooxidans* cells (Cu₀) is isotopically enriched relative to Cu₉₉aq in the medium (Δ₀-aq = 2.2 ± 0.23‰). Thus, cells are a sink for enriched Cu₉₉aq, accounting for the smaller biotic Δ₉₉aq-min fractionation during chalcopyrite dissolution.

In an effort to find similar abiotic and biotic fractionation signatures in a natural setting, we surveyed the Cu isotopic composition of primary minerals and stream water affected by acid mine drainage in an enargite- and chalcopyrite-containing drainage located in southwestern Colorado, USA. The δ⁶⁵Cu values measured for local enargite (δ⁶⁵Cu = -0.01 ± 0.12‰) and chalcopyrite (δ⁶⁵Cu = 0.16 ± 0.12‰) are within the general range of previously reported values for terrestrial primary Cu sulfides (-1 < δ⁶⁵Cu < 1). These mineral samples show lower δ⁶⁵Cu values than stream waters (δ⁶⁵Cu = 1.36 - 1.74 ± 0.12‰). The average fractionation between chalcopyrite and stream samples (Δ₉₉aq-min = 1.4 ± 0.17‰) is similar to that for previous abiotic chalcopyrite leach experiments.

Interestingly, the observed biotic Δ₉₉aq-min fractionation signature is not detected in the field. Mass balance supports the likelihood that the fraction of leached Cu that associates with microorganisms is less significant in the open field system compared to the closed batch experiments. Experiments designed to test potential Cu isotope fractionation during sorption of Cu₉₉aq onto *A. ferrooxidans* cells and onto mineral surfaces are ongoing. Our results suggest that Cu isotope measurements are a useful tool for better understanding Cu sources and mobility in the environment, and will aid in both ore prospecting and toxic metal remediation.
Hf isotope records of mélangé mixing and blueschist-facies metamorphism within the Catalina Schist

R.L. KING 1, G.E. BEBOUT 2 AND J.D. VERVOORT 1

1School of Earth & Env. Sci., Washington State University, Pullman, WA 99164, USA (rlking@wsu.edu)
2Department of Earth & Env. Sci., Lehigh University, Bethlehem, PA, 18015, USA

Prograde metamorphic mélangé zones developed within the Catalina Schist (CA, USA) record progressive digestion and assimilation of peridotites, basalts, and sediments into a hybridized composition that is probably characteristic of the subduction zone slab/mantle interface (Bebout, 1991; Bebout and Barton, 1993, 2002). Of the isotopic records available, most reflect some degree of fractionation or mixing due to the effects of fluid flow or mineral partitioning attending metamorphism (Bebout, 1991; King et al., 2006, 2007). We present new Hf isotope data for zones of lawsonite-albite (LA) and lawsonite-blueschist (LB) facies metamorphic mélangé matrix with the goals of reconstructing sources and patterns of mass transfer occurring during prograde mélangé formation as well as recognizing potential mobility of HFSE such as Hf along and across the slab/mantle interface.

The syn-metamorphic Hf-Nd isotopic array defined by the LA-LB mélangé matrix is broadly similar to modern arc data (εHf= +12 to -2, εNd= +12 to +2). These compositions predominantly reflect mechanical mixtures dominated by MORB vs. terrigenous components, with a minor influence of high Lu/Hf pelagic sediment. Within the LA-LB mélangé dataset, high Hf concentrations (>2ppm) define a restricted Hf isotopic composition (εHf= +6 to +8); this is most likely the signature of the coeval Peninsular Ranges Batholith, as PRB trench fill dominates detrital zircon age spectra for LA-LB mélangé (Grove et al., 2007; King et al., 2007).

LA-LB mélangé samples bearing lower Hf concentrations (<2ppm) preserve more varied isotopic compositions. Most notable are a suite of high Mg-Cr samples (MgO >14wt.%; Cr >1000ppm) with surprisingly low Hf isotopic ratios (εHf= +4 to -2). Association of this more continental isotopic signature within mélangé matrix dominated by Mg-Cr-rich mantle material suggests that redistribution of Hf by metamorphic fluids occurs and is recorded by these more “receptive” ultramafic mélangé zones. Petrologic descriptions and geochemical analyses of similar types of ultramafic rock within metamorphic subduction complexes represent the most promising target for recognition of metasomatic processes occurring during subduction.

The chemistry of Earth's dynamic surface

JAMES W. KIRCHNER

Dept. of Earth and Planetary Science, University of California, Berkeley, CA, USA (kirchner@berkeley.edu)

Physical erosion and chemical weathering shape many aspects of the living environment: the topography of the surface, the fertility of soils, the chemistry of natural waters, and, over long time scales, the composition of the atmosphere and thus the climate of the Earth.

Researchers studying the physics and chemistry of the Earth's surface are currently exploring questions such as: What processes regulate rates and patterns of physical erosion and chemical weathering? How episodic are erosion and weathering, over timescales from minutes to millions of years? How sensitive is chemical weathering to variations in climate, and thus how strong are the feedbacks regulating climate through geologic time? How much do chemical weathering rates depend on rates of mineral supply from physical erosion? And conversely, how much does physical erosion depend on weakening of rocks by chemical weathering?

Questions like these are now being probed using a range of geochemical techniques. Cosmogenic nuclide methods, in particular, have proven useful for studying rates and patterns of surface denudation over thousands of years, at spatial scales ranging from individual outcrops to small catchments. When coupled with the bulk composition and mineralogy of parent materials and the soils that are formed from them, cosmogenic nuclide measurements can also be used to infer rates of chemical weathering over millennial time scales.

These geochemical techniques are opening new windows through which we can observe the evolution of the Earth's surface. These methods have recently shown, for example, that denudation rates are surprisingly episodic over a wide range of time scales. They have also shown that chemical weathering rates may be closely coupled with rates of physical erosion, and may be relatively insensitive to climatic variations. This presentation will outline these and other insights into the physics and chemistry of Earth's surface, as revealed within the past decade by cosmogenic nuclide methods and related geochemical techniques.

The Coastal Range contains the earliest sedimentary archive of active, mountain building in eastern Taiwan. The sediments were deposited in a collisional basin adjacent to the developing accretionary wedge to the west during the Plio-Pleistocene. In this study we combine low temperature fission track thermochronology and higher temperature U-Pb dating of detrital zircons to reveal the history of the region pre- and syn-exhumation.

The new provenance data show that the sediment was derived primarily from south-east China and is thermally unrest by the collision of the Philippine Sea Plate with the passive China Margin. This suggests that early exhumation rates of 5-7 mm/year, determined in previous studies, are overestimates. A requirement of the data in this study is for accelerated exhumation to be a recent feature initiated in the Late Pliocene. This is consistent with a regional hiatus in sedimentation that marks a period of relative quiescence between ~3-2 Ma prior to a change in regional tectonic forcing.

Paired δ⁴⁴/⁴⁰Ca, Mg/Ca and Sr/Ca in cultured G. ruber

**B. KISAKÜREK**¹, A. EISENHAUER¹, J. EREZ², F. BÖHM¹ AND D. GARBE-SCHÖNBERG³

¹IFM-GEOMAR, Germany (bkisakurek@ifm-geomar.de)
²The Hebrew University, Israel
³Christian-Albrechts University, Germany

δ⁴⁴/⁴⁰Ca, Mg/Ca and Sr/Ca ratios were determined on a single species of cultured planktonic foraminifera (G. ruber) and the culturing solutions. The foraminifera were grown in seawater at (i) constant temperature but varying salinities of 32 to 44 ‰, (ii) constant oceanic salinity but varying temperatures of 18 to 30°C. In an additional culturing experiment, the carbonate system was manipulated so as to keep the total inorganic carbon constant but to alter the pH (and hence total alkalinity).

The δ⁴⁴/⁴⁰Ca value of cultured G. ruber shows a significant (R² =0.91, p<0.02) inverse linear correlation with salinity [δ⁴⁴/⁴⁰Ca (‰) = 1.27(± 0.36) - 0.016(± 0.009)*S]. Paired Mg/Ca and Sr/Ca both have negative linear correlations with δ⁴⁴/⁴⁰Ca (R² =0.84 and R² =0.94, respectively) in these salinity experiments, indicating a common control on all three proxies.

Ca isotopes have a nearly constant degree of fractionation between 21 and 27°C (δ⁴⁴/⁴⁰Ca ~ 0.77‰), but the degree of fractionation increases (δ⁴⁴/⁴⁰Ca < 0.77‰) at higher and lower temperatures. Mg/Ca shows 8% increase per °C. δ⁴⁴/⁴⁰Ca has no apparent correlation with Mg/Ca or Sr/Ca in the temperature experiments, but appears to reveal an optimum curve. δ⁴⁴/⁴⁰Ca values of G. ruber have a weak dependence (with a slope of +0.0005 ± 0.0002 ‰/µM) on [CO₃²⁻]. At [CO₃²⁻] < 200 µM, Mg/Ca increases by ~30% per 0.1 unit decrease in pH.

The data can be explained by a model based on our understanding of the mechanisms of calcite formation in planktonic foraminifera.
Influence of hydrothermal transformation of amorphous silica on amino acid adsorption capacity

NORIO KITADAI, SATORU NAKASHIMA AND TADASHI YOKOYAMA

Department of Earth and Space Science, graduate school science, Osaka University (nkitadai@ess.sci.osaka-u.ac.jp)

Silica is the major component of the earth’s crust and changes its structure with different crystallinity during diagenesis. Silica has been suggested to assist the chemical evolution of life because of its adsorption and catalytic capacities for organic matter (Bujdak and Rode, 1997). However, it is not known how these properties change with diagenesis. In this study, amorphous silica was hydrothermally transformed and its adsorption capacity for amino acid diagenesis. In this study, amorphous silica was hydrothermally transformed and its adsorption capacity for amino acid (Lysine) was investigated.

Methods

Silica gel (WakoSil-25SIL) was heated at 180°C until 48 hours with de-ionized water. The infrared (IR) absorption peak height ratio (Si-OH/Si-O-Si) was used as a measure of dehydration/polymerization degree (Ito and Nakashima, 2001). After this treatment, the silica was mixed with Lysine solution. Adsorbed Lysine was determined by Ion chromatography.

Results and Discussion

With increasing heating time of silica, the Si-OH/Si-O-Si ratio and the adsorbed Lysine gradually decreased (Fig. 1). The adsorption capacity of silica decreased by dehydration/polymerization. However, the adsorbed Lysine per specific surface area remains almost unchanged (Fig. 2). If the surface concentration of amino acid is the main factor for the chemical evolution of life, a variety of amorphous silica with different surface structures might be available for the amino acid adsorption process.

Fig. 1. The relationship between the Si-OH/Si-O-Si ratio and adsorbed Lysine [mmol/g]

Fig. 2. Changes with time of adsorbed Lysine per specific surface area [μ mol/m²]

Detecting the origin of saline solutions in salt deposits of the German Zechstein basin

J. S. KLAUS1, B. T. HANSEN1 AND W. W. BEER2

1Department on Isotope Geochemistry, Georg-August-University of Göttingen, Germany (jklaus@gwdg.de; bhansen@gwdg.de)

2Geology Division, K+S Aktiengesellschaft, Kassel, Germany (wolfgang.beer@k-plus-s.com)

Considering the fact that salt is soluble in water, the problem that salt mines intruded by external water encounter the risk of flooding is obvious. However, the chance that liquids were inclosed in salt deposits during or after compaction is also known, but poses a considerably lower risk. The distinction of these internal and external inflows is vital for salt companies to avoid the loss of a mine by taking appropriate preventive actions.

One method to distinguish between open and closed inflows is the comparison of δD and δ18O of the saline solutions to the global meteoric water line (e.g. Müller & Papendieck 1975). However, this method is indistinct when used stand-alone.

So far, we have analyzed 106 samples from 25 sites in 12 German mines and 11 groundwater wells for 87Sr/86Sr and the Sr concentration in addition to δD and δ18O. One approach is the comparison of 87Sr/86Sr and δ18O versus the stratigraphic position of the intruded salt rock. The isotopic oscillations of those saline solutions which are -for several reasons- considered to be of salt internal origin show approximately the same pattern. Since the two main processes -hydrothermal convection and continental runoff- that control both isotopic systems in seawater should generate anti-correlations for Sr and O isotopes in marine deposits, the genesis of the saline solutions has to be more complex. However, a link between the evolutions of 87Sr/86Sr and δ18O must exist.

Regarding the Sr concentrations in the internal solutions, the Sr content of <3 ppm is comparatively low. In contrast, the samples from most of the open system solutions show much higher amounts between 15-240 ppm, probably absorbed from detritical clays deposited in the beginning of each evaporitic cycle. In addition, their δ18O values of −12 to −10 % resemble those of the groundwater in the vicinity of the mines. The internal solutions cover a wide range of −12 to +3 ‰. Their main ingredient is MgCl2 which almost impedes the presence of Ca. Since the chemical attributes of Sr are similar to those of Ca, this could be one reason for the absence of Sr in salt internal solutions.

Based on the isotopic information, a distinction between open and closed system solutions is yet quite complex. However, the apparent usefulness of the Sr concentrations as a fast distinction tool is further to be evaluated.

Nano/microstructure of polymer-derived SiOC ceramics

HANS-JOACHIM KLEEIBE
Technical University of Darmstadt, Institute for Applied Geosciences, Geomaterial Science, Schnittspahnstr. 9. D-64287 Darmstadt, Germany

The formation of nanodomains in a carbon-rich SiOC ceramic was investigated depending on annealing temperature. The high carbon content of the pure SiCO system was achieved by utilizing divinyl benzene as an intrinsic cross-linking agent. The incorporation of carbon- and silica-rich regions within the amorphous matrix implies the questions about domain size and thermal stability of such local domains. The nanostructure of the carbon-rich material was studied in detail upon pyrolysis at 1000 °C and after additional thermal anneal at 1450 °C. High-resolution and energy-filtered TEM as well as electron energy-loss spectroscopy were employed to gain an understanding of the intrinsic micro/nanostructure of such polymer-derived ceramics. Although a progressive structural rearrangement within the SiOC matrix was confirmed with increasing temperature, the sample heat treated at 1450 °C remained predominantly amorphous. Based on the experimental observations, a structural model is presented, which is consistent with the high-temperature mechanical response.

Fe-Ni-O-S phase relations during serpentinization (MAR 15°N)

F. KLEIN¹, W. BACH¹ AND C.J. GARRIDO²
¹Geoscience Department, University of Bremen, Germany (fklein@uni-bremen.de, wbach@uni-bremen.de)
²Universidad de Granada, Spain (carlosg@ugr.es)

The strongly reduced nature of the vent fluids in ultramafic-hosted hydrothermal systems is due to the production of hydrogen by hydrolysis of ferrous iron in the host rock. The specific fluid-rock reactions and phase relations involved, however, are incompletely understood. To further our understanding of hydrogen production during serpentinization, we investigate the composition and phase relations of oxides, sulfides, native metals, hydrous silicates, and hydroxides in serpentinites. These phases are not only indicative of redox conditions, temperature and fluid flux during serpentinization, some of them are also important surface catalysts for organic synthesis reactions.

On thin section scale, opaque phases, except for Cr-spinel, are generally not randomly distributed. They are developed either in mesh rims or associated with serpentine and serpentine-magnetite veins. Primary opaque phases are Cr-spinel (Cr# ca. 0.5) and cobaltian pentlandite. While Cr-spinel shows only incipient alteration to magnetite, pentlandite is invariably desulfurized and altered to secondary Fe and Ni phases. The phase relations change systematically with increasing extent of serpentinization. In samples where relict olivine is present, pentlandite is replaced by an iron-nickel metal alloy, awaruite (Ni₃Fe), and/or heazlewoodite (Ni₃S₂) along with magnetite indicating very low oxygen and sulfur fugacities. In contrast, millerite is the dominant Ni-sulfide in completely serpentinized rocks. It is usually accompanied by pyrite(+/− polydymite), and the assemblage represents increased oxygen and sulfur fugacities, which develop when the reducing capacity of the rock is exhausted. These observations indicate that phase relations in the system Fe-Ni-O-S are sensitive indicators of the evolution of hydrogen and sulfur fugacity during serpentinization, as predicted by Frost (1985). Using geochemical modeling and concentration-fugacity relations, we were able to compare our observations with H₂S and H₂ concentrations determined in vent fluids from ultramafic-hosted systems. In the Rainbow and Logatchev field, those are consistent with metastable equilibria between pentlandite, awaruite, heazlewoodite and magnetite. Our calculations for the Lost City field yielded similar results, despite apparent environmental differences between these systems.

The abundance of talc in rocks with pyrite-millerite+/−polydymite assemblages indicate that high activities of aqueous silica and increased sulfur and oxygen fugacities are related. These relationships are explored in a companion paper presented in session S92.

Sr Isotopes and trace element patterns in sub-calcic garnets: A perspective on diamond-bearing fluids?

OFRA KLEIN-BENDAVID AND D. GRAHAM PEARSON

Department of Earth Sciences, Durham University, Science Labs, Durham, UK, DH1 3LE.
(o.k.benavidez@durham.ac.uk; d.g.pearson@durham.ac.uk)

Sub-calcic garnets are typical xenocrysts in kimberlites. They are found as inclusions in gem quality diamonds and as such have implications for the diamond growing area. This study focused on eight xenocrystic sub-calcic garnet crystals from the Ekati property, Canada. We studied the trace element and REE patterns of the garnets as well as the Sr and oxygen isotopic composition in order to investigate their origin and the nature of associated metasomatism.

Chondrite normalized REE patterns are sinusoidal, however, the slope of the curve varies (Nd/La = 1.7 to 70; Nd/Er = 1.9 to 48). The highest enrichment varies between LREE (Nd) and MREE (Eu). One crystal exhibits a pronounced Ce anomaly (Ce/Ce* = 3.3). Garnets have highly radiogenic Sr (87Sr/86Sr = 0.710371 to 0.731198). Enrichment in radiogenic Sr is coupled with increased concentrations of Ce, Sr, Nd, Sm, Pr, Nb, La, Th and U. The radiogenic Sr is not supported by the low Rb content of the garnets. The high Zr/Yb and low Sr/Yb ratios of the less radiogenic crystals indicate interaction with a Zr-rich and low Sr agent. The O isotopic composition of the garnets varies between 5.23 and 5.42‰, with a broad positive Zr-rich and low Sr agent. The O isotopic composition of the garnets indicates interaction with a low Rb content of the garnets. The high Zr/Yb and low Sr/Yb ratios of the less radiogenic crystals indicate interaction with a Zr-rich and low Sr agent. The O isotopic composition of the garnets varies between 5.23 and 5.42‰, with a broad positive Zr-rich and low Sr agent. The O isotopic composition of the garnets varies between 5.23 and 5.42‰, with a broad positive Zr-rich and low Sr agent.

We calculated the composition of possible metasomatic agents in equilibrium with the garnets using partition coefficients for carbonatitic, silicic and hydrous-silicic melts. Diamond-forming fluids show some similarities to the calculated metasomatic agents (positive Pb anomaly and negative Zr, Ti and Nb anomalies). However, REE concentrations in typical diamond forming fluids are much higher than those of the calculated metasomatic agent. Carbonatitic–silicic globules reported in lherzolitic clinopyroxene microcrystals closely resemble the trace element composition of the garnet metasomatic agent. Phase equilibria experiments indicate that sub-calcic, Cr-rich garnets have recrystallized from subducted Cr-rich protoliths. We propose that the garnets inherited an enriched Sr signature from old subducted oceanic lithosphere and were affected by extensive metasomatism of an agent not very different from carbonatitic-silicic melts and diamond forming fluids.

Hf-W chronometry and the thermal evolution of asteroids

T. KLEINE1, M. TOUBOUL1, C. BURKHARDT1, B. BOURDON2 AND A. HALLIDAY2

1Institut for Isotope Geochemistry and Mineral Resources, ETH Zurich, Clausiusstrasse 25, 8092 Zurich, Switzerland (kleine@erdw.ethz.ch)
2Department of Earth Sciences, Oxford University, Parks Road, Oxford OX1, United Kingdom

Hf-W chronometry has widely been applied for dating the differentiation of asteroids and terrestrial planets [1] but its potential for dating meteorites and constraining the thermal evolution of asteroids has yet to be explored. We determined Hf-W metal-silicate isochrons for various ordinary chondrites and acapulcoites and obtained the following ages: ~3 Myr for the H4 chondrite Ste. Marguerite; ~10 Myr for the H6 chondrites Kernouve and Estacado; ~6 Myr for acapulcoites Dhofar 125 and NWA 2775 (here Myr refers to time after formation of CAIs). These Hf-W ages are older than Pb-Pb ages for phosphates [2, 3] and pyroxenes [4] for the same or similar meteorites, indicating that the Hf-W closure temperature in these samples is higher than the ~780°C Pb-Pb closure temperature of pyroxenes. Hf-W ages therefore provide essential information on the earliest cooling history of meteorite parent bodies. Our new Hf-W ages combined with previously reported Pb-Pb ages for the same or similar meteorites [2-4] reveal that acapulcoites cooled more rapidly than H6 chondrites but similar to H4 chondrites. This suggests that either the acapulcoite parent body is smaller than the H chondrite parent body or that the burial depth of acapulcoites was shallower. Compared to H6 chondrites, acapulcoites were heated to higher temperatures (as is evident from the formation of FeNi-FeS melts) but cooled more rapidly, indicating that the acapulcoite parent body contained a higher amount of 26Al and hence accreted earlier than the H chondrite parent body. Acapulcoites may derive from a body that accreted as early as the parent bodies of the magmatic irons (<1.5 Myr [5]) but was too small to efficiently retain the heat produced by 26Al decay. Alternatively, the acapulcoite parent body might have accreted later than ~1.5 Myr but before accretion of the H chondrite parent body at ~3 Myr (as derived from the Hf-W age of Ste. Marguerite). The presence of relict chondrules in some acapulcoites suggests that the latter scenario might be more likely. The Hf-W data indicate that the early evolution of asteroids is largely controlled by the time of parent body accretion and hence the amount of 26Al present. This most likely reflects increasing accretion times with increasing distance from the Sun, consistent with the heliocentric zoning of the asteroid belt [6].

Is dehydration melting responsible for the evolution of high-K granitic melts throughout the Precambrian?

ILKA C. KLEINHANNS, NICOLE NOLTE, WIEBKE BAERO AND BENT T. HANSEN

GZG-Isotope Geology, Georg-August University, Goldschmidtstr. 3, 37077 Göttingen, Germany (ilka@geo.uni-goettingen.de)

Precambrian granitoid terrains mainly show two main intrusion events of granitoid rocks: a first phase of K-poor granitoid melts (granodiorites s.l.). The granodiorites (s.l.) intrude into pre-existing crust and are usually of juvenile character with higher influence of mantle material. The mechanisms of first phase granitoid melts experience a major change at the Archaean/Proterozoic boundary as indicated by the existence of TTG complexes only in Archaean times. TTG’s are special in their liquid line of descent as they are not following the main post-Archaean differentiation path (i.e. the “classical” calcalkaline differentiation) as seen in proterozoic first phase melts. In a second magmatic phase the pre-existing crust suffers an anatectic event that produces high K-granitoids. Second phase melts often intrude in a restricted time interval and field relationships indicate short transport distances for these melts. In this study K-rich granites of different precambrian granitoid terrains were compared: (i) Meso- and Neoarchaean K-rich granitoids from Barberton Mountain Land (Kaapvaal craton, South Africa/Swasiland), (ii) Paleoproterozoic K-rich granitoids from Västervik area (Baltic Shield, Sweden) and Huab metamorphic complex (Congo craton, Namibia). Archaean and Proterozoic K-rich granites show typical crustal geochemical characteristics. More importantly, Sr-Nd isotopes reveal ternary mixing relationships. Three end-members can be traced: (1) juvenile mantle material, (2) country rock material and (3) metasomatic fluids. Juvenile material is clearly under-represented and the two main contributing end-members are country rock material and metasomatic fluids. Highly radiogenic Sr initial ratios indicate mica breakdown and thus, dehydration melting as trigger mechanism for the sudden onset of the granite production factory throughout the Precambrian.

U-series crystal ages of plagioclase and zircon from the 1300 CE Kaharoa eruption, New Zealand

ERIK W. KLEMETTI AND KARI M. COOPER

Department of Geology, 1 Shields Ave., University of California Davis, Davis CA 95616 (klemetti@geology.ucdavis.edu)

The 1300 CE Kaharoa eruption of Tarawera Volcano in New Zealand offers an excellent opportunity to examine of uranium-series crystal ages of multiple phases in young rhyolitic magma. These lavas and pumices are crystal rich with abundant plagioclase feldspar and zircon (>35 volume % crystals) that can be dated using $^{226}\text{Ra}-^{232}\text{Th}$ and $^{230}\text{Th}-^{238}\text{U}$ disequilibria, allowing for a thorough comparison of the timing of crystallization for both major and trace phases in this single rhyolite eruption. The Kaharoa eruption at Tarawera produced 2.5 km$^3$ of rhyolite lava and 5 km$^3$ of pyroclastic material making it the largest eruption in New Zealand over the last 1,000 years (Nairn, 2002).

Samples from two pumice fall deposits (B and J Pumice) and the Ruawahia Dome and associated block and ash flow were chosen to examine the crystal ages of plagioclase and zircon. All of these samples have a whole rock silica content of 74-75 wt%, while their Zr contents vary: dome samples average 130 ppm and pumice average 93 ppm. This compositional difference is reflected in other trace elements. It is also seen in the An content of plagioclase grains (Figure 1). The pumice samples have a narrow range of average An content for both cores and rims (An$^{19-22}$) while the domes are much more diverse between the cores (An$^{30-45}$) and the rims (An$^{23-25}$).

Preliminary U-series analyses of whole rock samples using a Nu Plasma MC-ICP-MS at UC-Davis indicate that the pumice and dome samples have different Th isotopic compositions. Future analyses will include U-Th-Ra analyses of whole rock, glass and plagioclase separates in two different size classes (125-250 µm and 250-500 µm) along with U-Th analyses of single zircon (SHRIMP). Zircon separates will include crystals derived from the groundmass/glass and as inclusions within plagioclase. These analyses will elucidate the timescales of crystallization of major and trace phases within rhyolite magma and determine whether zircon and plagioclase ages record the same magmatic events.

Osmium isotopes as a provenance tracer? A case study from Cabrières

V. KLEMM\textsuperscript{1}, P. AMBERT\textsuperscript{2} and B. BOURDON\textsuperscript{1}

\textsuperscript{1}ETH Zürich, Dept. of Earth Science, Switzerland (klemm@erdw.ethz.ch)
\textsuperscript{2}Centre d’Anthropologie CNRS-EHESS, Toulouse, France

La Capitelle du Broum, located in the chalcolithic copper mining district of Cabrières (Hérault, France), is the first chalcolithic copper smelting workshop known in France dating to the beginning of the 3\textsuperscript{rd} millenium BC [1]. These fahlore mines are composed of tetrahedrite, and the secondary minerals malachite, azurite and cuprite [1]. The entire chain of production from ore to slags, droplets of copper, ingots and artefacts was located on the site [1].

To determine if Osmium (Os) isotopes can be used as a provenance tracer, primary and secondary minerals from different deposits around the archaeological copper smelting site as well as three ingots and six artefacts from within the excavation site, were analysed. That no additional flux agent had been added to the smelting process, which is important for a provenance tracer, was shown by the large variety of the slag compositions [2]. This proves that there was no intention to produce a liquid slag to separate the metal and/or matte from the host rock by adding a flux agent [2]. Beside the Os isotopes also the commonly used lead (Pb) isotopic composition for provenance tracing was applied.

The ore samples show a large spread in all the Pb/Pb isotope ratios, which is typical for fahlores, but no variation between primary and secondary minerals. The Pb isotopic variation of the ingots and artefacts are much smaller and plot within the large Pb/Pb ore field, which shows that during smelting the Pb isotopic composition homogenises and that high firing temperatures of the ore (1000-1200°C) [2] did not change the Pb isotopic composition. The artefacts are therefore most likely produced from those Cabrières ores.

This is different for the Os isotopes. The \textsuperscript{187}O\textsubscript{S}/\textsuperscript{184}Os of the ores spread between 20 and 60, whereas the ingots have decreased \textsuperscript{187}O\textsubscript{S}/\textsuperscript{184}Os ratios from 20 to 23 and the final artefacts show even lower \textsuperscript{187}O\textsubscript{S}/\textsuperscript{184}Os values of around 12. Therefore Os isotopes cannot be used as a source tracer like Pb isotopes. Furthermore the [Os] decreases from around 90 pg/g for the ores down to 12 pg/g for the ingots and artefacts, due to the volatility of OsO\textsubscript{4}, which must have been produced in the smelting process, indicating a primitive oxidising environment within the smelting process. The decrease in the isotopic composition and the [Os] from ore to ingots and artefacts shows that most of the Os was lost during smelting but that an ingrowth of the \textsuperscript{187}Os by the decay of \textsuperscript{187}Re had taken place. Rhenium concentration measurements on the ingots and artefacts will finally show if the Re/Os system can be used as a dating tool for metal artefacts.

Mimetite formation from goethite adsorbed lead

ANNA KLEŚCZEWSKA, MACIEJ MANECKI AND TOMASZ BAJDA

Department of Mineralogy, Petrography and Geochemistry, AGH-University of Science and Technology, Kraków, Poland (aklesczewska@geol.agh.edu.pl)

Immobilization of heavy metals widespread in contaminated soils is still an important issue in environmental research. High levels of arsenic are present as a contamination of agricultural soils where pesticides, herbicides, and fungicides were used (Comba et. al. 1988; Bajda et. al. 2007). These soils are often contaminated by lead as well. Bioavailability of arsenic in contaminated soils can be reduced to insignificant levels by precipitation of mimetite Pb\textsubscript{5}(AsO\textsubscript{4})\textsubscript{3}Cl. This results in conversion of bioavailable arsenate compounds into highly immobile mineral form resulting in neutralization of the toxicity without removal of As(V).

Goethite \(\alpha-\text{Fe(OH)}\textsubscript{3}\) is a mineral widespread in soil environment. It can easily adsorb arsenates or lead ions. The adsorption of lead ion onto these surface is reversible and desorption increase with decreasing pH (Cornell and Schwertmann, 1996). The objective of this study was the reaction between arsenic ions in the solution and a synthetic goethite saturated with adsorbed Pb(II). The sorption of lead ions (initial [Pb] = 50 mg/L) onto goethite at pH=4.8 caused 99% decrease of Pb concentration in the solution in 24 hours. The subsequent reaction between goethite-adsorbed lead and aqueous arsenate in the presence of CI results in crystallization of aggregates of mimetite crystals indicating homogeneous nucleation in the volume of the solution. Crystallization of mimetite is very rapid. The results suggest that the kinetics of lead desorption from goethite is fast, at least equal to the rate of diffusion and advection of AsO\textsubscript{4}\textsuperscript{3-} ions in the solution and the crystallization of mimetite. The decrease of As concentration in the solution after 48 hours of reaction indicates that apart from mimetite crystallization, adsorption of goethite took place.

This work was supported by research project 2P04 D01329.

Utah and Czech Mars analog concretions; Aquatic hematite and goethite characterization

GUNTHER KLETETSCHKA1,2,3, TOMOKO ADACHI1,2, JIRI ADAMOVIC3, VILEM MIKULA1,2 AND MARJORIE CHAN4

1Catholic University of America, Physics Department, Washington DC, USA (kletetschka@gmail.gov)
2Goddard Space Flight Center/NASA, Astrochemistry Code 691, Greenbelt, MD, USA (kletetschka@nasa.gov)
3Institute of Geology, AS CR, Prague, Czech Republic, (kletetschka@gli.cas.cz)
4Geology and Geophysics, University of Utah, Salt Lake City, UT, USA (chan@earth.utah.edu)

Terrestrial Jurassic Navajo Sandstone concretions from Utah show resemblance to the hematite spherules (“blueberries”) imaged by the Mars Exploration Rover (MER) Opportunity. Both the NASA MER team and terrestrial analog studies interpreted the Mars hematite spherules to be concretions precipitated from diagenetic aqueous solutions in the sediment.

Magnetic analyses of Utah and Czech hematite concretions show unusual and complex behavior of antiferromagnetic hematite-goethite composition. We developed a method allowing us to separate the magnetic signature of goethite from hematite and further show that although hematite saturates in 1-2 Tesla range, goethite continues to acquire magnetization even above 10T. Parallel Mössbauer spectra confirm the presence of both hematite and goethite in these terrestrial samples. Magnetic separation allows using the terrestrial concretions as paleofield recorders.

Magnetic signature is tied to aqueous hematite/goethite formation in the sediment. Hematite and goethite (occasionaly also magnetite), carry a record of past magnetization events. Such magnetic signatures help interpretation of their formation.

Based on field observation and laboratory analysis, we suggest that concretions may have formed along the fluctuating water table, that periodically left behind water saturated volumes. Slow evaporation of these volumes initiated precipitation of goethite/hematite from the aquatic solution. Fe isotope data reveal some lighter isotopic iron initiated precipitation of goethite/hematite from the aquatic solution.

Future Mars Rover and sample return missions should include instrumentation for in situ magnetic measurements. Hematite and goethite are well-studied terrestrial magnetic minerals and have magnetic properties suitable for resolving the origin of the spherules. Ferromagnetism of hematite and goethite should record ancient magnetic fields, and has magnetic grainsize in the range that can be used efficiently as a paleotemperature recorder. Thus the magnetic signatures give us tools to study the origin of “blueberries”.

Nd isotope records of the deep south Atlantic and the interpretation of Neogene δ13C gradients

V. KLEVENZ1,3, D. VANCE2, D. N. SCHMIDT2 AND K. MEZGER1

1Westfälische Wilhelms-Universität Münster, Institut für Mineralogie, Corrensstr. 24, 48149 Münster
2Bristol Isotope Group, Department of Earth Sciences, Univ. Bristol, Bristol BS8 1RJ, UK
3Jacobs University Bremen, School of Engineering and Science, Campus Ring 1, 28759 Bremen (v.klevenz@iu-bremen.de)

Records of the past Nd isotope composition of the deep ocean can resolve ambiguities in the interpretation of other paleocirculation tracers. For example, recently published records of Neogene δ13C gradients from the deep Atlantic [1, 2] can be interpreted either in terms of changes in the strength of deep water export from the North Atlantic, or due to variation in the pre-formed δ13C of southern-derived deep water in response to shifts in the surface paleoceanography of the Southern Ocean. Here we present the first Nd isotope data for benthic foraminifera and apply down-core deep water Nd records from this and other substrates to the resolution of ambiguities in nutrient-based tracers.

Comparison of the εNd of core-top foraminifera from a depth transect on the Walvis Ridge to published seawater data suggests that benthic foraminifera represent a reliable archive of the deep water Nd isotope composition. Though data obtained through leaching of Fe-Mn coatings often record the Nd isotope composition of local inputs to the ocean, in this case paired down-core leaching and foraminiferal analyses usually yield identical results, giving confidence in their paleoceanographic significance.

The new εNd datasets, along with Cd/Ca and Nd/Ca ratios from the same foraminiferal samples, are interpreted in the context of debates over the Neogene history of North Atlantic Deep Water (NADW) export to the south Atlantic. Our data suggest strong NADW export from 9 to 5.6 Ma, mostly in congruence with one interpretation of published δ13C gradients [1]. Where the εNd record differs from the nutrient-based records, such as between 7 and 6 and at 4 Ma, changes in the pre-formed δ13C or Cd/Ca of southern-derived deep water might account for the difference. Maximum NADW-export in the last 9 Ma is suggested by all proxies at around 4 to 3.5 Ma. Chemical conditions between 3 and 1 Ma are different suggesting, on average, the lowest NADW export of the entire record. Modern-day values are similar to average values from 9 to 4 Ma, implying NADW export today as strong as at any stage over the past 9 Myr.

The release of volcanic gases is monitored worldwide. The flux of \( \text{SO}_2 \) in the plume and the \( \text{S}/\text{Cl} \) ratio vary systematically with the style of volcanic activity [1]. In order to relate these volcanic gas signatures to processes inside the volcanic edifice the mechanisms of sulphur incorporation in melts and the transfer into a fluid phase has to be known. Sulphur has several oxidation states and \( f_O^2 \) is a crucial control on the sulphur solubility and hence the transfer of sulphur from a magma into a vapour phase.

In this study the sulphur solubility and speciation was determined for various hydrous iron-free silicate glasses equilibrated with sulphur at geological relevant P-T-\( f_O^2 \) conditions. Glass compositions include “simple” (e.g. \( K_2\text{Si}_4\text{O}_9, Rb_2\text{Si}_4\text{O}_9 \)) and more complex compositions (Albite, Trondhjemite). Experiments were performed in CSPV and with \( K_2\text{Si}_4\text{O}_9, Rb_2\text{Si}_4\text{O}_9 \) and more complex compositions (Albite, Trondhjemite). Experiments were performed in CSPV and with \( K_2\text{Si}_4\text{O}_9, Rb_2\text{Si}_4\text{O}_9 \) and more complex compositions (Albite, Trondhjemite). Experiments were performed in CSPV and with \( K_2\text{Si}_4\text{O}_9, Rb_2\text{Si}_4\text{O}_9 \) and more complex compositions (Albite, Trondhjemite). Experiments were performed in CSPV and with \( K_2\text{Si}_4\text{O}_9, Rb_2\text{Si}_4\text{O}_9 \) and more complex compositions (Albite, Trondhjemite). Experiments were performed in CSPV and with \( K_2\text{Si}_4\text{O}_9, Rb_2\text{Si}_4\text{O}_9 \) and more complex compositions (Albite, Trondhjemite). Experiments were performed in CSPV and with

The total sulphur solubility is a function of the degree of polymerisation of the silicate glasses and increases with increasing NBO/T. At reducing conditions (QFM) highly depolymerized glasses dissolve twice the amount of S (up to \( \sim 2 \) wt. %) compared to oxidising conditions (QFM+4). In runs that were saturated with sulphur, sulphate/sulfide blebs were identified, indicating the presence of an immiscible sulphate/sulfide liquid.

The oxidation state of sulphur dissolved in the glasses and the relative abundances of S-species were determined by XANES. Stable S-species in the glasses are sulfide (\( \text{S}^- \)) and/or sulfate (\( \text{SO}_4^{2-} \)) as previously demonstrated [2]. The occurrence of sulfite (\( \text{SO}_3^- \)) in the XANES experiments is demonstrated to be due to beam damage. The \( \text{S}^+/\text{S}^2- \) ratio in the glass is a function of \( f_O^2 \). At \( f_O^2 \geq \text{QFM}+1.5 \) sulphur is dissolved as \( \text{S}^0 \). At \( f_O^2 \sim \text{QFM} \) sulphur is dissolved as a mixture of \( \text{S}^0 \) and \( \text{S}^- \). The lowest fraction of \( \text{S}^0 \) was \( \sim 0.25 \) at \( f_O^2 \sim \text{QFM}-0.7 \). The relatively steep change of \( \text{S}^+/\text{S}^2- \) ratio with \( f_O^2 \) is in the range of QFM-1. This is at two orders of magnitude lower \( f_O^2 \) than previously reported for Fe-bearing systems (QFM+1, [2]). Thus, for a fixed \( f_O^2 \) at ~QFM sulphur is dissolved as mostly \( \text{S}^2- \) in Fe-bearing systems and as \( \text{S}^0 \) in Fe-free systems. This is of importance for natural processes that result in a dramatic change of the prevailing Fe/S ratio (e.g. slab melting, metasomatism, immiscible S-liquids) and has to be implicated in models aiming to quantify the sulphur flux at volcanoes.

\(^4\)Jet Propulsion Laboratory, Pasadena, CA 91109 , USA

The Mars Exploration Rovers (MER) Spirit and Opportunity have explored the Martian surface at Gusev Crater and Meridiani Planum for more than 3 Earth years, traveling more than ~ 10km (Opportunity) and ~ 7km (Spirit), each carrying our Mössbauer Spectrometer (MBS) MIMOS II [1]. Each of the instruments have analyzed more than 100 targets during their ongoing missions (>1100 sols). More than 15 different minerals have been identified so far by the Mössbauer instruments on board the two rovers [2,3,4]. Mössbauer spectroscopy identified the secondary Fe\(^{3+}\)-bearing minerals jarosite, hematite, and nanophase iron oxides in the sulfate-rich outcrop rocks at Meridiani Planum [3]. The sulfate rich outcrop material covers the whole area Opportunity traveled across so far, without significant changes in the mineralogical composition. At Gusev Crater rocks are much more diverse, ranging from little altered basaltic material in the plains to pervasively altered basalt in the Columbia Hills [2,4]. Secondary minerals include the Fe\(^{3+}\)-bearing minerals hematite, goethite, nanophase iron oxides, and an unspecified iron sulfate phase. The relation between primary and secondary minerals varies over short spatial scales. Recent results from Gusev Crater indicate the presence of hematite in greater abundance than in many targets at Meridiani.

In particular the minerals jarosite and goethite [5] found at Meridiani Planum and Gusev Crater, respectively, are clear mineralogical evidence for aqueous weathering processes active at both landing sites in the past.

A possible laser ablation xenotime U-Pb age standard: Reproducibility and accuracy

E. KLÖTZLI¹, U. KLÖTZLI¹ AND J. KOSLER²

1Center of Earth Sciences, University of Vienna, Vienna, Austria (eva.kloetzli@univie.ac.at)
2Dept. of Earth Sciences, University of Bergen, Norway (jan.kosler@geo.uib.no)

With the in-situ U-Pb dating of phosphates by SIMS and LA-ICP-MS new possibilities of linking geochronological and petrological data have been opened up. But wide application of the method is presently hampered by the absence of any accepted xenotime standard for U-Pb dating.

In order to establish such a well defined age standard, xenotime was separated from a Weinsberg granite sample (type Plochwald) from the Bohemian Massif (Austria). This xenotime has a concordant U-Pb TIMS age of 315 ± 2 Ma. No elemental zonation in the crystals was visible using BSE and CL imaging.

Instrumental and analytical setup: New Wave 193 nm solid state laser ablation system with He as carrier gas, Nu Instruments HR multi-collector double-focusing ICP-MS, Nu Instruments DSN-100 desolvating nebulizer. The MS was setup to allow the simultaneous acquisition of the masses $^{238}\text{U}$,$^{233}\text{U}$,$^{229}\text{Th}$,$^{207}\text{Pb}$,$^{206}\text{Pb}$,$^{206}\text{Pb}$,$^{205}\text{Ti}$,$^{204}\text{Pb}$,$^{203}\text{Pb}$. During analysis a $^{235}\text{U}$-Tl spike solution was added to the ablated material as a dry aerosol.

Data reduction: Raw signal intensities are corrected for gas blank using 40 sec of signal acquisition prior to sample analysis. Power law and $^{206}\text{Pb}/^{206}\text{Pb}$ and $^{207}\text{Pb}/^{205}\text{Pb}$ ratios. The U/Pb elemental fractionation is corrected for using an intercept method applying linear regression. The calculated intercept values are corrected for mass discrimination using standard bracketing.

115 measurements on 15 xenotime crystals of 150 to 200 µm size were performed on three consecutive days. Lines with 5µm spot size and 30 µm length were rastered with 5 µm/sec. 12 passes resulted in a total of 72 sec of ablation per analysis.

No significant day-to-day or grain-to-grain variations in age could be detected, nor did the orientation of the laser raster parallel to the prominent {110} cleavage or parallel to crystal faces result in any age discrimination.

Results: All analyses resulted in concordant data points. On average, ages from single line analysis have 2-sigma precisions of 7.6%, 8.3%, and 5.7% for the $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$, and $^{208}\text{Pb}/^{206}\text{Pb}$ ages, respectively. The total mean age of all analyses (without rejections) is 313.4 ± 1.9 Ma (2-sigma), in absolute concordance with the conventional TIMS data.

We propose that the investigated xenotime can effectively be used as a standard for in-situ LA U-Pb age dating with a spatial resolution as low as 5 µm.

External accuracy of laser ablation U-Pb zircon dating: Results from a test using five different standards

U. KLÖTZLI¹, E. KLÖTZLI¹, Z. GÜNES¹ AND J. KOSLER²

1Center of Earth Sciences, University of Vienna, Austria (urs.kloetzli@univie.ac.at)
2Dept. of Earth Sciences, University of Bergen, Norway (jan.kosler@geo.uib.no)

Using a state-of-the-art 193nm-LA-MC-ICP-MS system and thorough control on analytical procedures, the long term (months) external accuracy and reproducibility for Phanerozoic zircons using standard bracketing is 1% to 2% 2RSD for the $^{206}\text{Pb}/^{238}\text{U}$ and $^{207}\text{Pb}/^{206}\text{Pb}$ ages. This is true when using only one standard zircon, such as 91500, for the matrix matched calibration. When using different standards for the calibration (i.e. Plesovice, Sri Lanka, Temora) suspicious systematic shifts in the obtained ages and thus a reduction in the overall accuracy of the dating method become obvious. These shifts are in the range of a few percent of the U-Pb ages and seem to vary unsystematically with age and zircon composition. Two main causes could be made responsible for the effects: 1) matrix and or ablation process-related effects stemming from (subtle?) differences in standard and sample compositions; 2) instrumental effects from the laser system or the mass spectrometer.

In order to test which of the two is responsible, a ‘test of accuracy’ experiment was conducted. Any instrumental effects were reduced as far as possible by analysing five different standard zircons mounted on one single mount and analysed during one session using the identical protocol for all analyses and without changing any instrument parameters and keeping ion beam intensities as identical as possible. Each standard was analysed 8 times with two analyses per grain resulting in a total of 80 measurements. For data reduction, every standard served consecutively as calibration standard, the others were treated as unknown variables. The known standard age and the four calculated ages using the respective four other standards for calibration were then compared. Even using such a very strict analytical Protocol age shifts were still present. They vary non-systematically and range from -1 Ma to +20 Ma (i.e. 0.3% to 10%) for the investigated age range (1064 Ma to 220 Ma).

Conclusions: Accepting the absence of any instrumental effects (i.e. no memory effects, no effects from dead-time correction, non-linearity of ion counters and inter-detector calibration,…), the observed age shifts have to be attributed to matrix and/or ablation process-related effects. Therefore, to allow the comparison of laser ablation zircon U-Pb ages on an intra- and inter-laboratory basis, more rigorous than usual matrix matching procedures have to be applied, and the resulting reduction in the overall accuracy has to be included into the error propagation schemes for the final age data.
Fluid venting at a Cretaceous seamount, Canary Archipelago

A. KLÜGEL, T.H. HANSTEEN, P.V.D. BOGAARD AND H. STRAUSS

1Universität Bremen, Fachbereich Geowissenschaften, Bremen, Germany (akluegel@uni-bremen.de)
2IFM-GEOMAR, Kiel, Germany (hansteen@ifm-geomar.de)
3Geologisch-Paläontologisches Institut, WWU Münster, Münster, Germany (hstrauss@uni-muenster.de)

Henry Seamount is a 8-km-wide, 660-m-high edifice rising from 3700 m deep seafloor southeast of El Hierro, the youngest of the Canary Islands (1.1 Ma). Sonar and seismic data revealed that the seamount is an old volcano with radiating gullies and a sediment cover of several meters (Gee et al., 2001). Dredging during Meteor cruise M66/1 in 2005 recovered (i) slightly to heavily altered trachyte fragments covered by thin Mn-crusts; (ii) a fresh porous barite block overgrown by a coral stem; (iii) abundant shell fragments of vesicomyid clams up to 15 cm in size; and (iv) soft sediments and sediment rocks.

The trace element compositions of the trachytes indicate an origin by intraplate rather than ridge volcanism. Ar/Ar dating of feldspars and matrix of two trachyte samples gave an age range of 123.8 to 126.4 Ma, which is considerably older than any of the Canary Islands. The combined morphological and age data support the interpretation of Henry Seamount being an extinct volcano.

The recovery of shells from vesicomyid clams at Henry Seamount is surprising since this species is always associated with hydrothermal vents or seepage. 14C dating of two shells gave ages of 3.4 and 18.6 ka consistent with Recent venting activity. Fluid discharge at Henry Seamount is also indicated by the recovered barite block having δ34S values between 26.5 and 31.8 ‰ and δ18O values between 14.1 and 16.9 ‰. To our knowledge, this is the first reported finding of vesicomyid clams within the Canary Archipelago and also the first direct or indirect evidence of fluid venting in this area.

How can Recent fluid venting at Henry Seamount be reconciled with its early Cretaceous age? We propose that hydrothermal circulation within the Jurassic oceanic crust around El Hierro is driven by a mechanism similar to that proposed for young crust of the Juan de Fuca ridge flank (Fisher et al., 2003), the ultimate heat source being the hotspot beneath the western Canary Islands. Henry Seamount may thus work as a "breathing hole" where fluid discharge is facilitated by a rather thin sediment layer compared to the adjacent seafloor covered by thick impermeable sediment. Recharge may occur at adjacent basement outcrops such as the flanks of El Hierro island. Our results indicate that hydrothermal circulation through seamounts is not confined to young warm ridge flanks but may be a widespread phenomenon on the ocean floor.

Unfractionated excess air: The result of incomplete dissolution of entrapped air?

S. KLUMP, O.A. CIRPKA AND R. KIPFER

1Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland
2Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
3Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, Switzerland

Dissolved atmospheric (noble) gases in groundwater usually exceed their respective atmospheric equilibrium concentrations. This phenomenon is usually referred to as "excess air" in groundwater hydrology.

The formation of excess air has been suggested to result from the (partial) dissolution of entrapped air within the quasi-saturated zone. Excess air in groundwater crucially hampers the interpretation of environmental tracer data. Therefore, several lumped parameter models have been developed to parameterize the excess air component, which can then be separated from the total measured gas concentrations. However, these models do not include a mechanistic description of the gas exchange in porous media.

Excess air can be either unfractionated, i.e., the elemental composition is atmospheric, or fractionated with respect to atmospheric air. The most simple lumped parameter model was introduced by Heaton and Vogel (1981) and proposes the complete dissolution of entrapped air, leading to unfractionated excess air. Although most groundwater samples contain fractionated excess air, unfractionated excess air is also found. However, the amounts of entrapped and completely dissolved air proposed by the unfractionated excess air model are usually much smaller than typical values of entrapped air volumes observed in the field or in laboratory experiments.

Based on new experimental results and numerical investigations, we present an alternative conceptual model for the formation of apparently unfractionated excess air in the presence of a progressively dissolving entrapped gas phase. This new approach is of particular interest for the interpretation of environmental tracer data (e.g., determination of paleo-soil temperature using noble gases) and for the potential use of excess air as a proxy for the hydraulic conditions prevailing during groundwater recharge.

Excess air as a potential tracer for paleohydrological conditions

S. KLUMP1,2, T. GRUNDL3, R. PURTSCHERT4 AND R. KIPFER1,5

1Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland
2Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
3Department of Geosciences, University of Wisconsin-Milwaukee, USA
4Physics Institute, University of Bern, Switzerland
5Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, Switzerland

The formation of excess air, i.e., supersaturations of dissolved atmospheric gases in groundwater as the result of the dissolution of entrapped air in the quasi-saturated zone, depends on the environmental conditions during groundwater recharge. Excess air can therefore be viewed as a potential paleohydrological tracer for, e.g., groundwater table fluctuations during groundwater recharge.

The amount of excess air in samples of paleo-groundwater from a deep sandstone aquifer in southern Wisconsin changes considerably over time. The area investigated was intermittently ice-covered during the last glaciation from about 12 to 26 kyr BP. Noble gas data, in conjunction with 14C ages and stable isotope data, indicate a soil cooling of about 6.5 to 7 °C during the last glacial period compared with the modern soil temperature.

All samples, except for those recharged before the last glacial period, show a strong correlation between noble gas temperature and δ18O. By contrast, δ18O values of samples older than about 28 kyr BP are too heavy with respect to their noble gas temperatures. This might be due to a stronger influence of an isotopically enriched moisture source before 28 kyr BP.

The amount of excess air increased shortly before and at the beginning of the glaciation of the study area. At the same time, the degree of fractionation of the excess air with respect to the composition of atmospheric air decreased significantly. Both the increasing amount of excess air and the decreasing degree of fractionation indicate hydrological changes at the onset of the glaciation, proposing increasing fluctuations of the groundwater table in response to climatic changes or hydraulic changes due to the ice advance. After glaciation, the amount and fractionation of the excess air quickly changed to those values of modern groundwater, which is characterized by relatively few and strongly fractionated excess air.

In conclusion, the results show that excess air is a potential tracer for the pressure conditions during groundwater recharge in the past.

Study of native metals and alloys in natural deposits and soils:
A contribution to the understanding of the influence of natural and industrial objects on the environment

O.V. KNAUF, N.S. GUSEVA AND I.V. ESIPOVA

The application of highly sensitive (<1ppm) mineralogical methods (see details at www.natires.com) during geochemical exploration and environmental studies has revealed a wide range of native metals grains (NMG) and alloys in almost all samples of soils and natural deposits. Variable amounts of NMG have been observed in areas affected by industrial pollution, within city boundaries and also in areas remote (200-400 km) from any obvious sources of pollution.

The observed NMG include Si, Cr, Fe, Co, Ni, Cu, Zn, Pd, Cd, Sn, Sb, W, Pb, Bi, which were present as pure phases and also, in some cases as alloys of two or more elements.

Qualitative and quantitative determinations of the compositions of the NMG have shown that these depend on the locations of the samples. In some cases a precise correlation between the amount and chemical composition of the NMG and the composition of underlying host rocks has been established.

The NMG and alloys generally vary in size from n*1 to n*10µm, rarely reaching 200µm. Four morphological types of grains have been observed: spherical grains (are the most abundant), relatively isometric-angular grains, grains with irregular form and minor grains as peels.

Textural evidence of dissolution or supergene alteration of the NMG has not been observed, indicating that they form and exist stably under supergene conditions. The genesis of NMG requires further investigation, however the occurrence of these reduced native elements indicates that electro-chemical processes have been important in their formation under supergene conditions.

Detailed mineralogical studies of NMG and alloys in natural deposits and soils appears to be important in the evaluation of the influence natural and industrial objects on the environment, especially given that NMG can include toxic elements such as Cd, Pb etc (V. Cappuyns, et al., 2006).

A geochemical model of arsenic sorption on clay mineral functional sites

G. KNIEWALD AND Z. FIKET
Department of Marine and Environmental Research, Rudjer Boskovic Institute, POB 180, 10002 Zagreb, Croatia (kniewald@irb.hr)

The Method
The mobility of arsenic species in the environment is largely controlled by solid phase sorption reactions. Quantitative evaluations of the solid phase/water partitioning of many toxic metals, including arsenic, are best accomplished by a surface complexation approach. Equilibrium-based thermodynamic modelling is currently one of the most appropriate methods to evaluate the competitive geochemical processes that affect the transport and toxicity of arsenic, including predictions regarding arsenic persistance and mobility in the environment.

Computation
The USGS numerical computer code PHREEQC version 1.6 was used for all simulations. The code was used to simulate arsenic surface complexation from a small watershed with naturally high levels of arsenic on clay mineral components (kaolinite and montmorillonite) of a stream sediment. Surface complexation mass-action coefficients were obtained from the literature in the generalized two-layer model form, or from linear free energy relationships. The WATEQ4F thermodynamic database formed the core to which surface complexation parameters were added. The code was used for the calculation of saturation indices, sensitivity analysis of parameters such as Eh, pH and temperature, modelling the mixing of stream water of different compositions. The surface complexation routine was used in the generalized two-layer model and competition between arsenic and other ions for sorbing phases for a finite number of sites was allowed. Both mineral assemblages were allowed to come to equilibrium by simulating the flushing of many pore volumes through the sediment-mineral surface assemblage.

The model output was evaluated using the ratio "R" of modeled vs. expected arsenic concentrations. Small differences in the conceptual model and data acquisition techniques can have a large effect on the simulation error. The error of neglecting competition by common compounds such as bicarbonate or silicic acid can equal or exceed the bias resulting from inappprpriate choice of mineral phases.

Controls on schwertmannite transformation rates and products

KLAUS-HOLGER KNORR1 AND CHRISTIAN BLODAU2
1Limnological Research Station, Dept. of Hydrology, University of Bayreuth, 95440 Bayreuth, Germany (kh.knorr@uni-bayreuth.de)
2Limnological Research Station, Dept. of Hydrology, University of Bayreuth, 95440 Bayreuth, Germany (christian.blodau@uni-bayreuth.de)

The formation and transformation of schwertmannite is of geochemical significance in acid mine drainage (AMD) polluted surface waters. Sediments dominated by schwertmannite typically adjust to a pH around 3, as the mineral slowly transforms into more stable phases and thereby releases protons. At such low pH and only short supply of electron donors due to the low productivity of AMD polluted lakes, the sediments are characterized by an iron reducing regime. Sulfate reduction would be desirable to reverse pyrite weathering and sequester acidity, but was found to take place at significant extent only at a pH higher than 5, though. The impact of environmental factors such as dissolved organic carbon (DOC), high sulfate concentrations, pH or temperature on schwertmannite transformation is thus of particular interest when studying the biogeochemistry of AMD affected lake sediments.

To evaluate the effect of geochemical conditions on the fate of schwertmannite in AMD polluted sediments, we varied pH, concentrations of sulphate and DOC, and temperature in batch experiments. We quantified schwertmannite transformation by titration of released acidity and investigated the product with FTIR, XRD, SEM/EDX, and chemical extraction with 1N HCl. Transformation rates ranged from 0.0002 d-1 to 0.13 d-1 (transformed fraction / incubation time). Raising pH from 3 to 5 increased transformation by a factor of 5.8 (±2.1) and temperature from 10 to 20° C by a factor 3.8 (±1.6). Sulphate (20 mmol L-1) and DOC (20 mg L-1) lowered transformation by a factor of 2.5 (±0.4) and 2.4 (±0.5). The newly formed iron phase was less dissolvable in 1N HCl but goethite was not detected by XRD. The morphology did hardly change, even in sulphate-poor iron phases and no goethite-typical needle structures could be observed. Thus we concluded that an amorphous, sulphate depleted iron phase had formed. Most of the sulphate released from the schwertmannite structure remained bound to the solid phase. We interpreted changes in IR bands at 1108 cm-1 (ν3) and 984 cm-1 (ν2) as a relocation of sulphate.

The study documents the high potential of schwertmannite to buffer pH increase in sediments, particularly at low sulphate concentrations, and high temperatures. This coincides with the finding that strongly acidic sediments dominated by schwertmannite remain in an iron reducing state for a long time.

In contrast to other studies conducted in deionized water we could not identify goethite to be the transformation product under the conditions chosen.
Assessment of aquifer vulnerability using statistical methods and GIS

KYUNG-SEOK KO, DONG CHAN KOH, JIN-SOO LEE AND GITAK CHAE
Korea Institute of Geoscience & Mineral Resources, Dajeon, Korea (kyungsok@kigam.re.kr)

The purpose of the study for the development of the technologies of water quality monitoring and contamination protection at water resource aquifer is to secure the groundwater as potable water resources. The regional survey of groundwater quality for small potable water supply system were performed to know the effect of geology, soil properties, and land use for hydrochemistry at Nonsan area, Korea.

The geostatistical analysis, multivariate statistical methods, and GIS technique were used for the quantitative interpretation of groundwater chemistry. The monitoring results of groundwater in the study area showed that 13-21% of groundwater samples were exceeded the portable water results of groundwater quality for small potable water supply system. The monitoring methods, and GIS technique were used for the quantitative interpretation of groundwater chemistry. The monitoring results of groundwater in the study area showed that 13-21% of groundwater samples were exceeded the portable water guideline and the main causes were turbidity, bacteria, arsenic and nitrate-N. The high Cl, NO₃ and Na at granite area are caused by the high vulnerability of groundwater at granite region where the residential area and cultivated land are concentrated. The spatial distribution of components indicated the close relationships between groundwater quality and geology, land use, and topography. The results of principal component and discriminant analysis showed the close relationships between groundwater quality and geology (Fig. 1). From PCA, the three main variables explain 73% of the total variance and PC2 which is influenced by NO₃, Si, and HCO₃ is the major factors indicating geology induced factors.

It is considered that the anomalous distribution of Arsenic is related to metasedimentary rock of Ogcheon belt with high contents of sulfide minerals.

Figure 1. The results of multivariate statistical methods.

Garnet peridotite and associated UHP eclogite, equilibrated at 4.5-5.0 GPa, occur as lenticular bodies surrounded by migmatitic gneiss at Nove Dvory area in the Moldanubian Zone, Czech Republic [1] [2]. This geological setting is similar to UHP rocks in Dabie-Sulu. It is important to identify the timing and mechanism when and how UHP rocks juxtaposed with Gföhl felsic rocks which have no HP/UHP evidence in their matrix, except for the occurrence of kyanite and show various kinds of partial melting structures. We report possible UHP evidence predated the partial melting of the felsic rocks identified from the zircon inclusions using the Raman spectroscopy and CL study.

The Raman spectroscopy for more than 1500 zircon separates from Gföhl felsic rocks at Nove Dvory area shows that the most of SiO₂ inclusions are quartz with clear and intense peaks at 464 and 393 cm⁻¹, and a few SiO₂ inclusion has a weak but clear peak at 521 cm⁻¹, and a weaker peak at 179 cm⁻¹, which are the most fundamental vibration of coesite, along with typical quartz vibration mentioned above. The Raman spectrum composed of the intense vibrations at 464 and 393 cm⁻¹ of quartz and the weak vibrations at 521 and 179 cm⁻¹ of coesite were also obtained from the quartz proximal to relict coesite from the UHP rocks of the Dora Maira Massif. The similar Raman spectrum has been reported from quartz transformed from coesite in UHP rocks recovered from CCSD drillhole, eastern China [3]. Therefore, we propose that the SiO₂ phase showing the Raman spectrum with the weak vibrations at 521 and 179 cm⁻¹ was once coesite, along with the case of the Lanterman Range, Antarctica [4]. CL image observation of zircon grains displays that most zircon grains can be subdivided into two textural domains; the oscillatory zoned core and the rim separated by discontinuous CL pattern. All possible coesite inclusions are always detected from the core, although all SiO₂ inclusions in the rim were quartz.

These facts may suggest that the zircon of Gföhl felsic rocks at Nove Dvory once crystallized at UHP depths and most UHP evidence was obliterated by resorption and secondary growth of zircons during the exhumation stage.

Breakdown of hydrous ringwoodite to pyroxene and Fe$^{3+}$-bearing-wadsleyite at high P and T and oxidizing conditions

M. KOCH-MÜLLER, D. RHEDE, R. SCHULZ AND R. WIRTH

GeoForschungsZentrum Potsdam, Department Chemistry of the Earth, Potsdam, Germany

The stability relations in the systems M$_2$SiO$_4$ (M = Mg, Fe, Ni, Co) have been the subject of numerous studies because of their significance for the mantle transition zone. In the Mg$_2$SiO$_4$ system three polymorphs exist: at ambient conditions olivine, at pressure > 13 GPa (1000 °C) wadsleyite and at P > 18 GPa (1000 °C) ringwoodite. This is quite different to the Fe$_2$SiO$_4$ system where no intervening wadsleyite phase has been observed but fayalite directly transforms to Fe-ringwoodite at 5.3 GPa (1000 °C). Experiments in the system Fe$_2$SiO$_4$ – Fe$_3$O$_4$ by Woodland and Angel (1998) at 5.6 GPa (1100 °C) revealed that Fe-wadsleyite can only be stabilised if significant amounts of Fe$^{3+}$ are incorporated. To get deeper insight into the phase relation in the endmember system Fe$_2$SiO$_4$ as well as in the system Fe$_1$Mg$_1$SiO$_4$ we investigated the phase relations as a function of P, T and f O$_2$. The experiments were performed in a multi-anvil apparatus at 7- 14 GPa at 1100 °C. Oxygen fugacities were varied using the solid oxygen buffer systems Fe/FeO, QFM and Ni/NiO. The run products were analysed with electron microprobe, Raman spectroscopy, X-ray powder diffraction and transmission electron microscopy. The X-ray data were analysed using the GSAS software. At f O$_2$ corresponding to Ni/NiO Fe-ringwoodite transforms to ferrosilite and Fe$^{3+}$-wadsleyite according to the reaction: 9 Fe$_2$SiO$_4$ + O$_2$ = 6 FeSiO$_3$ + 5 Fe$_{2.42}$Si$_{0.58}$O$_4$. Refinement of site occupancies in combinations to stoichiometric Fe$^{3+}$ calculations show that 32 % of the total Fe is incorporated as Fe$^{3+}$ according to Fe$^{2+}$_1.60Fe$^{3+}$_0.40Si$_{0.62}$Fe$_{3+}$_0.39O$_4$. Similar phase relations are observed in the system Fe$_1$Mg$_1$SiO$_4$.

Miocene oceanography of the Mediterranean area deduced from C-, O-, Sr-, and Nd-isotopes

L. KOCSIS$^1$, T. VENNEMANN$^1$, D. FONTIGNIE$^2$, C. BAUMGÄRTNER$^3$, A. MONTANARI$^4$ AND B. JELEN$^5$

$^1$Institut de Minéralogie et Géochimie, University of Lausanne (laszlo.kocsis@unil.ch; torsten.vennemann@unil.ch)
$^2$Département de Minéralogie, University Geneva (denis.fontignie@terre.unige.ch)
$^3$Institut de Géologie et Paléontologie, University of Lausanne (claudia.baumgartner@unil.ch)
$^4$Osservatorio Geologico di Coldigioco Frontale di Apiro, Italy (sandro.ogc@fastnet.it)
$^5$Geological Survey of Slovenia, Ljubljana (bogomir.jelen@geo-zs.si)

A detailed study of the isotopic composition of fossils and whole samples from a composite Oligo-Miocene pelagic sequence of the Umbria-Marche region in Italy has been made with the goal to constrain oceanographic and climatic conditions of the Mediterranean Sea during this period. Stable C and O isotope compositions of benthic and planktic foraminifera mimic global changes, supporting that these fossils have been well preserved and that the regional climate of this area was controlled by global changes in climate.

Neodymium and strontium isotope compositions of bulk carbonate fossils were measured and compared to those of the detrital silicate fraction of the embedding sediment. The compositions of the fossils are expected to closely relate to the former seawater composition, while the sediment would represent the hinterland. The relation between the two signals helps to evaluate oceanic circulation in the region. To broaden the spatial distribution and trace connections between different water masses, marine deposits from northern Italy and Slovenia were also investigated.

Results to date indicate a strong local influence on the $\varepsilon$Nd value and possibly a weaker influence on the Sr isotope composition of the Mediterranean seawater during the Chattian-Aquitanian. During the Burdigalian-Serravallian a mixed seawater composition between the Atlantic and Indian Ocean water masses was registered with a stronger Indian Ocean influence in the Umbria-Marche region, while analyzes from the west (Moransengo) might reflect a strengthening Atlantic effect. The $^{87}$Sr/$^{86}$Sr is still lower than that of the Miocene open ocean, probably due to erosion and influence of Sr derived from Mesozoic carbonates. The dataset also shows short-term deviations in the $\varepsilon$Nd values of the fossils coinciding with major sea-level decreases.

During the Late Serravallian-Tortonian normal open ocean Sr values were recorded, while the $\varepsilon$Nd values vary considerably. A low $\varepsilon$Nd value at 12-11 Ma could indicate inflow of water from the Atlantic Ocean, which stopped at 10 Ma due to major regression and allowed for the development of a locally controlled water mass with $\varepsilon$Nd of –8.5. Thereafter, the $\varepsilon$Nd again approaches compositions typical for the Atlantic Ocean.

Sterols in the red and green algae and their relevance for interpretation of Paleozoic steranes

ROBIN B. KODNER1, ANDREW H. KNOLL1 AND ROGER E. SUMMONS2

126 Oxford St. Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA 02138 USA (kodner@fas.harvard.edu; aknoll@oeb.harvard.edu)
2E34 42-44 Carleton St., Department of Earth Atmosheric and Planetary Sciences, MIT, Cambridge, MA 02139 USA (rsummons@mit.edu)

Steroids are a diverse class of lipid with high preservation potential and that are abundantly preserved in the geologic record. These molecules are among the few traits that are shared across all eukaryotes; and thus, they are also important for understanding the molecular evolution of this group. Sterols most commonly used by eukaryotes are C27, C28, and C29 molecules which correspond to C27, C28, and C29 steranes. A diversity of these molecules is found in oils and sedimentary bitumens. Because all three classes of molecules are used by evolutionarily diverse eukaryotes, it can be difficult to ascribe any particular molecular class to a single group of organisms. Many geochemists and paleontologists, however, have tried to draw connections between the presence of C29 steranes in the latest Precambrian and Paleozoic to green algae.

Though C29 sterols have a cosmopolitan distribution among photosynthetic eukaryotes, the known diversity of C29 producing organisms is restricted prior to the Mesozoic. Using a large survey of sterol profiles from the most ancient lineages of algae, we investigate the hypothesis that green algae are the likely source of C29 steranes through the Phanerozoic. We discuss the phylogenetic and ecological relationships of the distribution of C27, C28, and C29 sterols in these groups, and how this impacts the current interpretation of the importance of green algae in pre-Mesozoic ecosystems.

Geochemistry of ocean-floor serpentinites: Implications for subduction zone inventory

J. KODOLÁNYI, C. SPANDLER AND T. PETTKE

Institute of Geological Sciences, University of Bern, Bern, CH-3012 Switzerland

Hydrated oceanic mantle is a significant carrier of H2O in subduction zones. Experimental studies and field observations demonstrate that serpentinites undergo major dehydration over a restricted -P-T interval (ca. 2-5 GPa, 650-700 °C; Ulmer and Trommsdorff, 1995; Trommsdorff et al., 1998). Fluids released during serpentinite dehydration may have a considerable effect on element recycling through subduction zones. Whole rock and mineral major and trace element data (EMPA, LA-ICP-MS) of 39 samples from 6 ODP drill sites representing different geodynamic settings (fast and slow spreading ridges, passive margins and forearcs) constrain the geochemistry of ocean-floor serpentinites, which are a proxy for the chemical inventory of subducted hydrated mantle.

The degree of serpentinization in the ODP samples varies between 65 and 100 vol%. Besides serpentine minerals (srp) and magnetite (mag), the most common secondary phases are chlorite (chl), brucite (brc), calcite (cal) iowaite (iow) and sulfides (sul). Excess brc component in srp is commonly observed in mesh rims and mesh cores. In few samples, the presence of iow has been inferred from high Cl and Fe content accompanying low silica. Minor and trace element compositions of srp in different textural settings generally reflect that of the precursor mineral (olivine and orthopyroxene). However, there are considerable variations due to varying degrees of element mobility and mass change during serpentinization. Elements like B, Sr, Rb and Ba show orders of magnitude enrichments in srp compared to the precursor minerals (B: 35-88 ppm, Sr: 1.0-1.3 ppm, Rb: 0.03-0.07 ppm and Ba: 0.1-0.7 ppm). Bastites tend to have about 1.5-4 times higher trace-element concentrations than mesh rims. This is probably related to local fluid chemistry, with relatively high dissolved SiO2 and relatively low pH around orthopyroxene during serpentinization. Boron values are highly variable even on the 100 µm scale, which may reflect structural effects besides srp mineral chemistry. By contrast, elevated Sr concentrations are fairly constant on the sample scale, which indicates that srp minerals may incorporate Sr.

Our results show that ocean floor serpentinization may be accompanied by appreciable incompatible trace-elements enrichment (e.g., B, Sr). Therefore, serpentinites may be important reservoirs for many trace elements in subducting slabs and, hence, may be of great consequence to geochemical recycling through subduction zones.

Fluid geochemistry in the Ivigtut cryolite deposit, South Greenland

JASMIN KOEHLER AND GREGOR MARKL

Universität Tübingen, Inst. f. Geowissenschaften, D-72074 Tübingen, Germany (jasmin.koehler@uni-tuebingen.de, markl@uni-tuebingen.de)

The 1.27 Ga old Ivigtut intrusion is part of the mid-Proterozoic Gardar Province in South Greenland. The Province represents a failed-rift structure where magmatic activity lasted from 1.35 to 1.14 Ga [1]. The Ivigtut intrusion is world-famous for its cryolite deposit [Na3AlF6] which is now mined out. The deposit is situated within an A-type granite stock where F- and alkali-rich fluids led to metasomatism and formation of cryolite, rare fluorides, sulfides and siderite [2].

Little has been known so far about the formation conditions of cryolite and the rare fluorides at Ivigtut. In order to estimate intensive parameters for the assemblages at Ivigtut, thermodynamic modelling was carried out with the computer program TWQ [3]. At a pressure of 1 kbar, most assemblages are stable below 450 °C at high water- and silica-activities.

Microthermometry of fluid inclusions shows that three types of inclusions can be distinguished: (1) pure CO2, (2) aqueous carbonic and (3) saline aqueous inclusions. Melting temperatures are about -56.6 °C for type 1 inclusions, range between -23 to -15 °C for type 2 and from -15 to -10 °C for type 3 inclusions. Most inclusions homogenise between 110 and 150 °C into the liquid.

Stable isotope compositions of CO2 and H2O were measured from crushed inclusions. δ18O values are about -5‰ PDB which is typical of mantle-derived magmas [4], δ18O (CO2) ranges between 21 and 42‰ VSMOW while δ18O (H2O) varies from -1 to -20‰ VSMOW. Theses values suggest low-temperature isotope exchange as proposed by [5]. δD (H2O) ranges from -19 to -123‰ VSMOW. The isotopic composition of inclusion water closely follows the meteoric water line and is comparable to Canadian Shield brines [6].

Our results show that the Ivigtut fluid has the typical characteristics of a hydrothermal, Na-dominated brine. Isotopic data suggest that the CO2 component is mantle-derived whereas the dominant H2O part is of meteoric origin and intensively interacted with the host granite.

In situ Fe isotope measurements in gabbros and basalts from the ocean crust

J. KOEPKE, G. STEINHOEFEL, J.A. SCHUESSLER, I. HORN, W. DZIONY AND R. BOTCHARNIKOV

Institut für Mineralogie, Leibniz Universität Hannover, Germany (koepke@mineralogie.uni-hannover.de)

Fe isotopes were measured in oxides and sulfides of gabbros and basalts drilled by IODP (Integrated Ocean Drilling Program) in recent oceans. Such studies may help to elucidate topics like state of equilibrium of the oxide/sulfide assemblages, temperature of formation, and imprint of seawater. We used the recently in Hannover developed LA-MC-ICPMS system consisting of a femtosecond laser and a multiple collector inductively coupled plasma mass spectrometer. For the analytical and methodical techniques, we followed Horn et al. (2006).

The used gabbro was a ferrogabbro from the Southwest Indian Ridge (drill hole 735B) showing ore mineral assemblages consisting of MT (magnetite), ILM (ilmenite) and PYR (pyrrhotite). The textural features suggest equilibrium formation for these assemblages. A temperature of 950°C was estimated as temperature of formation of these ore assemblages, obtained by amphibole geothermometry. In-situ Fe isotope analyses were performed both in the core and rim of the grains. No zoning with respect to Fe isotopes was observed.

The measured δ56Fe values, the relative isotopic differences between the mineral phases, and the comparison with literature data and equilibrium fractionation factors derived from Mössbauer data (Polyakov and Mineev, 2000), respectively, suggest the following working hypothesis: Below 950°C, at temperatures while PYR was still open, and MT and ILM closed for iron isotope exchange, the rock was infiltrated by a seawater-derived hydrothermal fluid shifting the δ56Fe values of PYR to significant lighter values. The temperatures for this process must have been fairly high (e.g., > 700°C), since PYR and the other Fe-Ti oxides do not show any sign of typical low- or medium temperature alteration. This method opens interesting perspectives in order to shed light on late stage and alteration processes in oceanic gabbros. Further in-situ Fe isotope measurements in gabbros and in fresh and progressively altered basalts from the IODP Expedition 312 which drilled the basalt/gabbro transition in fast-spreading ocean crust are in progress.

Isotopic signatures of the Siberian flood basalts and alkaline magmatism of Polar Siberia (age, genetic link, heterogeneity of mantle sources)

N.L. KOGARKO1 AND R. ZARTMAN2

1Vernadsky Institute of Geochemistry, Moscow (kogarko@geokhi.ru)
2Dept. Cosmochemistry Max-Planck Institute for Chemistry (rzart@yahoo.com)

A close association between alkaline magmatism and continental flood basalts is observed worldwide. Nevertheless, the problem of a genetic link between the Siberian flood basalts (SFB) and the ultramafic-alkaline rocks of the Maimecha-Kotuy province in Polar Siberia is still being debated. The SFB with a volume of 1.6x10^6 km^3 occur in the northern part of the Siberian platform. The Putorana plateau, where about 90% of all the basaltic volcanism occurred, is situated in the center of the SFB province, and some authors consider the Putorana basalts to be representative of the Siberian plume itself.

The ultramafic-alkaline Maimecha-Kotuy comprises the world’s largest ultramafic-alkaline Guli massif, the ultramafic-alkaline-phoscorite Kugda complex, and 31 smaller ultramafic-alkaline intrusions.

A whole-rock U-Pb age of 250±9 Ma was determined for the Guli massif, which lies within the range of ages previously reported for the SFB. The combined Pb, Sr, and Nd isotopic systematics of the SFB and the Guli and Kugda alkaline rocks identify several discrete source components. The first component dominates many of the Guli rocks and is characterized by low ^87Sr/^86Sr (0.7031 to 0.7038), high (Nd (+5.35 to +3.97), and relatively unradiogenic Pb (206Pb/204Pb = 18.3, 207Pb/204Pb = 15.8-15.46; 208Pb/204Pb = 37.33-37.70), which we associate with the depleted (or MORB signature). The second component dominating the Putorana plateau, where about 90% of all the basaltic volcanism occurred, is situated in the center of the SFB province, and some authors consider the Putorana basalts to be representative of the Siberian plume itself.

The ultramafic-alkaline Maimecha-Kotuy comprises the world’s largest ultramafic-alkaline Guli massif, the ultramafic-alkaline-phoscorite Kugda complex, and 31 smaller ultramafic-alkaline intrusions.

In situ detection of highly siderophile element micronuggets in peridotite by synchrotron radiation X-ray fluorescence mapping

T. KOGISO1, K. SUZUKI1, T. SUZUKI1, K. SHINOTSUKA1, K. UESUGI2, A. TAKEUCHI2 AND Y. SUZUKI2

1Institute for Reseach on Earth Evolution (IFREE), Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan (kogisot@jamstec.go.jp)
2Japan Synchrotron Radiation Research Institute (JASRI), Sayo, Hyogo, Japan

Abundances of highly siderophile elements (HSEs) in the Earth's mantle are key indices for understanding the Earth's formation processes and subsequent chemical evolution of the mantle. However, estimation of the primordial HSE abundances in the mantle from HSE concentrations in present-day peridotite samples is not straightforward, because the residence of HSEs in peridotite has not been well constrained. Sulfide minerals can account for whole-rock HSE abundances in some peridotite samples (e.g., Alard et al., 2000), but the existence of micrometer-scale HSE nuggets (e.g., Luguet et al., 2003; Lorand et al., 2006) implies that such HSE micronuggets could also influence the behavior of HSEs in the mantle. We report in situ discovery of HSE micronuggets from peridotite by microbeam X-ray fluorescence mapping using synchrotron radiation X-ray at SPring-8, Japan. We found a few grains of HSE micronuggets (1~10 µm in maximum dimension) included in single sulfide grains in an orogenic lherzolite from Horoman peridotite complex, Japan. Only two of sixteen sulfide grains investigated contain the HSE micronuggets, indicating strongly heterogeneous distribution of HSEs between sulfide grains. Pt-rich and Os-Ir-rich micronuggets were included in both of the two sulfide grains. HSE concentrations within sulfides themselves were below detection limits. These results suggest that distributions of HSEs within peridotite are strongly controlled by HSE micronuggets. We interpret that the coexistence of Pt-rich and Os-Ir-rich micronuggets and the strong heterogeneity of HSE distributions are not fully attributed to secondary processes such as metasomatism but are at least partly of primary signature in the uppermost mantle. Thus, HSE micronuggets may play a significant role in controlling HSE abundances in the mantle. It is essential to reveal the origin of HSE micronuggets and their spatial distribution in the mantle for understanding the HSE behavior in the mantle.

Nd and Sr isotopic characteristics of NE Aegean Ophiolites, Greece

N. Koglin1,2, T. Reischmann2 and D. Kostopoulos3

1Institut für Geowissenschaften, Johannes Gutenberg-Universität, Mainz, Germany (koglin@uni-mainz.de)
2Max-Planck-Institut für Chemie, Mainz, Germany (treisch@mpch-mainz.mpg.de)
3National and Kapodistrian University of Athens, Greece (dikostop@geol.uoa.gr)

In this study we report on the isotopic characteristics of ophiolitic complexes located in the northeastern Aegean region. These complexes are, from north to south, the Evros and Samothraki ophiolites, commonly considered as part of the Circum-Rhodope Belt (e.g. Kauffmann et al. 1976) and the Lesvos ophiolite, which forms the western continuation of the Karakaya Complex (W Turkey) (e.g. Koglin et al. 2007).

The Evros ophiolite comprises the typical characteristics of an ophiolite suite, namely mantle peridotites, gabbros, sheeted dykes and basaltic extrusives. The ophiolite of Samothraki is built up of gabbros intruded by dolerite dykes, diorites, sheeted dykes, and massive and pillow lavas. The Lesvos ophiolite consists of mafic extrusives, ultramafic rocks with an amphibolitic sole at their base and an ophiolitic mélange. This mélange consists of gabbros, massive basaltic flows, pillow basalts, marbles, phyllites and greenschists.

The Middle to Late Jurassic Evros and Samothraki ophiolites (SHRIMP zircon ages, Koglin et al. 2007) show supra-subduction zone geochemical characteristics. The latest Permian ophiolitic rocks of the mélange indicate an OIB source influence, while the basalts of Vatera, S Lesvos, display a geochemical signature of mid-ocean ridge affinity (Koglin et al. 2007).

The basalts and most of the gabbros of the Evros ophiolite have εNd160 values between +2.9 and +7.7 with a mean of +5. Their 87Sr/86Sr160 ratios range from 0.7037 to 0.7052. The Samothraki mafic rocks have εNd160 from +3.8 to +7.2, mostly clustering around +5. Their 87Sr/86Sr160 ratios range between 0.7034 and 0.7058. The εNd253 of the Lesvos ophiolite mafic rocks vary from +3.8 to +6.4 with a mean of +5.5. Their 87Sr/86Sr253 is between 0.7043 and 0.7051.

For the Evros and Samothraki ophiolites the isotopic data indicate a depleted mantle source with a subduction-zone influence. This is concordant with the observed enrichment in Th and other LILE compared to MORB. The isotopic data for the Lesvos ophiolite are similar to those of Evros and Samothraki. However, the subduction-zone input is less pronounced and an additional OIB component has to be considered.

Low temperature thermochronology of Phanerozoic kimberlites and Archaean basement, Slave Province, Canada

F. KOHLMANN1, B.P. KOHN1, A.J.W. GLEADOW1 AND K.G. OSADETZ2

1School of Earth Sciences, University of Melbourne, Vic. 3010, Australia (f.kohlmann@pgrad.unimelb.edu.au)
2Geological Survey of Canada, Calgary, Alberta T2L 2A7, Canada

In an effort to investigate the burial history of the Slave craton, NW Territories, Canada we report the first results of a low temperature thermochronology study applying apatite fission track and (U-Th)/He methods, from the Ekati (45-61 Ma), and the Jericho and Muskox (172-175 Ma) kimberlite pipes (including their crater facies sediments, and sedimentary and basement xenoliths) and their host Archaean granitic basement (2.71-2.58 Ga).

Previous vitrinite reflectance data (%Ro 0.24-0.42) and porosity analysis from unaltered shale xenoliths in the Eocene pipes of the Lac de Gras diamond field (including the Ekati pipes), suggest a maximum burial temperature of 60°C for mid Cretaceous strata with 1.2 to 1.4 km sedimentary cover in the Lac de Gras kimberlite field region prior to major uplift and erosion, which began around 90 Ma [1]. The nearest Paleozoic sediments are preserved more than 400 km southwest of the kimberlite fields in the foothills of the Mackenzie Mountains where they are typically 1-2 km thick.

Our data are used to obtain improved constraints on the thermal history of the Slave craton and provide more precise estimates on its denudation history. This will lead to new insights for assessing the long-term stability of continental interiors in relation to subtle sedimentation and denudation patterns, which may be related to dynamic topography driven by mantle convection and far-field tectonism.

Petrological Characteristics and LA-SF-ICP-MS U-Pb ages of S-type Granitoids from Central Turkey

SERHAT KÖKSAL1, ANDREAS MÖLLER2, DIRK FREI3, M.CEMAL GÖNCÜOGLU4 AND FATMA TOKSOY-KÖKSAL4

1Middle East Technical University, Central Laboratory, Radiogenic Isotope Laboratory, Ankara, Turkey (skoksal@metu.edu.tr)
2University of Potsdam, Department of Geosciences, Potsdam, Germany (amoeller@geo.uni-potsdam.de)
3Ministry of the Environment, Geological Survey of Denmark and Greenland, Department of Geological Mapping, Copenhagen K, Denmark (df@geus.dk)
4Middle East Technical University, Department of Geological Engineering, Ankara, Turkey (mcgoncu@metu.edu.tr; ftkoksal@metu.edu.tr)

The S-type Sinandi microgranite (SMG) and the Namlikisla biotite-granite (NBG) (Aksaray-central Turkey) intrude metamorphic basement rocks and gabbroic rocks of an ophiolitic sequence and is itself cut by I-type granitoids. SMG and NBG consist of orthoclase, quartz, plagioclase, biotite, muscovite ± hornblende ± pyroxene and accessory zircon, titanite, epidote, apatite and opaque minerals. They have calc-alkaline peraluminous character, LILE and LREE enrichment, low Ce, Zr, Hf, Sm contents and pronounced Eu-anomalies (0.63 and 0.59, respectively). SMG and NBG display a crustal isotopic signature with high initial 87Sr/86Sr ratios (0.712827 and 0.715168, respectively) and low εNd values (-9.1 and -9.7, respectively).

Based on zircon typology method (Pupin, 1980) zircon populations from both granitoids are described by low to moderate A and T indexes, typical aspect for crustal originated granitoids. SMG has abundant S7-12-13-18 types and lesser amounts of S2-9-10-17-19-23-24 types, whereas the zircon population of NBG is represented by preferential development of S2-7-12 types besides S1-3-4-5-6-8-11-13-16 and L1-2-3-4-5 types in lesser percentage. Zircon crystals from SMG and NBG commonly contain rounded to subrounded inherited cores overgrown by oscillatory zones displaying intermittent resorption surfaces and some secondary structures such as recrystallization and flow domains.

Rims and outer zones of zircons from SMG give a LA-SF-ICP-MS mean 206Pb/238U age of 81.5±0.84 Ma (2σ), while those of NBG yield 83.8±0.95 Ma (2σ). Ages of inherited cores range from 526 Ma to 1566 Ma for SMG, and from 144 Ma to 2304 Ma for NBG.

Consequently we suggest that Late Cretaceous S-type SMG and NBG were formed as a result of Alpine collisional magmatism during closure of the northern branch of the Neotethys Ocean. However, wide range of ages indicating cryptic igneous events were recorded. Moreover xenocrystic inherited zircon cores represent a variety of sources including the Proterozoic crust.

Platinum Group Element contents of the Kop Chromitites and its possible sources, (NE Turkey)

H. Kolayli1, M. Arslan1 and E. Ciftci2

1Geology Department, Karadeniz Technical University, 61080 Trabzon, Turkey (hkolayli@ktu.edu.tr)
2Geology Department, Nigde University, Turkey

The average contents of PGE in the chromitites from the Kop ultramafics are Os: 43.6, Ir: 39.5, Ru: 74.4, Rh: 8.7, Pt: 38.6, and Pd: 35.4 ppb. Chondrite-normalized PGE distribution patterns of all chromitites reveal a negative trend from Ir to Pd. The PGEs are sensitive to the degree of partial melting of source regions and the S-saturation status of resultant magma. Chondrite normalized PGE patterns range from nearly unfractionated in the chromitites (Pd/Ir=0.09-4.18) from the Kop ultramafics. Total PGE content of the chromitites range from 93-710 ppb.

Crystallization of orbicular rocks from Camlikaya, NE Turkey

H. Kolayli1, M. Arslan1, A. Lindh2 and E. Ciftci3

1Geology Department, Karadeniz Technical University, 61080 Trabzon, Turkey (hkolayli@ktu.edu.tr)
2Geology Department, Geocentre 2, Solvegatan 12, SE 22362 Lund, Sweden
3Geology Department, Nigde University, Turkey

Orbicular rocks crop out in a 25x100m size body in the granitic rocks at Camlikaya, NE Turkey. They have dioritic/gabbroic composition. The cores of the orbicules and the matrix between the orbicules have same mineralogical composition which may be crystallized from the orbicule-forming magma. The matrix and the cores of the orbicules are composed of pyroxene, hornblende, magnetite and andesine-labradorite and have poikilitic texture. Mafic cores are surrounded felsic shell composed of mainly plagioclase and perpendicular the core. After initial ‘normal’ crystallization of the magma, superheating probably triggered by a sudden addition of volatiles destroyed earlier formed nuclei and also affected the already crystallized part of the rock. Addition of felsic components and cooling causing plagioclase nucleation and rapid crystallization.

Fluid mixing at the depositional site of the Guelb Moghrein IOCG deposit, Mauritania

J. KOLB, S. PRANTL AND F.M. MEYER

Institute for Mineralogy and Economic Geology, RWTH Aachen University, Wüllnerstr. 2, 52056 Aachen, Germany; kolb@rwth-aachen.de

The Guelb Moghrein IOCG deposit is located 250 km northeast of Nouakchott, Mauritania. The mineralization is hosted by < 30 m wide tabular tectonic breccias in a carbonate-facies iron formation. It comprises Oam, Mag, Po, Ccp, Fe-Co-Ni arsenides, Apy, cobaltite, uraninite, and Bi-Au-Ag-Te minerals in a proximal ore breccia grading into a distal ore breccia with Oam and Mag. Hydrothermal monazite and xenotime were dated at 2492 ± 9 Ma.

Fluid inclusions were studied in siderite (Sd) of the iron formation. Three generations are discriminated: Sd1 is undeformed, locally idiomorphic and up to 5 cm in diameter. Sd2 represents variably sized, angular fragments with numerous sulfide inclusions. Sd3 is recrystallized carbonate. Two types of fluid inclusions are distinguished, which are interpreted to have formed contemporaneously: Type I are aqueous two-phase L-V inclusions, 6-10 µm in diameter that form trails in Sd1 and Sd2. They are spatially closely associated with the ore paragenesis. Type II inclusions are aqueous two- or three-phase (L-V, L-V-S) and form clusters and single inclusions in Sd2 and Sd3. They are up to 50 µm in diameter. Trapped sulfides are present if the cluster is intersected by a type I trail. The Te of both types show a wide scatter between -10°C and -80°C. The Te peaks are characteristic of NaCl-H2O and NaCl-MgCl2-H2O mixtures, where type I inclusions are NaCl-dominated and type II inclusions are MgCl2-dominated. The Cl- content ranges between 0-4.5 mole/kg Cl-. Th for types I and II inclusions have, both, a maximum at about 300°C.

Type I and II inclusions (1) occur on trails in brecciated Sd2 and/or in recrystallized Sd3, (2) they are spatially associated with sulfides, (3) sulfides are trapped in type II inclusions and (4) uniform Th is consistent with trapping at 410 ± 30°C and 1-2 kbar, which are the P-T conditions of mineralization. The variable salinity and composition, the uniform Th, and the paragenesis of both fluid inclusion types with the ore minerals point to isothermal fluid mixing at the depositional site as a mechanism for ore formation. A MgCl2-dominated fluid probably equilibrated with the Fe-Mg carbonate in the host rock and mixed with an externally derived NaCl-dominated fluid during progressive deformation.

The ore fluids at Guelb Moghrein have a relatively low salinity of < 20 wt.% NaCl, and lack a carbonic phase. This is unusual especially for magmatic IOCG deposits. The geological setting of Guelb Moghrein and the fluid composition suggests that this deposit formed in a metamorphic setting by fluid mixing during regional-scale thrusting.

Iron enrichments in salt marshes of NW Germany

K. KOLDITZ1, J. BARKOWSKI2, O. DELLIWIG1,3, H. FREUND2 AND H.-J. BRUMSACK1

1ICBM, Oldenburg, Germany, (kolditz@icbm.de), (brumsack@icbm.de)
2ICBM Marine laboratory, Wilhelmshaven, Germany, (Jan.Barkowski@icbm.terramare.de; Holger.Freund@icbm.terramare.de)
3IOW, Rostock, Germany, (olaf.dellwig@io-warmemuende.de)

Salt marshes are a major, widely distributed, intertidal landscape. The salt marshes of the summer polder area of the East Frisian barrier island Langeoog (NW Germany) were protected by a summer dike until 2004. In 2004 this dike was removed and rebuilt toward centre of the island. Thus the Langeoog summer polder is afresh under tidal influence and the opportunity was given to investigate the effects of a simulated sea level rise on pore water geochemistry.

For in situ sampling four pore water samplers (Beck et al. 2007) were installed in the salt marsh sediments. These lances are aligned on a N-S transect including sites at high salt marsh, low salt marsh and transition zone low salt marsh/tidal flat. Pore water sampling started in June 2005 and samples were taken in monthly intervals.

Iron enrichments in pore water were observed at all different salt marsh sites. The transition zone low salt marsh/tidal flat is characterized by high iron concentrations up to 373 µM at 0.5 m depth. In contrast, at the low marsh site iron enrichments were observed in greater depths. We found iron concentrations of 588 µM at 1.25 m, 328 µM at 2.5 m and 633 µM at 5 m depth. Further, there is an increase of iron concentration with increasing depth at the high marsh site. In addition to this general trend, distinct iron enrichments of 285 µM at 2.5 m and 325 µM at 4 m depth were observed.

These high iron concentrations in salt marsh pore waters likely result from reduction of their corresponding oxides and partly coincide with sediment lithology. Portnoy & Giblin (1997) described implications of seawater flooding on salt marshes after decades of diking. Amongst others this could mobilize a large pulse of iron (II). The extreme iron enrichments at this marine-terrestrial transition could provide an indication of pyrite enrichments within Holocene coastal deposits.

Melt inclusions from the Galápagos plume: Mirrors and mirages of the deep

A.M. Koleszar1, A.E. Saal1, E. H. Haury2 and M.D. Kurz3

1Dept. of Geological Sciences, Brown University, Providence RI 02912, USA
2Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015, USA
3Dept. of Marine Chemistry & Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA

Melt inclusions provide an advantage over erupted magmas because they are samples of very small amounts of melt commonly trapped at pressures exceeding the pressure of eruption, and their chemical compositions have remained unchanged since entrapment. Thus, melt inclusions are an invaluable tool to characterize the composition of pre-aggregated lavas prior to differentiation and mixing in magma chambers, and to determine the pre-eruptive volatile contents of basalts. However, there are two serious disadvantages to using melt inclusions to evaluate mantle melting processes: 1) the composition of melt inclusions can reflect localized, grainscale, wall-rock reaction processes within the shallow magmatic plumbing system, and 2) the host crystal may not effectively isolate the inclusion as a closed system (e.g., preventing H2O diffusion).

We have analysed major, trace element, and volatile contents in more than 100 olivine-hosted (Fo81-87) melt inclusions in submarine and subaerial lavas from the Galapagos Islands. Our results indicate that enriched and ultra-depleted melt compositions coexist in the magmatic plumbing system beneath Galapagos volcanoes. Furthermore, the trace element compositional variations found in melt inclusions from a single sample reproduce the total geochemical variation defined by the whole rock data for the Galapagos lavas. Establishing the processes responsible for such variations will therefore have direct implications on the origin of the compositional variation of basalts throughout the Archipelago. Our new volatile data provide limits on the concentration of CO2, H2O, F, S, and Cl for the high 3He/4He and depleted mantle components beneath the Archipelago. The CO2- H2O data give an entrapment pressure of ~1 kbar, corresponding to a depth of ~3 km. A subgroup of inclusions is characterized by significant depletion in incompatible trace elements with unusual (Sr/Nd)PM and (Ba/Th)PM ratios greater than unity, suggesting the interaction of melts with a plagioclase-rich cumulate during melt percolation within the oceanic lithosphere. The volatile data for these inclusions suggest that a) the interaction of melt with lithospheric gabbros decreases the S and Cl content of the melt, and b) the H2O and F content in these inclusions have been modified by open system behavior due to diffusion of H and F through the olivine host.

Mercury, trace elements, and organic constituents: A combined approach to sampling atmospheric particulate matter (PM)

Allan Kolker1, M.A. Engle1, W. H. Orem1, J.E. Bunnell1, H.E. Lerch1, D. P. Krabbenhoft2, M.L. Olson2 and J. D. McCord3

1U.S. Geological Survey, Eastern Energy Resources Team, Reston, VA 20192, USA (akolker@usgs.gov)
2U.S. Geological Survey, Water Resources Discipline, Middleton, WI 53562-3581, USA
3U.S. Geological Survey, Central Energy Resources Team, Denver, CO, 80225, USA

Compliance with USA air quality PM regulatory standards (PM10 and PM2.5) is based on meeting average 24-hour and yearly mass-per-unit-volume limits, regardless of PM composition. In the present work, we combine filter-based sampling of particulate-bound mercury, trace elements, and organic constituents to determine compositional variation of atmospheric aerosols in three contrasting environments in the USA, and assess potential human health impacts.

Along the U.S. Gulf of Mexico coast, Hg wet deposition is especially elevated. PM sampling conducted together with a mobile lab Hg speciation unit shows a significant portion of particulate Hg bound to particles larger than 2.5 µm, including sea-salt aerosols derived from marine air masses. Mercury speciation results show a diel pattern of photochemical Hg oxidation. Adsorption of oxidized and elemental Hg on NaCl aerosols increases Hg available for deposition in this Hg-sensitive coastal ecosystem.

At an inland suburban site in the eastern USA, trace element enrichment factors in PM2.5 show elevated ratios of Se, Sb, Ag, Bi, Cd, Mo, Pb, Zn, and Tl, vs. Zr (crustal affinity), compared to crustal abundance ratios of these elements, suggesting influence from industrial, transportation, and fossil fuel combustion sources.

Studies in the Navajo Nation of New Mexico focus on human exposure to domestic coal combustion, shown to be correlated with the incidence of respiratory difficulties. Extractable organic compounds in PM2.5 include abundant alkanes and low abundances of various polycyclic aromatic hydrocarbons (PAHs). The predominance of low molecular weight alkyl-substituted PAHs is indicative of a coal source.
Thermodynamic modeling of REE fractionation during the interaction of monazite with chloride-carbonate fluid

G.R. KOLONIN AND G.P. SHIRONOSOVA
Institute of Geology and Mineralogy of Siberian branch RAS
Novosibirsk, 630090, Russia (kolon@uiggm.nsc.ru)

Monazite is the most abundant REE mineral, which forms in various geochemical conditions including rare metal deposits of hydrothermal and metamorphogenetic type. Besides, lanthanide-actinide phosphate matrixes are very perspective for radioactive waste disposal. It is worth to reveal the trends of REE fractionation depending on physical-chemical conditions of fluid/monazite interaction.

The thermodynamic data base for lanthanide phosphates of Vieillard and Tardy (1984) as well as SUPCRT98 for aqueous species were used. A model of ideal solid solution for (Ce,La,Nd,Eu)-monazite was calculated as a first step for the following numerical experiments. The behavior of xenotime in the modeling system was used to compare the leaching ability of Y-HREE group with the LREE one. Two type of initial modeling fluid containing 4.0m NaCl + 1,5m H\text{2}CO\text{3} were under attentions: acid (pH = 3.1 because of 0.1m HCl addition) and alkaline (pH = 7.3 because of 0.1m KOH addition). The following particular tasks were tested: 1) the estimation of a possible selective solubility of some LREE+Y as compared to each other during the cooling of the chloride-carbonate fluid within the 500 - 100 °C interval; 2) the calculation of the influence of fluid/REE phosphate solid phase ratio (within 10\text{−}4 – 10\text{4} interval) on possible correlations between various LREE+Y in solid phases after “leaching”.

The principal results under discussion: 1) in the acid fluid, expected concentrations of La-, Ce- and Nd are higher by two order of magnitude as compared with the alkaline one; 2) the Eu-minal of monazite demonstrates the anomalous high solubility at elevated temperatures; 3) the solubility of xenotime minal is lower by two orders of magnitude as compared with the monazite one; 4) at low ratios of fluid/REE-phosphate intensive leaching of EuPO\text{4} with the following leaching of (La, Ce, Nd)PO\text{4} takes place with leaching of YPO\text{4} at the last stage of the process only.

Extensive set of new ICP-MS and XRF-SI data about REE patterns in natural monazites will be used for verification of thermodynamic models under development.

The work is supported by RFBR, grant N 07-05-00404.

Decoupling photochemical Fe(II) oxidation from shallow-water BIF deposition

KURT KONHAUSER\textsuperscript{1}, STEFAN LALONDE\textsuperscript{1}, LARRY AMSKOLD\textsuperscript{1}, NICOLE POSTH\textsuperscript{2}, ANDREAS KAPPLER\textsuperscript{2} AND ARIEL ANBAR\textsuperscript{3}

\textsuperscript{1}Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, Canada T6G 2E3 (kurtk@ualberta.ca)
\textsuperscript{2}Center for Applied Geosciences, University of Tuebingen, 72076 Tuebingen, Germany
\textsuperscript{3}School of Earth & Space Exploration, Arizona State University, Tempe, Arizona, USA, 85287-1404

Oxidized Fe minerals in Archean-Paleoproterozoic banded iron formations (BIFs) are commonly taken to indicate the presence of biogenic O\textsubscript{2} or photosynthetic Fe(II)-oxidizing bacteria in the oceans’ photic zone. However, prior to the rise of atmospheric oxygen and the development of a protective ozone layer, the Earth’s surface was subjected to high levels of ultraviolet radiation. Bulk ocean waters that were anoxic at this time could have supported high concentrations of dissolved Fe(II). Under such conditions, Fe(OH\textsuperscript{3})\textsuperscript{+} would have absorbed radiation in the 200-400 nm range, leading to the formation of dissolved ferric iron [Fe(III)], which in turn, would have hydrolyzed to form ferric hydroxide [Fe(OH\textsubscript{3})\textsuperscript{−}] at circumneutral pH. We evaluated the relative importance of photochemical oxidation using experiments that simulated the chemistry of ambient Precambrian seawater mixing with Fe(II)-rich hydrothermal fluids with, and without, UV irradiation. We found that if Fe(II) was effused from relatively shallow seamount-type vent systems directly into an anoxic photic zone, the photochemical contribution to solid-phase precipitation would have been negligible. Instead, most of the Fe(II) would have precipitated rapidly as an amorphous precursor phase to greenalite and/or siderite, depending on different simulated atmospheric pCO\textsubscript{2} levels. Conversely, in experiments where Fe(II) was exposed either to phototrophic Fe(II)-oxidizing bacteria or to O\textsubscript{2}, ferric hydroxide formed rapidly, and the precipitation of ferrous iron phases was not observed. If, as suggested on mass balance grounds, BIF deposition requires that Fe be sourced from shallow seamount-type systems, then we are driven to conclude that oxide-facies BIF are the product of a rapid, non-photochemical oxidative process, the most likely candidates being direct or indirect biogenic oxidation.
New insights into the geochemical behaviour of W by high precision isotope dilution measurements

STEPHAN KÖNIG1,2, CARSTEN MÜNKER1,2 AND STEPHAN SCHUTH1,2

1Universität Bonn, Germany (wayangkulit@web.de)
2Universität Münster, Germany

The geochemical behaviour of W during silicate Earth differentiation is only poorly constrained, largely due to its low abundance that makes high precision measurements difficult. Previous results (e.g., [1]) indicate a lower W/Th of the mantle (ca. 0.19) compared to the Earth’s crust, (ca. 0.26), suggesting that W appears to be more incompatible than Th. New data for MORB [2], however, demonstrate that W/Th is not significantly fractionated during dry peridotite melting, rather suggesting a fractionation of the two elements during crust formation by subduction related processes.

In order to assess the geochemical behaviour of W closer, we determined concentrations of W together with those of other high field strength elements by isotope dilution, using a mixed 183W-180Ta-242Zr-180Hf-176Lu tracer and multiple collector inductively coupled plasma mass spectrometry (MC-ICPMS). In contrast to concentrations of other HFSE, which typically can be reproduced to within ±1%, W concentrations obtained for replicates display a larger scatter, ranging up to a few percent. The external reproducibility obtained for W concentrations (typically 3-4% 2σ) appears to depend on petrological properties, suggesting an influence of sample heterogeneity effects. For the BHVO-2 standard, significant variations in both Ta and W concentrations can be observed between multiple analyses. However, whereas measured W concentrations display large variations (200 – 350 ppb), Ta/W ratios (4.96-5.16) still yield an external reproducibility of ±4% (2σ). Altogether, our results confirm a similar compatibility of Th-W and Ta that is also reported for variably depleted MORBs [2], where measured Ta/W ratios only range from 4 – 6.

First Ta-W abundances determined in basaltic glasses and whole rock powders from various island arc settings display Ta/W ratios of 0.6 – 1.7, significantly lower than the values reported for MORB. These systematic differences indicate a higher mobility of W relative to Ta in subduction related processes, which possibly causes the selective W enrichment in the continental crust.

The speciation of carbon dioxide in silicate melts from in situ infrared measurements

ALEXANDER KONSCHAK AND HANS KEPPLER
Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
(Alexander.Konschak@uni-bayreuth.de, Hans.Keppler@uni-bayreuth.de)

Carbon dioxide may dissolve in silicate melts either as molecular CO$_2$ or as carbonate. The ratio of the two species strongly depends on composition. While molecular CO$_2$ predominates in silica-rich, polymerized glasses, only carbonate can be detected in depolymerized basaltic glasses. However, the diffusion coefficient of CO$_2$ in rhyolitic and basaltic melts is nearly the same at identical temperatures, despite the fact that CO$_2$ speciation in the quenched glasses is very different. This suggests that the speciation observed in quenched glasses may not be representative for CO$_2$ speciation in silicate melts.

In order to determine CO$_2$ speciation directly in the silicate melt, we measured the infrared absorption spectra of silicate melts inside an externally heated diamond cell to more than 1000 °C. Samples include an alkali silicate melt with a degree of polymerization similar to a basalt and a dacite melt. Type II a diamonds of reduced thickness were used to minimize absorption due to the anvils. Measurements to about 700 °C were carried out using a globar source, experiments at higher temperature were carried out at the ANKA synchrotron source in Karlsruhe.

Only carbonate was observed in the alkali silicate melt to the highest temperatures studied. In the dacite melt, molecular CO$_2$ and carbonate were found to coexist in the melt. The quantification of speciation was complicated by the fact that the extinction coefficients of both molecular CO$_2$ and of carbonate were found to significantly decrease with temperature. This effect can be attributed to the changes in the population level of the vibrational states with temperature.

The high-PT stability of apatite: Constraints on transport and storage of phosphorus and halogens in the Earth’s upper mantle

JÜRGEN KONZETT$^1$ AND DANIEL J. FROST$^2$

1Institut für Mineralogie und Petrographie, Universität Innsbruck, Innrain 52, A-6020 Innsbruck, Austria (juergen.konzett@uibk.ac.at)
2Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (dan.frost@uni-bayreuth.de)

High-PT experiments were performed in a range 3-15 GPa and 850-1450°C in order to constrain the stability field of OH- and Cl-apatite and to study the partitioning of phosphorus between apatite or its high-P breakdown-product and the coexisting phases. The following starting materials were used: (1) an average MORB, (2) an Fe-free simplified MORB equivalent in the system SiO$_2$-Al$_2$O$_3$-MgO-CaO-Na$_2$O-TiO$_2$ and (3) a fertile lherzolite. The starting materials were doped with 3% synthetic OH-apatite or Cl-apatite and with a trace element mix. In the average MORB, OH-apatite is stable to 7 GPa/950°C coexisting with grt + cpx + SiO$_2$ + TiO$_2$. From 7.5-11 GPa and 950-1200°C, OH-apatite is replaced by tuite (γ-Ca$_3$(PO$_4$)$_2$ [1]) coexisting with the same assemblage. At higher P and T, no phosphate-phase was found due to increasing partitioning of phosphorus into coexisting grt or grt + melt. The P$_2$O$_5$-concentration in grt buffered by apatite, tuite or quenched melt is between 0.2-0.3 wt% but rises to 0.6-0.8 wt% in the absence of a phosphate-phase. Compared to MORB, the lherzolite system shows notable differences in the stability of phosphate-phases and in the P$_2$O$_5$-concentration of coexisting silicates. Apatite is stable to slightly higher pressures of ≥7.5 GPa/≥1000°C and was found to coexist with tuite at 8.5 GPa/1000°C in an assemblage ol + cpx + cpx + grt. In addition, apatite in the lherzolite incorporates significant amounts of Mg and Fe, reaching a total of 4.0 wt% at 8.5 GPa. This may be a reason for its increased P-stability in bulk (3). By comparison, (MgO+FeO) in eclogitic apatite does not exceed 1.0 wt% at 7.0 GPa. In coexisting apatite and tuite, the latter strongly partitions Sr and REE. The P$_2$O$_5$-concentration in lherzolitic grt is always higher than in MORB-grt, ranging from 0.7 wt% at 6 GPa/1100°C coexisting with apatite to 1.9 wt% at 13 GPa/1200°C in the absence of a phosphate-phase. The results of this study show that apatite in both MORB and lherzolitic bulks has a much smaller PT-stability field than previously assumed [1] and, consequently, that halogens cannot be transported and stored in apatite to depths > approx. 250 km.

Distribution of environmentally significant trace elements of the Tertiary bituminous shale deposits in NW Anatolia, Turkey

SADETTIN KORKMAZ AND REYHAN KARA GÜLBAY
Karadeniz Technical University, Department of Geological Engineering, Trabzon/ Turkey (korkmaz@ktu.edu.tr; kara@ktu.edu.tr)

There are 1.6 billion tones of bituminous shale reserve in 6 different fields in NW Anatolia, Turkey. In this study, environmental element concentrations (As, Cd, Cr, Cu, Hg, Mn, Pb and Zn) and enrichment factors of bituminous shales and element-organic matter relations were investigated and characteristics of fields were compared.

The maximum and minimum concentrations of environmental elements are As: 3.16-55.58 µg/g, Cd: 0.06-0.22 µg/g, Cr: 8.69-114.14 µg/g, Cu: 18.69-38.67 µg/g, Mn: 401.13-1451.50 µg/g, Pb: 4.62-16.32 µg/g, Zn: 23.93-50.02 µg/g and Hg: 17.33-77.07 ng/g. With enrichment factors (EF) less than one, Cr, Hg and Pb concentrations of the Bahçecik field and Hg contents of the Gölpazar field are depleted with respect to average shale values while other elements are enriched. In general, Hg shows the least enrichment and the highest enrichment was calculated for As. The highest and lowest enrichments for As were found in the Hatıldag (EF=35.28) and Bahçecik (EF=1.01) fields, respectively. In general, all elements are highly abundant in the Beypazar and Seyitömer fields and they have low concentrations in the Himmetoğlu, Bahçecik and Gölpazar (except for As) fields.

It was determined that the average Cd, Cu, Pb, Zn and Mn concentrations in all the fields are below the critical levels proposed for the soil (however, manganese concentration of the Bahçecik field is very close to the critical value). As concentrations in the Hatıldag and Gölpazar fields, Cr concentrations in the Hatıldag, Gölpazar and Seyitömer fields and Hg concentrations in the Himmetoğlu, Hatıldag and Seyitömer fields are higher than critical soil levels. A positive correlation between total organic carbon (TOC)-As and TOC-Pb at a significance of p≤0.01 and 0.05 was found in none of the fields. A positive correlation at significance of p≤0.05 was observed for TOC content with Cd in four of the fields, with Cu in two fields and with Cr, Mn and Zn in only one field.

40Ar-39Ar dating of mineral separates of shergottite Dhofar 019

E.V. KOROCHANTSEVA1,2, A.I. BIUKIN1,2, J. HOPP1, A.V. KOROCHANTSEV2 AND M. TRIELOFF1

1Mineralogisches Institut Universität Heidelberg, Heidelberg, Germany (trieloff@min.uni-heidelberg.de)
2Vernadsky Institute of Russian Academy of Sciences, Moscow, Russia

40Ar-39Ar thermochronology of SNC-meteorites yields insights into the thermal history, crystallization and cratering events of the martian lithosphere. We applied high-resolution 40Ar-39Ar dating to the olivine-phryic shergottite Dhofar 019 (whole rock, mineral separates). The intermediate/high temperature extractions of Dhofar 019 maskelynite, pyroxene and olivine separates suggest trapped argon with 40Ar/39Ar=300-400. Corrected age spectra show plateaus with similar ages of 642±72 Ma for maskelynite (~91% 39Ar release) and 603±96 Ma for pyroxene (~60% 39Ar release), the latter separate being dominated by maskelynite impurities. These ages are compatible with Sm-Nd and Rb-Sr ages [1]. In the olivine separate, the melt inclusions within olivine megacrysts [2] control the age spectrum. After correction for trapped argon, the extractions releasing 26-81% 39Ar display an age of 1086±252 Ma. This age could date the entrapment of a magmatic liquid during crystallization. On the other hand, the higher age of the olivine separate compared to maskelynite could be caused by incomplete degassing during shock metamorphism. 38Ar CRE ages determined from stepwise release age spectra of Dhofar 019 pyroxene and maskelynite are highly concordant with an average age of 15.7±1.1 Ma.

The young Rb-Sr/Sm-Nd and Ar-Ar ages of shergottites were usually regarded as crystallization ages [3]. Currently, there are strong debates about the interpretation of young Rb-Sr/Sm-Nd and Ar-Ar ages for shergottites, envisaging much older crystallization ages [e.g., 4, 5]. Although shergottites are severe shocked rocks, Rh-Sr, Sm-Nd and Ar-Ar chronometers cannot suffer a major reset by mere shock effects, e.g. conversion of feldspar to maskelynite causes only minor 40Ar loss [5]. Complete reset by 40Ar would require much stronger local shock wave effects (e.g., melt formation as observed for L chondrites [6]) or substantial accompanying heating effects (e.g., impact melt sheet covering, as could be the case for eucrites [7]).

High-temperature Raman spectroscopy and thermodynamic modelling of silicate melts, based on the problem-oriented database
“Thermo-melt”
O.N. Koroleva¹, V.N. Bykov¹, A.A. Osipov¹ and I.L. Khodakovsky²

¹Institute of mineralogy UrB RAS, Miass, Russia (koroleva@mineralogy.ru)
²Dubna International University of Nature, Society and Man, Dubna, Russia (igor-kho@yandex.ru)

The work is devoted to theoretical and experimental researches of a structure of silicate melts M₂O-SiO₂, where M - Li, Na, K. The thermodynamic model of silicate melts, founded on spectroscopic data about their real structure was used. As a basis to construction of model the approach elaborated for oxide glasses in work [1] was applied. But as against the given approach the standard Gibb's free energy is expressed through the sum on Qₙ-structural units of a silicate melt. Search of a minimum of free energy of system is carried out by the decision of the system of equations of mass balance of the components and the law of mass action for all reactions proceeding in system.

For the definition of thermodynamic characteristics of these structural units data of silicones were used as initial parameters which have been received for the given systems at the project on creation of the database «Thermo-Melt». At the first stage, the collecting of bibliographic information for anhydrous crystal silicones and their glasses formed in systems O-Si-Me (where Me = Li, Na, K, Rb, Cs) is carried out and files of the literary data are created. The evaluation of the experimental thermodynamic information for the substances formed in considered chemical systems is carried out. Standard values of entropy, enthalpy and standard Gibb's free energy of silicates of alkaline metals are recommended. The new equations for the temperature dependences of the heat capacity of these substances are obtained.

For the testing the model and definition of Qⁿ-distribution of structural units experimental quantitative investigation of structure of lithium, sodium and potassium silicate melts were carried out by high-temperature Raman spectroscopy [2]. It is shown, that experimental values of concentration of structural units for these silicate melts and glasses are in a good agreement with the model. It is established that the temperature dependence of Qⁿ-distribution in the system Li₂O-SiO₂ differs from the dependence of Qⁿ-distribution in sodium and potassium silicate melts.

Boron isotopes of K-tourmaline from the Kokchetav UHP massif
A.V. Korsakov¹, H.R. Marschall² and O.A. Kozmenko¹

¹Institute of Geology and Mineralogy SB RAS, Novosibirsk (korsakov@uiggm.nsc.ru)
²Department of Earth Sciences, University of Bristol, UK

Recently, high-K tourmaline (Tur; 2.76 wt% K₂O) co-existing with microdiamond was discovered in quartzofeldspathic rocks from Kumdyl-kol in the Kokchetav UHP massif, northern Kazakhstan [1]. The sample investigated in our study from the same locality is dominated by quartz, K-feldspar and Tur (~10 vol%), with minor titanite, phengite, chlorite, zircon, biotite, apatite, graphite and sulphide. Mineral assemblages preserved as inclusions in zircon consist of garnet, phengite and coesite. Despite an extensive search, no Tur inclusion was identified in ultrahigh-pressure (UHP) minerals (e.g. zircon, garnet, K₂O-bearing clinopyroxene). Furthermore, numerous quartz grains, but no coesite or microdiamond was identified as inclusions in Tur in our sample. We therefore interpret K-Tur in our sample to have formed under retrograde P conditions in the quartz stability field. The chemical compositions of Tur, however, is similar to the Tur for which [1] reported microdiamond inclusions.

Tur in the Kumdyl-kol sample is a K-analogue of dravite (0.35 Na pfu; Mg#: ~87) with remarkable contents of tetrahedral B (~3.3 B pfu) and Ca (~0.3 pfu), K₂O contents are as high as 1.57 wt % (~0.3 K pfu). The Tur displays a very low X-site vacancy (~0.05) and high OH (~3.4 pfu) and F (0.27 pfu) contents. At their rims and along cracks, all Tur grains show a strong decrease in K content to less than 0.05 wt%, accompanied by an increase in Na (~0.5 pfu), in X-site vacancies (0.2 to 0.3 pfu), and a slight increase in Al. All other elements are unzoned.

Tur cores are homogeneous in B isotopes (δ¹¹B = +10.6 ‰; analysed by SIMS in Heidelberg, Germany). Towards the rims, δ¹¹B values decrease to +5.5 ‰. These values are significantly higher than values reported previously for Tur from metasedimentary rocks or any (U)HP rocks (typically ~10 ‰). Heavy-B Tur (δ¹¹B > +5 ‰) has been described only from metapelitic-marble contacts [2,3], from partially melted granulites [2], from evaporites, and from hydrous reaction zones around HP metamorphic blocks formed by an influx of external hydrous fluids [4].

Hence, the high modal proportion of heavy-B Tur in the Kokchetav samples is best explained by a post-peak pressure influx of B-rich fluids or melts generated in biogenic-chemical sediments, i.e. carbonates or meta-evaporites.

Historical carbonate mortar and plaster – Proxies for ancient environments

B. Kosednar-Legenstein1, M. Dietzel1, A. Leis2, K. Stingl1, B. Wiegand3 and M. Baumgartner1

1Institute of Applied Geosciences, Graz, Austria (martin.dietzel@tugraz.at)
2Institute of Water Resources Management, Hydrogeology and Geophysics, Joanneum Research Graz, Austria
3Dept. of Geological and Environmental Sciences, Stanford University, USA

Main focus of this study lays on mineralogical, chemical and isotopic composition of carbonate binders of historic roman, medieval and pre-industrial buildings as well as local limestone deposits (Styria, Austria). The respective mortars and plasters mostly consist of calcite as cement with aggregates of calcite, dolomite, quartz, and other silicates like clay minerals or mica.

E.g. 87Sr/86Sr, Sr/Ca, and Mg/Ca ratios of the cement may reflect the composition of the natural deposits used for manufacturing of lime mortar. Values depend on the geologic environment and mineralogical composition of the primary limestone.

δ13C/12C and δ18O/16O composition of the carbonate cement comprise a wide range and for an ideal case δ13C vs. δ18O shows an almost linear correlation. In general, calcite is isotopically lighter at the exterior versus the interior mortar layer. Range and systematic correlation of the data reflect isotopic fractionation effects upon setting of the cement and during the history (e.g. re-crystallization and weathering) of the cement. From another point of view isotope signatures can be used as a proxy for calcite formation conditions.

As one may use historical carbonate binder for 14C dating a promising pre-selection of suitable samples can be done by exclusively using carbonate cement or especially lime pops with specific δ13CCaCO3 and δ18OCaCO3 values.

Fe isotopic composition in sulphides from hydrothermal deposits at the Arctic mid-ocean ridge

Jan Kosler and Rolf B. Pedersen

Department of Earth Science, University of Bergen, Allepatten 41, Bergen, N-5007 Norway (jan.kosler@geo.uib.no)

Hydrothermal vents represent an important source of iron for the deep ocean water. Their iron isotopic composition has been reported as constant relative to Fe residence time in the ocean but also as highly variable with respect to the sampling sites. It has been proposed that sedimentary record of Fe isotopic composition can be used locally to study the past fluxes of Fe but such study is limited by our poor understanding of Fe isotopic fractionation in the hydrothermal systems.

On average, the hydrothermal vent fluids have a slightly lighter (~ -0.5‰ δ56Fe; Sharma et al., 2001) iron isotopic composition compared to the oceanic crust (~ 0‰ δ56Fe; Rouxel et al., 2003), suggesting that seafloor hydrothermal systems fractionate iron isotopes. The isotopically light hydrothermal emanations of Fe2+ become progressively lighter through subsequent oxidation and precipitation processes within the water column (Severmann et al., 2004). The isotopic fractionation of Fe between the fluids and the precipitated sulphides is not yet fully understood but it varies with redox conditions, progress of the reaction and reaction rates.

We have studied isotopic composition of Fe in sulphides associated with newly-described hydrothermal systems along the Mohns Ridge in Norwegian-Greenland Sea. Pyrite from a tectonic breccia recovered from deep parts of the upflow zone is isotopically heavier compared to the pyrite from chimney fragments and sulphide precipitates on the sea floor. The studied pyrite precipitated at ca. 300-330 °C, i.e. at temperatures similar to many black smoker fluids, and higher than can be tolerated by thermophile bacteria. It also formed before the redox conditions were significantly changed by interaction of the Fe-bearing fluids with the deep sea water. The heavy iron isotopic composition in the pyrite from the tectonic breccia suggests that a significant fractionation may take place in the deeper parts of the upflow zone, and that this could explain the shift towards lighter iron seen in many vent fluids. The enrichment of heavy iron in pyrite from the deeper part of the upflow zone is probably related to factors other than the fluid temperature.

Electrokinetic potentials of metal oxides in highly concentrated electrolyte solutions

M. Kosmulski¹ and J.B. Rosenholm²

¹Lublin University of Technology, Lublin, Poland (mkosmuls@abo.fi)
²Abo Akademi University, Abo, Finland (jrosenho@abo.fi)

The sign and the magnitude of the surface charge at the solid/liquid interface define the adsorption behavior of ionic species. The surface charge and the point of zero charge derived from potentiometric titrations are frequently used in adsorption modeling, while the electrokinetic potential is used chiefly in assessment of colloid stability, and very seldom in adsorption modeling. Limited usefulness of electrokinetic data was partially due to the fact that older-generation zetameters produced reliable results only at low electrolyte concentrations. This situation has changed over the recent decade, namely the new-generation instruments are able to measure the zeta potentials at electrolyte concentrations in excess of 1 M. The instruments based on electroacoustic method (electric sonic amplitude ESA or colloid vibration current CVI) are especially useful for this purpose. The problem with electroacoustic method is that electrolyte solutions also produce ESA and CVI signals, which is roughly proportional to salt concentration. At high electrolyte concentrations the ESA and CVI signal of salt is higher than the signal produced by a colloid. This problem is solved by electrolyte background subtraction procedure, which is a standard feature in commercial instruments. Thus, the zeta potentials are obtained as a result of subtraction of two large and almost equal numbers, and the value of the difference is very uncertain.

We suggest an alternative method to solve the problem of electrolyte background correction in electroacoustic measurements. By mixing two salts with common ion (e.g., LiNO₃ and LiCl), which give electroacoustic signals of opposite signs we prepared electrolytes, which give negligibly weak electroacoustic signal. Electroacoustic measurements in such electrolytes do not require electrolyte background correction, even at very high electrolyte concentrations, when the proportions of the components of mixed electrolyte solution are properly adjusted.

The electrokinetic potential of anatase (pristine isoelectric point IEP at pH 6.8) was studied as a function of pH in 1.73 m Li(NO₃,Cl) solution. The zeta potential at high ionic strength was positive at pH up to 10.5. This result confirms the phenomenon reported by several research groups, namely, Li salts at high concentrations induce a shift in the IEP of anatase and of other metal oxides to high pH. Such a shift is due to preferential adsorption of Li, which is observed at high salt concentrations, and which is absent at low concentrations. This preferential adsorption is cation-specific, and the role of the anion is less significant. Very likely, in the studied system there is no IEP at all, and the zeta potential of anatase is positive also beyond the data range.

Aspects of deep biosphere in intertidal sediments from the Wadden Sea (southern North Sea, Germany)

J. Köster¹, B. Engeelen¹, J. Fichtel¹, H. Sass², M. Seidel¹, G. Webster², H. Cypionka¹ and J. Rullkötter¹

²School of Earth, Ocean and Planetary Sciences, Cardiff University, Cardiff CF10 3YE, Wales, UK

Holocene intertidal sediments deposited in the backbarrier tidal system south of Spiekeroog Island (Northwest Germany) show similarities to those of the deep biosphere in various aspects. The research group on “BioGeoChemistry of Tidal Flats” sampled sediment cores down to a depth of about six metres by means of a vibration corer and studied them with microbiological and geochemical methods.

Sediment sequences and pore water profiles differ between the study sites. The sediments become anoxic at a few centimetres depth. Sulphate concentrations decrease within the upper several decimetres, but zones with a maximum of pore water sulphate were observed at greater depth. Methane concentrations mirror those of sulphate. Molecular biological analyses and the presence of intact phospholipids containing archaeol and hydroxyarchaeol show the presence of ANME-2 consortia and suggest that anaerobic methane oxidation occurs in the sulphate-methane-transition zones.

Organic matter is present throughout the core, but the content strongly varies with grain size. Mud-rich sediments contain up to 2% total organic carbon. With increasing depth organic matter shows a more terrestrial geochemical signature, becomes more recalcitrant and thus is harder to degrade. Molecular biological analyses of the microbial community composition shows clear depth zonations which reflect the pore water chemistry and organic matter quality and availability. Bacteria in the upper parts of the sediment sequences are dominated by Proteobacteria. In deeper layers, Chloroflexi and other groups of non-cultivated bacteria often found in the deep biosphere prevail indicating that subsurface tidal flat sediments harbour similar prokaryotic populations as those found in the deeper sub-seafloor biosphere.

Resting, inactive cells present as bacterial endospores represent up to 10% of total bacterial cells. The spore numbers, estimated from the content of dipicolinic acid as a spore-specific biomarker, strongly depend on the type of sediment. Pure cultures obtained from deeper samples were dominated by the spore forming Firmicutes.

The results show that various aspects of the deep biosphere can be studied in a relatively easily accessible but complex environment.
Identifying environmental sources of mercury using stable mercury isotopes

PAUL G. KOSTER VAN GROOS1, BRADLEY K. ESSER2, ROSS WILLIAMS2 AND JAMES R. HUNT1

1Department of Civil and Environmental Engineering, University of California, Berkeley, CA, USA (pkostervangroos@berkeley.edu)
2Chemical Sciences Division, Chemistry, Materials & Life Sciences Directorate, Lawrence Livermore National Laboratory, Livermore, CA, USA

There are many anthropogenic and natural sources of toxic mercury in the environment. As analytical methods for mercury isotopes improve, there is increasing interest in using stable isotopes of mercury to identify sources. San Francisco Bay is significantly impacted by nearby mercury mines, where anthropogenic activities have drastically influenced both the distribution and speciation of mercury. These mines have multiple sources of mercury, including unprocessed and processed wastes, as well as liquid elemental mercury. To determine whether mercury isotope composition can be used to distinguish mercury sources at these mining sites, we modeled mercury ore roasting and subsequent condensation processes used to recover liquid elemental mercury. Using simple Rayleigh fractionation models and estimates of mass-dependent fractionation factors, 202Hg/198Hg ratios in processed waste tailing piles are projected to be 3-4‰ larger than unprocessed mercury ores, whereas 206Hg/198Hg ratios in the liquid elemental mercury product are projected to be 0.5-0.9‰ smaller than unprocessed ores. These projected changes in mercury isotope composition appear to be large enough to distinguish between different anthropogenic sources, and can potentially be used to direct remediation efforts by quantifying relative source contributions to receiving waters.

An analytical method utilizing liquid sample introduction, rather than cold vapor generation, with sample reproducibility approaching 0.1% for 206Hg/208Hg ratios, will be presented. When applied to samples from locations downstream of mercury mines, this analytical method will help distinguish anthropogenic source contributions. Additionally, observations of isotope fractionation under laboratory conditions will be described.

Hf-W and U-Pb ages of the Earth core formation: A solution of the paradox

YURI A. KOSTITSYN AND ERICK M. GALIMOV
Vernadsky Inst of Geochemistry and Analytical Chemistry, Moscow, Russia (kostitsyn@geokhi.ru)

In most mantle processes involving only silicate phases Hf, W, U, and Pb behave like lithophile elements, however if a metal phase is present W and Pb demonstrate moderately siderophile properties. Radioactive decay of 182Hf to 182W, 238U to 206Pb and 235U to 207Pb make it possible to use these elements to study processes of silicate/metal differentiation. If Hf/W and U/Pb ratios of the Earth mantle had been changed by the core formation before 182Hf extinction, then mantle derived rocks should bring us consistent information about timing of the process in both isotopic systems.

Assessments of the core formation time based on Hf-W isotopic system vary from 45±5 My (Wood, Halliday, 2005) to about 30 My (Jacobsen, 2005) depending of the assumption about initial 182Hf/180Hf and some features of the accretion and core segregation styles. The time here is given relative to the Sun System Start (SSS).

Effective core segregation time as assessed from U/Pb delayed fractionation was rather more prolonged. Our best assessment based on 1150 MORB analyses is 120 My. We show that a solution of this discrepancy lies in an assumption of a gradual batch-by-batch differentiation of the proto-mantle material. Observed long-term Pb-Sr-Nd-Os isotopic heterogeneity of mantle rocks suggests impossibility of fast W isotopic equilibration as well between undifferentiated and metal-silicate differentiated portions of the young Earth mantle. In such an assumption different scenarios of one and two-stage core evolution were tested by numerical modeling. In two-stage core formation models the first stage is related with primary metal segregation and the second one – with Fe2+ disproportionation on silicate Fe3+ and metallic Fe0 (Galimov, 2005; Wood, Halliday, 2005).

One-stage linear (lasting ~130 My) and exponentially damped (<~ ~117 My) core growth models bring almost good agreement for Pb and W isotopic theoretical results with available data. Two-stage models involving the fist stage of fast and linear core growth (80-90% of the today core mass for 100-120 My) and the second one of slower linear or exponentially damped growth give exact solution for both isotopic systems.

In general, we show that in case of relatively fast Earth accretion and prolonged core growth, both Pb and W isotopic data could bring concerted model ages for Earth mantle rocks.

3Institut für Geowissenschaften, Johannes-Gutenberg Universität, Mainz, Germany (cornelius@uni-mainz.de)
4Max Planck Institut für Chemie, Mainz, Germany (treisch@mpch-mainz.mpg.de)

The Rhodope Massif in northern Greece is a newly established ultrahigh-pressure metamorphic (UHPM) province in the world (Mposkos and Kostopoulos, 2001).

Microscopic observations on zircons separated from a garnet gneiss revealed a simple zoned structure consisting of a somewhat rounded detrital core and a metamorphic overgrowth rim. Numerous mineral and fluid inclusions were found in the metamorphic rim especially near the interface of the two domains.

We carried out a detailed laser µ-Raman spectroscopic study of the inclusions and their zircon host in both domains. Quartz and monazite were identified in the detrital core whereas diamond, albite, phengite, hematite, rutile and CO2 gas were identified in the rim. Interestingly, albite occurs always in pockets with phengite and diamond whereas the latter two phases can occur independently. We interpret these pockets as precipitates from a melt phase at high pressures.

The microdiamonds were probably formed by dissociation of CO2; the thus liberated oxygen was combined with iron available from the fluid/melt phase to precipitate hematite. Importantly, there is clear-cut distinction in the Raman spectra of detrital and rim zircon, with the latter being additionally characterised by a broad band at Å1332 cm-1. What is more significant is that by approaching the included diamonds the above band in zircon increases dramatically in intensity. This can either be assigned to carbon occupying interstitial sites in zircon and in all probability reflects a luminescence band or to enhanced carbon solubility in zircon (Shcheka et al., 2006), with the diamonds reflecting sites locally supersaturated in carbon.

We favour the former explanation since similar bands, often associated with CO2 peaks, were also observed in inclusions in garnet for which C solubility is negligible.

An experimental basis for eco-safe geoconservation of radioactive nuclides in aluminosilicate matrixes based on fusible bentonites

V.P. KOVALEV, T.A. BUL’BAK, A.E. BOGUSLASKY, V.V. REVERDATTO AND O.P. POLYANSKY

Institute of Geology and Mineralogy, SB RAS, Novosibirsk, Russia (taras@uiggm.nsc.ru)

The most important requirements to matrixes for burring of radioactive wastes are recognized characteristics of absorption of radiation by substance with its warming up and tension relaxations, and also admissible levels of saturation by radioactive nuclides of bonding skeletons.

The authors suggest the creation of cheap silica-alumina matrixes based on fusible bentonitic cation-exchange clays. Using these clays it is possible to develop almost “pure” technologies for production of silica-alumina matrixes separately for products of nuclear fission (PNF) and separately for transuranium elements (TUE). At a “wet” (exchange) stage of charge preparation it is possible to separate radioisotope cations from anions of strong inorganic acids at once. As the exchange capacity of clays is insignificant, the demanded level of saturation of an initial material can be reached by addition of absorbing radioactive nuclides of humus substances. At the subsequent thermal treatment the organic compounds will burn out completely with formation of dense glass ceramic shard of lithoidal structure. The nearest natural analogues of such silica-alumina matrixes are high-temperature metamorphic rocks and volcanic glasses, which have been stable in watered systems for millions years.

Experiments at different temperature modes with modeling nitrate raffinates of PNF containing stable Cs, Ce and Sr have confirmed that they active replace exchange cations of clays - Ca, Na and K. Moreover, the cation exchange capacity achieves 190 mg/100g. Fast saturation of clays by PNF simulators within the first hour was established. This gives necessary information for a substantiation of wet technology processes at low temperatures. During sorption from modelling solution within 6-7 hours up to 80 mass. % of Ce, up to 50 mass. % of Cs and up to 30 mass. % of Sr pass into clays. Mechanisms of the thermal sintering of silica alumina matrixes were determined. With the purpose of definition of the maximal concentration of organic substances (peats), which possible to enter into bentonite matrix with preservation of its integrity after baking and without critical increase in porosity, a 40 experiments series was carried out. The results show that bentonites are perspective materials for production of glasses and ceramics, which strongly immobilize not only highly radioactive isotopes of alkaline, alkaline-earth elements and lanthanoids but also actinoids and other metals forming at nuclear fission and neutron activation.

The effect of $[\text{Ba}^{2+}] / [\text{SO}_4^{2-}]$ ratio on the mechanism of barite growth at constant supersaturation

M. KOWACZ, C. PUTNIS AND A. PUTNIS

Institut für Mineralogie, Universität Münster, Correnstrasse 24, 48149 Münster, Germany
(magdakowacz@uni-muenster.de)

We investigated the mechanism of barite growth in a fluid cell of an Atomic Force Microscope by passing solutions of constant supersaturation ($\Omega$) but variable $[\text{Ba}^{2+}]$ to $[\text{SO}_4^{2-}]$ ratio over a barite substrate. We observed that the potential for two-dimensional nucleation increases with increasing $[\text{Ba}^{2+}] / [\text{SO}_4^{2-}]$ ratio and the mechanism of crystal growth changes from advancement of pre-existing steps to massive island spreading as the cation:anion ratio increases.

Experiments were carried out at two different degrees of supersaturation (7.2 and 12.6) with $[\text{Ba}^{2+}] / [\text{SO}_4^{2-}]$ ratios varying over several orders of magnitude. We observed advancement of pre-existing cleavage steps to be responsible for crystal growth for $[\text{Ba}^{2+}] / [\text{SO}_4^{2-}]$ ratios up to 0.25, while two-dimensional nucleation was not observed. At higher cation:anion ratio two-dimensional nucleation occurs with the island density generally increasing with increasing cation concentration in solution.

The results suggest that the rate limiting factor for two-dimensional nucleation to occur is the frequency of cation attachment, which is determined by the barrier for cations to approach the surface. We carried out further experiments using water-methanol mixtures for the growth solution to corroborate the hypothesis that the solvation water of the crystal surface and of the cation effectively hinders the ability of the cation to reach the surface and that desolvation is the rate-limiting kinetic process in crystal growth. Massive island nucleation was observed on the barite surface in contact with water/methanol solutions with $[\text{Ba}^{2+}] / [\text{SO}_4^{2-}]$ ratio two orders of magnitude lower than 0.25 (while adjusting the ion concentration to the desired $\Omega$ in the solvent mixture). Step advancement and island-spreading velocity also changes with varying cation to anion ratio with the tendency to reduce growth velocity while moving towards extreme values of ion ratio.

Our findings show that barite crystal growth under the same supersaturation conditions occurs by different mechanisms with the cation adsorption on the surface being the rate limiting factor for two-dimensional nucleation. This conclusion is relevant in considering natural systems where crystals grow from solutions of highly variable stoichiometry.

Distribution of Platinum-group element and minerals within the chromitites of Tauride Ophiolite Belt (Pozanti-Karsanți, Pınarbaşı, Mersin), Southern Turkey

H. KOZLU-ERDAL

General Directorate of Mineral Research and Exploration, Mineralogy-Petrography, 06520, Balgat, Ankara, Turkey (haticerdal@mta.gov.tr)

The Tauride Ophiolite Belt was emplaced in southern Turkey. Total bulk platinum group element (PGE) concentrations of chromitites from the Pınarbaşı area range from 67.5 to 253 ppb. The total bulk PGE values of Pozanti-Karsanți chromitites are between 38.2-2730 ppb. The PGE distribution of Tauride chromitites exhibits a negative slope in chondrite normalised diagram. Their Pd/Ir ratio is between 0.01-0.95 which may reflect a magma source which has a severely depleted character. Although most of the chromitite samples from the Tauride Ophiolite Belt have negative slopes in chondrite normalised diagrams, one of the samples from the Pozanti-Karsanți ophiolite is unexpectedly PPGE-enriched (Rh: 150; Pt: 1390 ve Pd: 832 ppb) and has a positive slope in the normalised chondrite diagram. The PPGE values of the chromitites from Pozanti-Karsanți are recorded in the literature as one of highest determined PGE values of chromitites in Turkey (Kozlu-Erdal and Melcher, 2006). The primary PGM inclusions (Pınarbaşı) are laurite, Ir-sulphide, cuproiridsite, Ru-Os (Pozanti-Karsanți) alloys and Os-Ir alloys (Mersin) (Kozlu-Erdal and Melcher, 2007).

Conclusions

The geochemical character of chromitites from Tauride ophiolites and their PGE and PGM composition reflect crystallization from severely depleted boninitic magmas in the supra-subduction zone.

Basalt weathering at high-latitude regions on Mars

M.D. Kraft¹, T.G. Sharp¹, J.R. Michalski² and E.B. Rampe¹

¹School of Earth and Space Exploration, Arizona State University, Tempe, AZ 85287-1404, (mdkraft@asu.edu, tsharp@asu.edu, liz.rampe@asu.edu) 
²Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109 (jimichals@jpl.nasa.gov)

Thermal-infrared (TIR) spectroscopic analyses of Mars indicate that, although bulk regolith SiO₂ contents are globally constant (Karunatillake et al., 2006), high-silica mineral(oid)s are common in dark regions at middle-to-high latitudes (Bandfield et al., 2000; Michalski et al., 2005). Near-infrared (NIR) data from northern-hemisphere regions rich in high-silica materials are consistent with ferric oxide coatings on basaltic substrates (Mustard et al., 2005). Yet, the NIR data lack hydration features, indicating that coating formation may have been anhydrous (Bibring et al., 2006; Poulet et al., 2007). From laboratory experiments, however, we have determined that NIR hydration features of hydrous, amorphous silica are absent from spectra of rocks with thin coatings of silica. The same coatings significantly affect TIR spectra. Such coatings could explain why there are high-silica materials at higher latitudes on Mars despite globally similar bulk SiO₂ contents. Formation of silica coatings by the materials at higher latitudes on Mars despite globally similar spectra. Such coatings could explain why there are high-silica coatings of silica. The same coatings significantly affect TIR determined that NIR hydration features of hydrous, amorphous silica are consistent with ferric oxide coatings on basaltic substrates (Mustard et al., 2005). Yet, the NIR data lack hydration features, indicating that coating formation may have been anhydrous (Bibring et al., 2006; Poulet et al., 2007). From laboratory experiments, however, we have determined that NIR hydration features of hydrous, amorphous silica are absent from spectra of rocks with thin coatings of silica. The same coatings significantly affect TIR spectra.

We suggest that low-temperature, aqueous weathering of basaltic materials has occurred at Martian middle-to-high latitudes, in agreement with Wyatt et al. (2004). We further suggest that the weathering under these conditions has occurred in soils, where liquid water formed periodically as a result of percolation of melt water from surface ice or snow, or when soil ice melts at grain interfaces. Because dissolution and precipitation likely occurred in small, transient pockets or films of liquid water, weathering products would be poorly crystalline and metastable, while thermodynamically favored phases would be kinetically inhibited from forming. It is further likely that weathering would favor dissolution of high-surface-area aeolian dust, which could supply SiO₂ to form rock and particle coatings like those found in some icy soils on Earth (e.g. Dixon et al., 2002). Authigenic minerals in icy Martian soils may be dominated by amorphous silica, formed as coatings on coarser particles of basalt, contributing the spectral signals detected from orbit.

Adsorption of As in rice paddy soils of West Bengal

U. Kramar, S. Norra, Z. Berner and D. Stüber

Institut für Mineralogie und Geochemie, Universität Karlsruhe, 76131 Karlsruhe, Germany (utz.kramar@img.uka.de)

Worldwide in large areas groundwater is naturally polluted by As. Millions of people are drinking this water without any treatment. In many areas large portions of the groundwater is even used for irrigation purposes (Sanyal and Naras, 2002).

The groundwater investigated in the area near Kaliachak, West Bengal can be ranked as highly polluted (to 817 µg/L As, WHO recommends 10 µg/L). In groundwater, the more toxic As(III) species dominates. After flooding the rice fields with this highly contaminated water, more than 90% of the As is retarded in the soil within 24 h resulting in an increasing accumulation of As in paddy fields.

The spatial distribution of As and other major and trace elements in soil particles from different soil depths was mapped by using µ-SXRF. Iron and As- speciation was determined by µ-XANES (FLUO-Beamline, ANKA/ Karlsruhe; Beamline L, HASYLAB/ Hamburg).

Statistical evaluation of the µ-SXRF data and extended µ-XANES suggest that mica (biotite or illite) and chloride host the minor concentrations of As. Tiny goethite grains embedded in the clay matrix seem to be a major phase for As immobilisation of irrigation water.

Redox conditions in soils control the abundances of the redox sensitive species of Fe and As immitted by irrigation water. The decrease in the relative small As(III) proportions with depth give strong hints for changing redox conditions.

Arsenic is mainly co-precipitated with Fe-oxides forming directly after irrigation. A considerable portion of As in rice paddies is adsorbed to Fe rich coatings which have been formed by O₂ release of rice roots. Highest total As concentrations (up to 1600 mg/kg As) as well as the highest As(III)/As(V) ratios have been observed at the innermost side of the coatings (Kiczka, 2005). In Fe- rich coatings considerable amounts of limonite, a mixture of Fe(OH)₃ and FeO(OH) are observed additionally to mica and goethite in soil matrix. These coatings are an important sink for As in rice paddies acting as barrier for the soil plant transfer of As.

A ~4.3 Ga U-Pb age from lunar meteorite SaU169 and the chondritic Sm/Nd of the Moon

J.D. KRAMERS1, E. GNOS2, B.A. HOFMANN3 AND A. AL-KATHIRI1

1Institut für Geologie, Universität Bern, Baltzerstrasse 3, 3012 Bern, Switzerland (kramers@geo.unibe.ch)
2Musée d'Histoire naturelle, Genève, 1 route de Malagnou, CP 6434, 1211 Genève 6, Suisse (edwin.gnos@ville-ge.ch)
3Naturhistorisches Museum d. Burgergemeinde Bern, Bernastrasse 15, 3005 Bern, Switzerland

A remarkably consistent set of $^{142}$Nd/$^{144}$Nd and $^{146}$Nd/$^{144}$Nd data of lunar rocks reported by Rankenburg et al. (2006) provides evidence for a chondritic Sm/Nd ratio of the Moon. An apparent minor inconsistency is present for the most fractionated lunar rock in their data set, the Imbrian high-KREEP lunar meteorite SaU169, which yielded a subchondritic initial $\varepsilon_{142}$Nd value if this parameter was calculated for its reported SIMS zircon date of 3909 ± 13 Ma (Gnos et al., 2004). The zircons dated were skeletal grains that crystallized from the impact melt.

We have carried out a leaching experiment on a 2 mg heavy mineral concentrate from the same impact melt, containing zircon and some merrillite, as follows. Step 1: 4N HNO$_3$, 25°C, 15 min. Step 2: 4N HNO$_3$, 100°C, 8 hrs. Step 3: Inverse aqua regia, 100°C, 16 hrs. Step 4: HF + 4N HNO$_3$, 150°C, 3 days. Isotope ratios of the $^{235}$U + $^{208}$Pb spiked leaches were measured on a Nu Instruments® MC-ICP-MS.

The final HF+HNO$_3$ step has $^{208}$Pb/$^{206}$Pb = 0.37 and $^{206}$Pb/$^{204}$Pb = 440 and dominantly reflects zircon. It yields a near-concordant U-Pb date of 4290 ± 30 Ma. This is robust, but significantly older than the SIMS dates of 3909 ± 13 Ma reported by Gnos et al. (2004), which give the age of the Imbrium impact melt. We suggest that our older age reflects a mixture of zircons crystallized from the impact melt, such as dated by Gnos et al. (2004), and much smaller, but collectively dominant crystals that might have survived impact melting and had a lunar crustal or KREEP source origin, with ages of 4300 Ma or older (Papike et al., 1998).

If the $^{142}$Nd/$^{144}$Nd ratio of Rankenburg et al. (2006) for SaU169 is extrapolated back to the age of 4.3 Ga suggested by our result, the initial $\varepsilon_{142}$Nd value plots precisely on the chondritic evolution curve, consistent with their models. This further strengthens the case for a chondritic Sm/Nd ratio of the Moon and therefore, terrestrial fractionation after the Giant Impact.

Sr-isotopes and trace elements in feldspar and clinopyroxene: Tracer of magma mixing in gabbros from Uralian-Alaskan-type complexes in the Ural Mountains, Russia

J. Krause1,2, G.E. Brügmann1,2 AND E.V. Pushkarev3

1Inst. für Geowissenschaften, Universität Mainz, Becherweg 21, D-55099 Mainz, Germany
2Max-Planck-Institut für Chemie, Becherweg 27, D-55020 Mainz, Germany
3Inst. of Geology and Geochemistry, Russ. Acad. Sciences, 620151 Ekaterinburg, Russia

We applied LA-ICPMS techniques to determine Sr isotopes and trace element concentrations of rock forming minerals in gabbroic rocks from zoned mafic-ultramafic complexes (Nizhnii Tagil and Kytlym) in the Ural Mountains in Russia.

These gabbros have porphyritic textures with clinopyroxene phenocrysts in a matrix of olivine, clinopyroxene and spinel ± plagioclase. Based on the composition of additional matrix minerals two types of gabbro can be distinguished. One is silica saturated, contains plagioclase (An56-97) and in places orthopyroxene as matrix phases (bytownite gabbro). The second gabbro type is silica undersaturated and contains in the matrix plagioclase (An26-41) and pseudoleucite, an intergrowth of nepheline and K-feldspar (Or53-93).

Clinopyroxene of gabbros from Nizhnii Tagil and the western part of the Kytlym Complex is enriched in LREE (87Sr/86Sr 0.70384-0.70405 ±0.00004). These features imply that silica undersaturated gabbros are derived from thin section scale.

\(^3\)S-prep GmbH, Im Amann 7, D-88662 Ueberlingen, Germany (sabine.mann@s-prep.com)

Laser Ablation ICP-MS has come a long way since its introduction in the mid-eighties. Most common commercial systems are using 266 nm, 213 nm or 193 nm. Laser energy in the deeper UV range is more efficient at delivering the laser energy to a wider variety of samples, allowing uniform sampling of even transparent materials. This is of special importance when analysing a variety of geological samples.

The CETAC LSX-213 Laser Ablation system is operating at a wavelength of 213 nm and is optimised to deliver homogenized “flat-top” energy profile with > 4mJ, 5 ns laser pulses with repetition rates of 1-20 Hz. The use of Helium as a carrier gas improves sample transport efficiency and reduces fractionation. It finds its application in the analysis of several types of geological samples, such as soils and sediments, Otoliths, gemstones, quartz samples, and other materials. Various applications are discussed.

For the most challenging and highly transparent samples the best suitable wavelength is 193 nm. Due to the use of a very stable Excimer Laser, its high energy density of up to 45J/cm² at 193 nm, and a highly homogenized beam profile, the GeoLas Pro has advantages for very precise geochronology and fluid inclusion analysis, especially for very small craters down to 4 µm in diameter. The use of a powerful petrographic microscope enables the identification of even very small features of a few micrometers. Features and Applications for this 193 nm Excimer Laser system are discussed.

**Petrology of shoshonitic lamprophyres and related carbonatites in the Svecofennian Domain**

T. KRAVTSOV AND J. WOODARD

Department of Geology, University of Turku, FIN-20014
Turku, Finland (ttkrav@utu.fi; jdwood@utu.fi)

The latest stage of magmatism related to the Svecofennian Orogen involved numerous, low-volume bimodal shoshonitic granitoid intrusions. Several contemporaneous shoshonitic lamprophyre dyke swarms are found throughout the Svecofennian Domain, as well as three small calciocarbonatite dyke swarms. We present petrological data on these dyke rocks and consider their genetic relationships.

The shoshonitic lamprophyres in the Lake Syväri area of eastern Finland occur as a swarm of narrow dykes. Additional lamprophyre dykes are found in the west Lake Ladoga region, Russian Karelia. Age determinations (SIMS U-Pb, zircon) from both areas give concordant intrusion ages of 1.78-1.77 Ga. Petrographically, these lamprophyres are characterized with aggregates of biotite in a fine-grained matrix of K-feldspar, plagioclase, calcite and apatite. Typical accessory minerals are titanite, magnetite, baryte, pyrite, ilmenite, diopside and allanite. Blebs or vesicles of carbonate minerals have been found in samples from both areas. They are strongly enriched in LREE, P, Sr and Ba. Similar enrichment is seen in shoshonitic lamprophyres in the west Lake Ladoga region, Russia, and their plutonic equivalents in the easternmost part of the Svecofennian Domain.

The three calciocarbonatite intrusions occur at Halpanen in southeast Finland as a single, relatively large dyke as well as at Naantali, southwest Finland and Panjavaara, east-central Finland as swarms of small dykes. In addition to calcite, the dykes contain 5-10% modal fluorapatite. Typical accessory minerals include magnetite, bastnäsite, monazite, titanite, allanite and baryte. The carbonatite intrusions also show strong enrichment in LREE, P, F, Sr and Ba, along with depletion in Nb and Ta. Preliminary age determinations from monazite suggest an intrusion ages between 1.78-1.76 Ga. \(\varepsilon_{Nd}(1800)\) was found to be near zero, indicative of metasomatic mantle enrichment from ca. 1.9 Ga subduction. \(\delta^{13}C\) ratios fall between ~8 and ~15‰ for all carbonatite intrusions as well as the carbonate vesicles in the Lake Ladoga region lamprophyres. Intensity of enrichment as well as the \(CO_2/H_2O\) ratio increases from west to east, a trend parallel to that described by Andersson \textit{et al.} (2006).

Despite the wide geographic distribution of these intrusions, the combined petrological and geochemical evidence suggest a genetic relationship between the lamprophyre and carbonatite dykes, as well as the shoshonitic granitoid intrusions.

The geochronology of HP/LT metamorphism constitutes a major challenge in the reconstruction of subduction zones. In Cuba, the Escambray metamorphic complex comprises a nappe stack involving both HP/LT subduction-related metamorphic rocks as well as island-arc-related LP/HT units [1]. A Mesozoic age has been suggested for the protoliths of these rocks based on poorly preserved fossils [2]; final exhumation is indicated by the appearance of pebbles of metamorphic rocks in conglomerates at about 45 Ma.

Although the timing of the rapid exhumation of the Escambray nappe stack is well constrained between 75 and 65 Ma [1, 3], available age data on earlier stages of subduction history are in conflict. A concordant U/Pb age of 102±2 Ma for zircons has been reported for an eclogite [4]; however, other eclogites yield discordant populations with a lower intercept at 148 Ma [3]. SHRIMP analyses of single-grain zircon show a broad spectrum of ages between 105 and 176 Ma. Only metamorphic sphene provides a U/Pb age of about 71 Ma interpretable as a “metamorphic age”.

New results from Lu–Hf dating on eclogites and garnet amphibolite from subduction-related nappes help to shed light on this discrepancy. The eclogites and garnet amphibolite yielded ages of 72-67 Ma and 80 Ma, respectively. If garnet nucleated before peak P, eclogite ages may even predate attainment of maximum subduction depth. This new result will have to be integrated into models of the geodynamic development of Central Cuba.

Speciation of organometal(lloid) compounds in landfill gas and landfill leachate by hyphenation of GC with ICP-MS

DANIEL KREMER AND MICHAEL KERSTEN
Johannes-Gutenberg Universität Mainz, Intitut für Geowissenschaften, Becherweg 21, 55099 Mainz, Germany (kremerd@uni-mainz.de)

Organometal(lloid) compounds, metal(lloid) species bearing at least one metal-carbon bond, are usually more toxic than their inorganic representatives. These compounds can be formed in wet environments and occur as methyl or hydride derivates in the gas phase, while ionic species stay in the liquid phase. Organometal(loids) are also present in landfill gas and landfill leachate. Amongst them toxic compounds like Tetramethyltin, Tetraethyltin, Tributyltin or Dimethylmercury. The total amount of metal(loids) being alkylized in landfill sites still remains unknown. Organotins are the most abundant metal(loid) species in landfill gas and landfill leachate. Determination of these metal species in landfill samples turns out to be difficult, as they occur in ultratrace levels which requires a good trace-matrix separation and a powerful detection technique. Coupling of capillary gas chromatography (GC) with inductively coupled plasma - mass spectrometry (ICP-MS) provides a very sensitive analytical tool for organometal(loid) speciation.

A self-made cryotrapping (CT) - cryofocussing (CF)-GC-ICP-MS system was used for the analysis of landfill gas. We found more than 15 volatile organotins, with a concentration range from 11 pg/L to 31ng/L. But also Dimethylmercury, Dimethylselenide and Dimethyltelluride were found in landfill gas.

Landfill leachate is analysed using GC-ICP-MS for liquid injections of organic solvent extracts. Water soluble organotins were transferred into peralkylated compounds by derivatization with sodium tetra-(n-propyl)-borate and extracted with n-hexane. By using propylation instead of ethylation we were able to find ethylated organotin species in leachate. For the first time we found more than 10 organotins with concentrations from 0.1 to 7.9 ng/L. But we could not find any Hg, Se or Te species in the leachate yet.

This indicates that organometal(lloid)s are produced within a landfill site in large number and can be carried out of the system via gas and leachate.
Radiohaloes in cordierite: Radiochemical transformation of channel constituents

R. KRICKL1, L. NASDALA1 AND A. MÖLLER2

1Institut für Mineralogie und Kristallographie, Universität Wien, Austria (robert.krickl@univie.ac.at, lutz.nasdala@univie.ac.at)
2Institut für Geowissenschaften, Universität Potsdam, Germany (amoeller@geo.uni-potsdam.de)

Yellow pleochroic radiohaloes are frequently observed in cordierite. Their formation is caused by the impact of alpha particles originating from actinoid-bearing inclusions, which create scattered point defects in the cordierite structure. This process may result in a significant disturbance of the short-range order of this mineral (Nasdala et al., 2006).

Cordierite is well known to contain hydrous species and CO2 in structural channels that are oriented parallel to the c axis (Aines and Rossman, 1984). Our micro-spectroscopic investigations yield evidence for radiochemical changes of such molecules. Raman and infrared (IR) spectra of radiohaloes are characterized by less intense OH stretching and CO2 bands when compared to the host cordierite, whilst concurrently an extra band appears at \( \sim 2135\text{cm}^{-1} \) (Fig. 1). This band is assigned to CO stretching vibrations (Khomenko and Langer, 2005). Our observations suggest that carbon monoxide (observed only in radiohaloes) must have formed from CO2 caused by the impact of alpha radiation.

Figure 1: Polarised IR absorption (left) and Raman spectra (right) taken inside a radiohalo and in the unaltered host cordierite, indicating irradiation-induced CO2 → CO transformation.

Boron isotopic compositions of tourmaline from a hydrothermal gold deposit – Constraints on fluid sources

M.-S. KRIENITZ1, R.B. TRUMBULL1, A. HELLMANN2, J. KOLB2, F.M. MEYER2 AND M. WIEDENBECK1

1GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (krieni@gfz-potsdam.de, bobby@gfz-potsdam.de, michawi@gfz-potsdam.de)
2Institut für Mineralogie und Lagerstättenlehre, RWTH Aachen, 52056 Aachen, Germany (Andre.Hellmann@rwth-aachen.de, kolb@rwth-aachen.de, m.meyer@rwth-aachen.de)

The ultimate sources of ore forming fluids still remain a key question in orogenic gold research. In this regard the boron isotope and chemical compositions of tourmaline provide important constraints on the source compositions of the mineralizing fluids because tourmaline (a) is a common gangue mineral in many Archaean lode gold deposits and is often closely associated with gold mineralization, (b) is stable over a wide p/T range and is resistant to alteration and weathering, (c) is indicative of source lithology as reflected by its compositional variability, and (d) is the main host for boron in most rocks, where the boron isotopic composition in tourmaline is controlled by the composition of boron in the source, the p/T conditions of crystallization, and by fractionation effects related to phase changes.

We investigated tourmalines from the Hira Buddini Gold Deposit within the Archaean Hutti-Maski Greenstone Belt in southern India. The tourmalines belong to the dravite-schorl series with major element variations being related to their host lithology. SIMS determined \( \delta^{11}\text{B} \) values vary in a wide range from -13‰ to +9‰ with 95% of the values are between -4‰ and +9‰. The bimodal distribution with peak \( \delta^{11}\text{B} \) values at about -2‰ and +6‰ is consistent with the presence of at least two isotopically distinct fluids which penetrated the hydrothermal system along different access-pathways and were subsequently mixed. The calculated \( \delta^{11}\text{B} \) values of the fluids being about 0‰ and +10‰, respectively, rule out a crustal origin for the source fluids, suggesting an involvement of metamorphic and/or magmatic sources. The isotopically lighter fluid may have been generated during metamorphic devolatilization reactions, whereas the heavier fluid is attributed to degassing of I-type granitic magmas that provided heat and fluids to the hydrothermal system.
SEM-CL analysis of quartz gangue in the Big Creek Mining District, Idaho, USA indicate that CL textures predate quartz crystal formation and final optical orientation

DAVID H. KRINSLEY1 AND PATRICK F. O’HARA2

1Dept. of Geological Sciences, University of Oregon, Eugene, Oregon, USA 97403-1272
2Kaaterskill Exploration, 3260 Tower Rd., Suite 3, Prescott, Arizona, USA 86305

SEM-CL textures uniquely identify quartz in veins and alteration assemblages with various stages of hydrothermal deposition in the Big Creek Mining District of central Idaho. These mesothermal veins and disseminated mineralization associated with hydrothermal alteration are related to the Idaho batholith, and are located within a large structural zone that is enriched in gold and silver locally.

In a number of slides CL textures do not correspond to grain contacts identified using polarized light microscopy with crossed nicols (PLM). This indicates that the CL patterns formed prior to crystallization and associated optical characteristics. In several slides, grain boundaries do correspond to CL patterns and in others the relationship between specific grains and CL texture is vague. SEM-CL reveals textural evidence of deposition and brecciation events in quartz prior to crystal formation with associated grain boundaries and the establishment of optical properties. Later recrystallization may change original optical properties in specific grains but not the original CL texture.

Hydrogen isotope ratio of Acid Volatile Sulfur in saltmarsh sediments

R. KRISHNAMURTHY AND T.A. GEBREHIWET
Western Michigan University, Kalamazoo MI 49008, USA (r.v.krishnamurthy@wmich.edu; tsigabu.gebrehiwet@wmich.edu)

Reported what probably are the first δD measurements of Acid Volatile Sulfur (AVS) extracted from sediments. The samples represent the upper 50 cm of a salt marsh from Sapelo Island, GA, USA. The site is sparsely vegetated by Spartina alterniflora. Sediment core and pore water samples were collected, the core samples being taken within few centimetres from the pore water sampling sites. The sampling devices, pore water diffusion equilibrators (“peepers”), were covered using 0.2 µm pore sized dialysis membrane. Sampling of the pore waters was done anaerobically at 1-2 cm intervals from the sediment water interface. The AVS from the sediment samples was released using a novel method, which involved treatment of pre-weighed, dry samples (5 cm interval) with 100% phosphoric acid under vacuum conditions. The gases produced by this reaction included CO2, SO2 and H2S. The H2S was converted to hydrogen by reacting with hot cupric oxide and then passing the resulting water over hot uranium. δD of this hydrogen was measured and the values ranged from -500 to -615 ‰. The δD of the 100% phosphoric acid used was -140‰. The SO2: H2S ratio was ~2 for all samples. The δD values strongly point to organically bound sulfur as the source of H2S. This organically bound sulfur in turn can be considered to have resulted from methane oxidation in the presence of sulfate via the pathway:

\[
\begin{align*}
\text{CH}_4 + \text{SO}_4^{2-} & \rightarrow \text{HS}^- + \text{HCO}_3^- + \text{H}_2\text{O} \\
\downarrow & \downarrow \\
\text{AVS} & \rightarrow \text{CaCO}_3
\end{align*}
\]

This argument is supported by the down core variation in pore water SO4 and Dissolved Inorganic Carbon (DIC) concentrations and the relatively low δ13C values (-19.5±5‰) for the carbonate fraction ‰.
New data concerning the high-Mg rocks of the Siberian trap formation in the Noril’sk region

N.A. Krivolutskaya¹, A.V. Sobolev¹, V.N. Mikhailov² and N.M. Svirskaya¹

¹Vernadsky Institute RAS, Moscow, Russia (nakriv@mail.ru)
²Institute of Geology, Tomsk State University, Tomsk, Russia

The problem

The huge Siberian trap province consists of the tholeitic basalts in general. High-Mg rocks are very rare, especially in its Western part. Meanwhile their composition and origin are very important to the reconstruction of the evolution of the whole magmatic system and the ore-forming processes.

There were described two main horizons of the picritic basalts in the Noril’sk region: inside the Gudchikhinsky and the Tyklonsky Formations (Godlevsky, 1959; Dodin, 1964; Fedorenko et al., 1996 etc.). Numerous basic-ultrabasic intrusions located here contain the picritic gabro-dolerites as well, sometimes with Pt-Cu-Ni deposits. It is believed that they are the result of the interaction between the Tuklonsky magma and the surrounding rocks, and thus they belong to the Nadezhdinsky Formation (Naldrett, 1992; 1996; Lighthfoot et al., 1997). But the relationships between intrusive and effusive rocks are not recognized enough.

The main goal of this study was to understand the origin of high-Mg intrusive rocks in terms of their connection with the effusive rocks. To solve this problem we have investigated the complete section of the Nadezhdinsky Formation in the Mikhangda river basin. It consists of two different units: the lower part is represented by layered flow (about 70 m thickness) and the upper part consists of 7-10 massive flows (140-150 m thickness). The lower part is the most interesting because it contains the interlayers of picritic basalts (17-19 mas.% MgO, the summary thickness is about 15 m) among the tholeiitic basalts. All rocks of the layered flow are characterized by very similar features: they have high LIL concentrations, Ta-Nb negative and Pb positive anomalous, very low Cu, Ni, Co contents. Olivine composition not vary significantly: Fo content changes from 76 up to 78 mol.%, NiO = 0.09-0.11 mas.%, HREE =0.1-0.3 ppm. In contrary, picritic gabro-dolerites of the ore-bearing intrusions possess another behaviour of these elements – average LILE, high metal contents and another typomorphical features of olivines (Fo₇₈₋₈₃, NiO = 0.2-0.3 mas.%, HREE=3 ppm).

Conclusions

For the first time the high-Mg rocks were established in the Nadezhdinsky Formation. This is the third level of the tholeiitic basalts in the vertical sector of effusive rocks in the Noril’sk region. They can be formed from the tholeiitic basalts to adding 32 % olivine crystals (Krivolutskaya et al., 2005). These picritic basalts are not comagmatic rocks for the picritic gabbro-dolerites from intrusions with unique Pt-Cu-Ni ores. The latters were formed from another magmas.

This study was supported by Russian Foundation for Basic Researches (project № 07-05-01007).

Age distribution and geochemistry of cinder cones in the Bandas del Sur, South Tenerife (Canary Islands)

J. Kröchert and E. Buchner

Institut für Geologie, Universität Stuttgart, Herdweg 51, 70174 Stuttgart, Germany
(joerg.kroechert@geologie.uni-stuttgart.de, elmar.buchner@geologie.uni-stuttgart.de)

The three shield massifs of Anaga, Roque del Conde and Teno (constructed between 11.9 and 3.9 Ma, Guillou et al. 2004) are the oldest volcanic units exposed on Tenerife island. In the central part of the island, the prominent Las Cañadas volcano formed between ~3 and 2 Ma. Three caldera-forming eruptions occurred between 1.59 and 0.17 Ma (Marti et al. 1994; Bryan et al. 1998) and are collectively responsible for the development of the Las Cañadas Caldera (Marti et al. 1994, 1997). The Bandas del Sur Formation, in the south of Tenerife, records two explosive volcanic cycles of basaltic to phonolitic eruptions with more than seven ignimbrite sheets, erupted from the Las Cañadas edifice. These cycles correlate with the caldera-forming eruptions. Each cycle started with flank eruptions of the Las Cañadas volcano associated with alkali basaltic lavas and the formation of cinder cones within the Bandas del Sur (Bryan et al. 1998).

The cinder cones within the Bandas del Sur are important volcanic units for understanding the explosive volcanic cycles on Tenerife during the Pleistocene. Palaeomagnetic studies, major and trace element geochemistry, as well as Y/Nb ratios, Zr/Nb plots, and radioisotopic dating (K-Ar) have been carried out on prominent cinder cones to discover their stratigraphic position. Combining our results with previous K-Ar data, the cinder cones and lavas can be subdivided into three stratigraphic units. Each unit shows specific Y/Nb ratios and distinctive remanent magnetization. Multielement plots, as well as variation diagrams depicted for each unit yield further information with respect to mantle source and degree of partial melting. The first two units were constructed between 0.948-0.779 Ma and 0.323-0.300 Ma. These units define volcanic cycles ending in violent plinian eruptions. The third and youngest unit possibly marks the beginning of a further volcanic cycle 0.095 Ma ago.

References

On the basis of geophysical constraints (P- and S- wave velocities, moment of inertia and mass of the Moon) and method of mathematical modeling of phase relation and physical properties in the system CaO-FeO-MgO-Al$_2$O$_3$-SiO$_2$, we examine the hypothesis of chemical differentiation of the Moon as a result of partial melting of initially homogeneous material (hypothetical magma ocean). We consider models of internal structure of the Moon with five layers including a crust, a three-layer silicate mantle, and a Fe–10 wt.% S-core ($\rho = 5.7$ g cm$^{-3}$). The general methodology is to combine geophysical and geochemical constraints and thermodynamic approach, and to develop, on this joint basis, the self-consistent model of Moon, accounting for its chemical composition and internal structure. The Al$_2$O$_3$ content in the lunar crust ($\rho = 2.9-3.0$ g cm$^{-3}$) varied between 25 and 30 wt%. The concentrations of major oxides for the entire mantle varied in the ranges $2 \leq$ CaO and Al$_2$O$_3 \leq 8\%$, $25 \leq$ MgO $\leq 45\%$, $40 \leq$ SiO$_2 \leq 54\%$, $6 \leq$ FeO $\leq 20\%$. The technique of Gibbs free energy minimization was used, and equations of state of minerals and solid solutions were included in the database. The solution of the inverse problem is based on the Monte Carlo method. We determine the ranges of chemical composition, mineralogy, velocities and density in the upper, middle and lower mantle as well as core sizes. The results of our inversion procedure generate velocity and composition distributions in the lunar mantle. The bulk composition of the silicate portion of the Moon (mantle+crust) is estimated (wt. %): 3.8< CaO<3.8%, 3.7< Al$_2$O$_3$<4.7%, 11< FeO<12.5%, 28< MgO<30%, 49< SiO$_2$<51%, MG# ~81. The chemical composition of the Moon bears no genetic relationship to the terrestrial material as well as to any of the known chondrites. This research was supported by RA S under Programs 9 and 18, and by RFBR grant (06-05-64308).

We used EMPA to measure sodium in olivine and glass in type I and II chondrules of UOC Semarkona (LL3.0). Goal of our study is to show whether alkalis were present in the liquid during olivine crystallization. Na in olivine was analyzed with a beam current of 300 nA for 600 s on the peak and 2 x 300 s on the background. The detection limit was determined to be $\sim 10$ µg/g.

Na$_2$O-concentrations in mesostasis vary in the range of 0-12 wt%. Na$_2$O in olivine in chondrules varies in the range of 0-68 µg/g (type I) and 40-110 µg/g (type II).

Our data show that Na was present in chondrules during olivine crystallization. The apparent $D_{Na}$ (ol/mesostasis) is 0.0005 for type I and 0.001 for type II chondrules, respectively. Calculating the $D_{Na}$ between olivine and bulk gives a $D_{Na}$ of 0.005 for type I and II. Borisov et al. (in prep.) give a $D_{Na}$ (ol/melt) of $\sim 0.003$. This value is in agreement with our data. Absence of loss of alkalis requires either high alkali partial pressures and/or a very rapid heating and cooling of chondrules. Our interpretation of the presence of Na in chondrule olivine explains the absence of K-isotope fractionation in chondrules in the way that evaporation did not take place during chondrule melting.

Relict refractory inclusions in chondrules from the metal-rich carbonateous chondrites

ALEXANDER N. KROT1, KAZUHIDE NAGASHIMA1, MARTIN BIZZARRO2, GARY R. HUSS1, FRED J. CIESLA3 AND ALEXANDER A. ULYANOV4

1HIGP/SOEST, University of Hawai‘i at Manoa, USA
2Geological Institute, Denmark
3Carnegie Institution, USA
4M. V. Lomonosov Moscow State University, Russia

We have recently concluded that the CH/CL-like chondrite Isheyevo and other CH chondrites contain multiple generations of chondrules (Krot et al. 2007a): (i) magnesian chondrules with cryptocrystalline and skeletal textures, similar to those in CB3 chondrites, which may have formed from a gas-melt plume resulted from a large-scale asteroidal collision (Krot et al., 2005); (ii) ferromagnesium and Al-rich chondrules with porphyritic textures which appear to have formed by melting of solid precursors. Here, we report the discovery of abundant Ca,Al-rich inclusions (CAIs) inside porphyritic chondrules from Isheyevo and CH chondrites Acfer 182/214 and PAT 91546. These, now relict CAIs formed before the host chondrules, were subsequently mixed with the chondrule precursor materials and melted to various degrees during chondrule formation. About half of the relict CAIs belong to a population of 26Al-poor, very refractory inclusions dominated by grossite and hibonite; other relict CAIs consist mainly of spinel. Grossite and hibonite of the relict CAIs and anorthetic plagioclase of the host chondrules show no evidence for 26Mg excesses related to decay of the short-lived 26Al radionuclide. The only two exceptions are grossite-rich CAIs having small 26Mg/28Mg ratios corresponding to an initial 26Al/27Al ratios of (1.7±1.3)×10^-6 and (3.3±3.0)×10^-7. The 26Al-poor grossite-rich and hibonite-rich igneous CAIs comprise about 50% of all refractory inclusions in the metal-rich chondrites studied (Krot et al. 2007b,c). Such CAIs, however, are virtually absent in ordinary, enstatite and other carbonaceous chondrite groups. We infer that this isochronally and mineralogically unique population of CAIs was present in the region where ferromagnesian porphyritic chondrules of CH and CH/CL-like chondrites formed, suggesting that these chondrules formed at a different time or in a different nebular region than chondrules from other chondrite groups. Since most CAIs outside chondrules in Isheyevo and CH chondrites show no clear evidence for being affected by the chondrule-forming processes, we infer that either the scale of chondrule-forming event(s) was relatively small and a number of chondrule-forming events in a localized nebular region where these chondrules formed was limited, or chondrule-forming event(s) had little effect on compact objects, like CAIs.

Pine Point, Canada Pb-Zn deposits: Better resolved S-isotope study

H. ROY KROUSE, YINGCHUN LI AND AKIRA UEDA

Isotope Science Laboratory, Department of Physics and Astronomy, University of Calgary, Calgary, AB, Canada T2N 1N4. Correspondence to (roystrains@hotmail.com)

Introduction
Insight on the formation of the Pine Point (NWT, Canada, 60°41'N, 114°30'W) Pb-Zn deposits was acquired four decades ago using traditional stable isotope methodology (Sasaki and Krouse, 1969; Fritz 1969; Fritz and Jackson, 1972). This presentation summarizes δ34S data from better resolved sampling techniques. (1) Trace sulfate and sulfide in carbonate (Ueda and Sakai, 1983), (2) different organic components (Krouse et al., 1987), and (3) laser probe produced SO2 from mineral surfaces (Kelley and Fallick, 1990).

Results and Discussion
Fritz (1969) and Fritz and Jackson (1972) identified at least three dolomitization events in the deposits. In the current study, trace sulfide and sulfate from an early dolomite had δ34S values of +18.5% (the mean value of the ore) and +25.7%, consistent with partially reduced Devonian seawater sulfate. The δ34S values of sulfate and sulfide in a vug were +28.0 and +57.7% respectively, consistent with low temperature bacterial sulfate reduction and sulfide loss.

Powell and Macqueen (1984) found unaltered bitumens to have lower S-content and bulk δ34S values than altered bitumens. Below 300°C, H2S evolved during pyrolysis had low δ34S values consistent with post ore deposition low temperature sulfate reduction. Most H2S was evolved between 300°C and 500°C with δ34S in the range associated with the ore. H2S released at higher temperatures had δ34S values found for unaltered bitumens. Altered bitumens released more H2S in the 300°C to 500°C range than unaltered bitumens.

Laser probe produced SO2 revealed systematic δ34S variations in a single PbS crystal of the order of 2‰ which is comparable to data for hand specimens throughout the deposits (Sasaki and Krouse, 1969). This supports low temperature (<100°C) estimates for ore deposition.

Conclusions
Better chemically and spatially resolved sampling provided δ34S data which complement those of traditional stable isotope methodology at the Pine Point Pb-Zn deposits. Overall, the newer techniques better describe processes involved during and post ore deposition.

The role of mantle fluid in formation of modern oceanic sulfide ore: Os isotope evidences

R.S. KRYMSKY¹, J.-L. BIRCK², B.V. BELYATSKY³, G.A. CHERKASHCHEV³, T.V. STEPANOVA³ AND S.A. SERGEEN¹

¹Centre of Isotopic Research, VSEGEI, St.Petersburg, Russia (robert_krymsky@yahoo.com)
²IPGP, Paris, France (birck@ipgp.jussieu.fr)
³VNIIookeangeologia, St.Petersburg, Russia

Great potential of Re-Os isotope system as a tool for hydrothermal sulfide ore study and searching of the metal sources has already been demonstrated (Ravizza et al., 1996; Brügmann et al., 1998; Gannoun et al., 2003; Sharma et al., 2000; Cave et al., 2003). It was shown that the main sources for Os and Re in submarine hydrothermal systems are seawater, rocks of hosted oceanic crust (sediments, basalts, ultramafics), hydrothermal fluid and extraterrestrial dust. But, the data about pristine plume component with prominent mantle-like signatures are very limited (Cave et al., 2003; Sharma et al., 2000) and lacks further investigation in order to find out the true significance of this source in the process of oceanic ore formation. The main goal of the present investigation was to study behavior of Re-Os isotope system in the process of modern hydrothermal sulfide formation and to determine the role and share of mantle substance in this process. To solve these problems we choose modern (active from 7 thousand years ago till nowadays) Ashadze hydrothermal field developed over ultramafic basement and represented by different types of sulfide formations – from massive sulfides and smokers (up to 7-10 m high) to secondary Fe-Mn and hydrogenic crusts. The Ashadze hydrothermal field as a whole is located on the western slope of the MAR rift valley at 13°N, 44°50’W. Re and Os concentration and Os isotope composition of 15 hydrothermal sulfide samples and 14 host rocks were determined by NTIMS methods for detecting synthetic chalcogenide (MeX, X = S,Se,Te) nanoparticles at trace levels in the environment are of interest in view of possible large-scale commercialization of nanotechnology (1). Natural aquatic metal sulfide nanoparticles already have been observed (2). Nanoparticles composed of several metal sulfides sorb strongly at Hg⁰ electrodes (2-4), where cumulative deposits can be quantified by cathodic scans (MeSÆMe⁰ amalgam). Thus Hg⁰ electrodes can serve both for preconcentration and for determination of chalcogenide nanoparticles. Detection at <10⁻⁶ M (as Me⁰) has been demonstrated and lower limits are probably feasible.

Understanding the preconcentration mechanism is the key to optimizing detection of chalcogenide nanoparticles. In a detailed study of semi-spherical, copper sulfide (Cu,S) aggregate particles having mean diameters of 5-20 nm, a three-step mechanism is required to explain preconcentration. The first step involves Brownian diffusion of particles to the Hg⁰ surface. When both the electrode and particles have negative surface potentials, this process resembles charge-impeded coagulation, obeying the Schulze-Hardy rule in various electrolytes. The second step involves atomic reordering of Cu,S, probably to Cu₅S₆ adlayers. A very significant (~0.3 V) negative shift in the Cu,S reduction potential results, owing to a free energy decrease from release of the nanoparticles’ surface energy and from favorable chemical interactions between Cu₅S₆ adlayers and Hg⁰. The third step, which competes with the second, involves size-dependent, reductive loss of electroactive Cu₅S₆ prior to the cathodic scan. This loss is greatest for the smallest particles with greatest surface free energy.

Methods for detecting synthetic chalcogenide (MeX, X = S,Se,Te) nanoparticles at trace levels in the environment are of interest in view of possible large-scale commercialization of nanotechnology (1). Natural aquatic metal sulfide nanoparticles already have been observed (2). Nanoparticles composed of several metal sulfides sorb strongly at Hg⁰ electrodes (2-4), where cumulative deposits can be quantified by cathodic scans (MeSÆMe⁰ amalgam). Thus Hg⁰ electrodes can serve both for preconcentration and for determination of chalcogenide nanoparticles. Detection at <10⁻⁶ M (as Me⁰) has been demonstrated and lower limits are probably feasible.

Periodic density functional theory (DFT) calculations
using the programs CASTEP and VASP were carried out to
model the H2O-TiO2 and the H2O-SnO2 (100) and (110)
interfaces. These two minerals have the same crystal structures
but different unit cell dimensions and dielectric constants.
Comparisons of the behavior of H2O at each surface can be
used to test the effects of these two parameters on H2O
dissociation and interfacial structure. Energy minimization
and molecular dynamics (MD) simulations were conducted
with periodic DFT methods to examine the relative energetic
stability of a variety of configurations. In order to more
completely sample configuration space, interatomic force
fields were developed for the H2O-TiO2 and H2O-SnO2
interfaces using the program GULP. Thus, classical MD
simulations could be carried out over longer time periods than
practical with the DFT method. The force field reproduces
structures calculated with DFT reasonably well and the
relative energies of configurations are similar between the two
methods. In addition, the effects of deprotonating the surfaces
to mimic the negative surface charge on real surfaces are
examined. Differences in H2O adsorption mechanisms are
attributable to unit cell parameters and basicities of surface
oxygen atoms. Starting with the associated H2O molecules we
have obtained the mixed associative-dissociated structure in
the case of SnO2. The most interesting observation is that
dissociation of H2O occurred indirectly. In the first stage, the
H+ bonds to a bridging oxygen from one of nearest H2O,
forming the intermediate OH– state. In the second stage, the
terminal H2O H+ transfers to the OH– ion forming the new
H2O molecule and terminal OH–. No such process was
observed for TiO2 surface. A stable mixed adsorption structure
was obtained by optimization after manual H+ transfer on the
same path as was spontaneously passed in the case of SnO2.
Analogously, starting with the broken H2O molecules in the
first layer, we have obtained the stable dissociated structures
both for TiO2 and SnO2 where hydroxyls were attached to
5-fold Me and H+ were bonded to the bridging oxygens.

Innovative technology
Costs for carbon dioxide (CO2) sequestration into deep
saline aquifers can be transformed into a benefit in
combination with ecologically desirable geothermal heat or
power production. The current “CO2Trap” project aims to
develop a scientifically and technically feasible new
technology to achieve a safe and economically attractive longterm storage of CO2 trapped in minerals. Numerical models
are applied to study injection of aqueous CO2 into the
subsurface and to quantify subsequent precipitation of calcite
(CaCO3) in potential geothermal reservoirs.

Geothermics and CO2 storage
Exploitation of geothermal energy in Germany is mainly
provided from deep sandstone aquifers. The common
arrangement of boreholes is the well doublet, consisting of one
well for hot water production and one well for cooled water
re-injection. The cooled water is loaded with dissolved CO2
generating carbonic acid. After re-injection into the reservoir
this cold water becomes enriched in calcium e.g. due to
dissolution of anhydrite (CaSO4). Because the solubility of
anhydrite increases with decreasing temperature, injecting
cold water dissolves anhydrite in a growing region around the
well. The favored reaction path, the transfer of anhydrite into
calcite, leads to a surplus of acid. Alkalinity to buffer the
reaction can be provided from rock forming minerals (e.g.
oligoclase). Subsequently CO2 will react with the calcium ions
to form and precipitate calcium carbonate.

Conclusion
We demonstrate the feasibility of transforming anhydrite
into calcite by reactive transport modeling. Buffering capacity
(alkalinity) from the reservoir rock is necessary for the
transformation of anhydrite into calcite. Although it turns out
that anhydrite is not the major player from the chemical point
of view, its dissolution with concurrent pore space increase is
important to balance the pore space reduction by precipitation
of calcite and secondary silicates in the geothermal reservoir.


Aqueous-solid solution model of strontium uptake in C-S-H phases  
D.A. KULIK, J. TITS AND E. WIELAND  
Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland  
(dmitrii.kulik@psi.ch)  

Cement wasteforms are composed mainly of calcium silicate hydrate (C-S-H) phases which can incorporate divalent cations such as Sr (including the fission product ⁹⁰Sr relevant in nuclear waste disposal). In this context, our C-S-H Aq-SS model was extended with Sr, Na, and K end members. We used our Sr uptake data in pure water and in artificial cement water (ACW); Nagra-PSI chemical thermodynamic database; and the GEMS code (http://les.web.psi.ch/Software/GEMS-PSI) in forward chemical modeling and inverse dual-thermodynamic calculations (DTC).  

DTC can retrieve unknown stoichiometry and standard molar Gibbs energy G° of an ideal solid solution end member from several experimental bulk compositions of co-existing aqueous solution and solid solution phases. Using DTC with 13 end member candidates, the following “optimal” stoichiometries were found: Sr(OH)$_2$SiO$_2$H$_2$O (SrSH); [(NaOH)$_{2.5}$ SiO$_2$H$_2$O]$_{0.2}$ (NaSH); [(KOH)$_{2.5}$ SiO$_2$H$_2$O]$_{0.2}$ (KSH), with the associated mean G°$_{298}$ values and 2σ uncertainty intervals.  

Two extended C-S-H quinary ideal solid solutions were used in forward modeling of our Sr uptake data (ca. 90 experiments at ambient T,P). Two modeled cement degradation scenarios show that Sr is retained much stronger in the “carbonation” than in the “dilution” (CO$_2$-free leaching) process.  

The Aq-SS approach requires somewhat different G°$_{298}$(SrSH) value for modeling Sr uptake in C-S-H (Ca:Si ~ 1.1±0.1) prepared in water than that prepared in the alkaline ACW. The difference (ca. 3.4 kJ mol$^{-1}$) could be explained by a weaker silicon tetrahedra polymerization in C-S-H during synthesis with alkali cations. Preliminary studies also indicate that the Ca-Na-K-Sr ion-exchange model on “tobermorite” sorbent may be more precise in predicting Sr uptake by C-S-H in ACW than the ideal solid solution model.

Binding of metal ions by natural organic matter (NOM) – Investigated by lanthanide ion probe spectroscopy (LIPS)  
M.U. KUMKE, SASCHA EIDNER, BETTINA MARMODEÈ AND STEFFANIE KUKE  
Institute of Chemistry, University of Potsdam, Karl-Liebknecht-Str. 24-25, 14476 Potsdam-Golm, Germany  
(Kumke@chem.uni-potsdam.de)  

The binding to natural organic matter (NOM) determines transport, bioavailability, and toxicity of metal ions in water and soil environments. The understanding of the underlying interaction mechanisms between NOM and metal ions is therefore indispensable for the development of reliable models for the prediction of mobility and fate of metal ions in the environment. Because of their outstanding spectroscopic properties lanthanide ions (Ln$^{3+}$) are excellent probes for the direct investigation of metal binding to NOM. Especially, the spectral sensitivity to changes in the close coordination sphere of the Ln$^{3+}$ ion as well as the dependence of the luminescence decay time on the type of ligand coordinated can yield valuable information on the stoichiometry and symmetry of metals bound to NOM.  

In our experiments Eu$^{3+}$ and Tb$^{3+}$ ions were used as luminescence probes to investigate the binding of metal ions to humic acids (HA) and fulvic acids (FA), which represent a major part of NOM. The Ln$^{3+}$ luminescence was excited either directly or via sensitization by radiationless energy transfer from HA or FA ligands. The intra- and intermolecular energy transfer processes were investigated in detail using H$_2$O and D$_2$O as solvents.  

Because of the high complexity of NOM simpler organic model ligands such as aromatic and aliphatic hydroxy carboxylic acids were investigated as well. In ultra-low temperature measurements at 4 K the non-degenerated $^5D_0$-$^7F_0$ transition of Eu$^{3+}$ and the Stark splitting of the $^7F_1$ and $^7F_2$ levels were used to evaluated the stoichiometry and the symmetry of the complexes formed. Furthermore, time-resolved luminescence spectra of Ln$^{3+}$-L (L = NOM or model ligand) measured in H$_2$O and D$_2$O were analyzed and the number of coordinated water molecules was determined.

A comet nucleus sample return (CNSR) mission in ESA’s Cosmic Vision program

M. KÜPPERS1, H. U. KELLER1, E. KÜHRT2 AND THE CNSR TEAM

1Max-Planck-Institut für Sonnensystemforschung, Katlenburg-Lindau, Germany (kkeppers@mps.mpg.de, keller@mps.mpg.de)
2Institut für Planetenforschung, DLR, Germany (ekkehard.kuehrt@dlr.de)

Rationale
We propose a comet nucleus sample return (CNSR) mission in the context of ESA’s Cosmic Vision plan. After the detailed investigation of comet 67P/Churyumov-Gerasimenko by the Rosetta orbiter and lander, a sample return mission is the logical next step in cometary exploration.

Scientific background
In comets we find a mixture of original interstellar grains with material that was re-processed in the solar nebula. That mixture is of particular interest for the study of the formation of the solar system. Laboratory investigation of samples brought back from different (active and inactive) regions of a comet allows to reveal this mixture of low and high temperature compounds. The Stardust mission has shown that those compounds are intimately mixed on small scales (Brownlee et al. 2006, Mc Keegan et al. 2006). The analysis of the returned sample from a cometary nucleus will determine the processes of the formation of the planetary system and their chronology (the amount of material collected by Stardust was too small to achieve that goal). It will be possible to determine how far out and in which proportion material processed near the Sun during the formation of our planetary system was transported out into the Kuiper belt where it was mixed with pristine interstellar material. A stratigraphic sample from a cometary nucleus will reveal the structure of the intricate porous mixture of ice-dust grains that make up a comet nucleus and provide for its unique activity.

The mission
A relatively small spacecraft will be launched into its interplanetary trajectory to a short period comet. After a short monitoring period near the cometary nucleus, needed to find suitable sampling spots, the spacecraft will touch down on the surface of the nucleus to collect samples. The sampling depth will be several decimeters. Finally the cooled samples will be returned to Earth. The mission is proposed to ESA’s Cosmic Vision and exploration programs, in co-operation with the Russian space agency.

Modeling study on glacial-interglacial variations of atmospheric CO2 concentration: The effect of Southern Ocean

TAKASUMI KURAHASHI-NAKAMURA1, AYAKO ABE-OUCHI1,2 AND YASUHIRO YAMANAKA1,3

1Frontier Research Center for Global Change, JAMSTEC, 3173-25 Showamachi, Kanazawa-ku, Yokohama, 236-0001 Japan (kijun@jamstec.go.jp)
2Center for Climate System Research, The University of Tokyo, 5-1-5 Kashiwanoha, Kashiwa, 277-8568 Japan (abeouchi@ccsr.u-tokyo.ac.jp)
3Graduate School of Environmental Earth Science, Hokkaido University, N10W5, Kita-ku, Sapporo, 060-0810 Japan (galapen@ees.hokudai.ac.jp)

Ancient air trapped in Antarctic ice cores shows that the atmospheric CO2 concentration, pCO2, was lower during the ice ages than it is today. For example, at the Last Glacial Maximum (LGM), pCO2 was 180-200 ppm which is roughly 80-100 lower than the pre-anthropogenic value. Although many hypotheses have been proposed to explain the pCO2 variations for two decades, there is no widely accepted explanation for the variations.

Geological records suggest that, during the LGM, the extent of sea ice in the Southern Ocean was greater than that at present. In this study, we used an ocean general circulation model (COCO3.4, an ocean component of our atmosphere-ocean coupled general circulation model, MIROC3.2 (K-1 Model Developers, 2004)) coupled with a simple biogeochemical model (Yamanaka and Tajika, 1996). We examined the model sensitivities to changes in sea ice extent in the Southern Ocean on pCO2 and discussed the effect of the Southern Ocean on the low pCO2. We obtained the following two results. First, the reduced ventilation due to the sea-ice expansion would have had only a small effect on the reduction of atmospheric CO2 concentration. The effect of reduced ventilation is much weaker than that predicted by a box model in a previous study. The difference resulted from the different efficiencies of water exchange between the surface water and the deep water in southern high-latitude regions. Second, sea-ice cover may have had the additional effect. If biological activity was reduced below the sea ice, the effect of decrease in consumption of CO2 through biological activity might exceed that of decrease in the supply of CO2 from the atmosphere. We propose that this effect was opposite and possibly stronger than the reduced-ventilation effect. These results suggest that sea-ice expansion was far from the principal mechanism for low CO2 concentration during the LGM.

Composition, temperature, and thickness of the lithosphere of the Kaapvaal craton

O.L. KUSKOV, V.A. KRONROD AND A.P. ZHIDIKOVA
Vernadsky Institute of Geochemistry and Analytical Chemistry Russian Academy of Sciences, 119991 Moscow, Russia (kuskov@geokhi.ru)

A new model is proposed for the structure of the Kaapvaal craton lithosphere. Based on self-consistent thermodynamic approach, profiles of the chemical composition, temperature, density, and S-wave velocities are constructed for depths of 100–300 km. For the computation of the phase diagram for a given chemical composition (garnet-bearing lherzolite xenoliths and primitive mantle composition, we have used a method of minimization of the total Gibbs free energy combined with the Mie-Grüneisen equation of state. Our forward calculation of phase diagram, seismic velocities and density and inverse calculation of temperature includes anharmonic and anelastic parameters as well as mineral reaction effects, including modes and chemical compositions of coexisting phases. The estimated temperatures depend rather strongly on bulk composition and proportion of phases stable at various depths of the upper mantle. We find that the upper mantle (normal and cratonic) cannot be treated as uniform in terms of bulk composition because a fixed uniform composition leads to a non-physical behaviour of geotherms. The mantle beneath the Kaapvaal craton is chemically stratified: an upper layer at depths between 100 and ~200 km consisting of depleted garnet peridotite and a lower layer (below ~200-220 km) made of a more fertile material [1]. The material composing the cratonic root at a depth of ~275 km does not differ in its physical and chemical characteristics from the composition of the normal mantle, and this allows one to estimate the thickness of the lithosphere at 275 km. The results of this work are compared with data of seismology, thermal investigations, and thermobarometry.

This research was supported by RAS under Programs 18 and ONZ-6, and by RFBR grant (06-05-64151).

Radiocesium distribution in North-West coast of the Kola Bay

N. V. KUZMENKOVA AND A. Y. MIROSHNIKOV
Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry Russian Academy of Sciences (nvkouz@igem.ru)

Introduction
The migration of $^{137}$Cs in North territories was investigated to better identify specieshes of its prevalence in tundra landscapes. The territory of interest is located from north-west coast of Kolskiy bay to Norway border.

Methods
Our method is based on landscape approach developed by A. I. Perelman. Depending on the relief character, the territory was subdivided into four geochemical landscapes. The eluvial landscape is located at the top of nipples, the transit landscape – on the slopes, accumulative and aqual (water) landscapes – on the bottom lands. According to this approach the geochemical map (scale 1:50 000) was created. During the investigation, about 500 samples of soils and lichens (cladonia, cetraria) from 154 points was taken.

Results and Discussion
Data of radiocesium distribution in soil genetic layers and plants were obtained. Areal with maximum $^{137}$Cs concentrations in soils and plants were determined. The highest $^{137}$Cs content in soil is 332 Bk/kg, in plant is 194 Bk/kg. The regularities of $^{137}$Cs distribution on the territory studied depending on location of supposed sourses is revealed.

The results of investigation of $^{137}$Cs vertical in the soil profile are obtained. It was defined that the most polluted components of landscapes are plants and top soil layer. The latter consists of indecomposable organic relics more than one half. This layer sustainibly retains $^{137}$Cs.

Conclusion
The detected levels of radiocesium pollution are much less than 1 ku/km², thus it is not dangerous to the people living on territory investigated.

Fluid inclusions of metamorphic rocks and a late-orogenic granitic intrusion

E.V. KUZMINA

Institute of Precambrian Geology and Geochronology RAS, Saint-Petersburg State University (EK@EK6762.spb.edu)

The Ladoga region is considered a typical example of andalusite-sillimanite type of metamorphic zoning in the southern part of the Baltic shield. On the basis of mineral assemblages and compositions, as well as the amount of leucosome in metapelitic rocks, the Ladoga region is divided into five metamorphic zones. The PT-estimates of the Early Proterozoic Ladoga metamorphic complex range from 3–4 kbar and 400–500°C to 5–6 kbar and 800–900°C.

The Tervu granite massif (intrusion) is one of the late-collision granites that intruded a high-grade core of the Early Proterozoic Ladoga metamorphic complex. The Tervu massif consists mainly of two feldspar mica granites with rare veins of aplite and pegmatite. The U-Pb age of zircon of the Tervu massif is 1.86 Ga. The age of monazite from the latest veins of the Tervu massif is 1.85 Ga. Minerals of the Tervu granite massif consist of different types of fluid inclusions such as H2O, H2O–salt (up to 1–3 % NaCl, KCl, CaCl2, MgCl2), CO2, CH4, N2. Original homogeneous allocation of a fluid phase is expected at the moment of crystallization of the massif. This is supported by the monotonic mineral composition of rocks of the massif, absence of significant bulks of facies and phase varieties. Fluid inclusions of the massif have more or less the same compositions, but there are also specific features of their allocation: 1) CO2 inclusions occur only in the northern and central parts of the massif, 2) aqueous, mineralized by salts Ca, Mg (Cl2) occur in the northern peripheral part, 3) methane - nitrogenous inclusions occur in the northern and central areas, 4) only aqueous occur in the south-east and northern areas of the massif, 5) aqueous inclusions with NaCl and KCl mineralization occur in the southern, central and northern parts, 6) aqueous inclusions with a low mineralization occur everywhere within the intrusion. Such variability of compositions of fluid implies that most likely the total contents of fluid in samples varied from the moment of crystallization because of new volatile phases, which have caused variations in composition of fluid inclusions in the most fluid-enriched rocks.

Comparison of compositions of fluid of the Tervu massif with composition of fluid of metamorphic rocks demonstrates mostly their similarity. However, the fluid inclusions enriched with salts CaCl2 and MgCl2 are not characteristic for the metamorphic rocks. It is possible to consider that genesis is primary magmatic for such fluid inclusions.

CO2 inclusions are unusual for the Tervu intrusion but the surrounding migmatitic leucosomes have a lot carbonic inclusions. Thus, the Tervu massif is characterized by unequal fluid compositions, and strong variations in density and salt contents in different parts of the massif. The specified features of allocation of fluid may be a consequence of redistribution of the fluid phases within the massif during post-crystallization tectonic and thermal processes.

30Si isotopic signature of major terrestrial and aquatic pools

YAKOV KUZYAKOV1, JÖRN BREUER2, AND MICHAEL SOMMER3

1Dep. of Agroecosystem Research, University of Bayreuth, Bayreuth, Germany (kuzyakov@uni-bayreuth.de)
2Dep. of Agricultural Chemistry, University of Hohenheim, Stuttgart, Germany (breuer@lachemie.uni-hohenheim.de)
3Institute of Geocology, University of Potsdam, Potsdam, Germany (sommer@zal.f.de)

Silica is the second most important element in the Earth crust. Weathering of minerals in soils as well as global Si fluxes have strong effects on the global cycling of many other elements including carbon. Despite the important role of Si in terrestrial and marine ecosystems and for living organisms, the knowledge about Si fluxes in biogeosystems is strongly limited. An important gap in the knowledge on global Si cycling is the absence of a clear explanation of the enrichment of marine ecosystems with 30Si – the heavy stable Si isotope. Therefore, we aimed this review on 1) critical evaluation of the 30Si data existing for various pools of terrestrial and marine ecosystems, and 2) linking 30Si signatures in terrestrial and marine pools by considering isotopic fractionation of 30Si by biological processes.

Based on the δ30Si values, the following processes can be reconstructed: Si dissolved by weathering of primary minerals becomes a component of soil solution. The elements in the soil solution, including Si, are mainly subject of two mass flows: upward uptake by plants and downward transport by leaching. As light isotopes are preferred for uptake in biological processes, δ30Si values in plants are negative: -1 to -2.5‰. The remaining soil solution will be enriched by 30Si. The 30Si depleted phytoenic Si remains in terrestrial biogeosystems, mainly in the upper soil horizons and will be reused by plants and microorganisms in further cycles. Therefore, at least a part of secondary minerals is 30Si depleted, which was biologically recycled at least once. The 30Si enriched soil solution discharge into rivers, seas and oceans. Further biological depletion by continental transport (limnic and fluvial systems) leads to additional accumulation of 30Si up to +0.5…+1.4‰ in discharge systems and seas.

O isotope exchange during the breakdown of dolomite: An experimental study

Dolomite commonly breaks down to periclase + calcite in the presence of an H2O-rich fluid in contact-metamorphic environments. We investigated the kinetics of the reaction in dolomite rock samples experimentally to determine whether 18O from the external fluid exchanged only with the neomorphic calcite and periclase or whether exchange between the fluid and preexisting dolomite occurred as well. We sealed 4×6 mm cylinders of rock in gold capsules with an aliquot of 18O enriched H2O and heated the capsule to 700 °C at 100 MPa for a period of up to 8 weeks. Samples were examined after experimentation by electron and ion probe techniques. The x-ray images indicated that some reaction took place along grain boundaries, even in the interiors of the sample. Ion images of the reacted sample were obtained from Cameca 4f, 7f, and 1280 ion probes to determine the distribution of 18O. Calcite produced during reaction showed an enrichment in 18O wherever the breakdown reaction had occurred. In addition, the dolomite shows a distinct 5–10µm-wide zone adjacent to the grain boundary that is also enriched in 18O (figure right). Point analyses across the exchanged zone at a scale of 1 µm indicate that the boundary between the exchanged and unexchanged dolomite is a step, although there is some indication of a diffusion profile at the boundary. That step suggests that the exchange occurred by solution-reprecipitation, but there is no secondary porosity or optical misorientation found. It appears that H2O does it again, greatly facilitating isotope exchange between a fluid and a preexisting mineral grain.

Evolution of the basal dense magma ocean: The ultimate deep mantle rug!

S. Labrosse1, J.W. Hernlund2, and N. Coltice3

1Laboratoire des Sciences de la Terre, Ecole Normale Supérieure de Lyon, CNRS, Université Lyon 1, France (stephane.labrosse@ens-lyon.fr)
2Department of Earth and Ocean Sciences, University of British Columbia, Canada (hernlund@gmail.com)
3Laboratoire des Sciences de la Terre, Ecole Normale Supérieure de Lyon, CNRS, Université Lyon 1, France (coltice@univ-lyon1.fr)

Since the discovery of the ultralow velocity zones in the lowermost mantle, evidences for the presence of partial melt at the bottom of the mantle have continually accumulated. The maintenance of the magnetic field for at least 3.2 Gyr requires cooling of the core over that period and implies an even larger quantity of melt in the lowermost mantle in the past than at present. We investigated the implications of such an hypothesis in terms of thermal and chemical evolution of the mantle and found that it can offer an explanation for several different observations. The crystallization of melt, controlled by the energy balance, is exponential to first order, with a time scale of about 1 Gyr. The melt is denser than the overlying solid that crystallizes from it, due to a larger Fe content. In addition, the huge viscosity contrast renders entrainment of melt by convection in the mantle negligible, preventing any sampling through surface magmatism. The melt is then the ideal hidden reservoir and can contain about 20% of the Earth’s budget in incompatible elements. Moreover, because of the difference between the partitioning coefficients of Sm and Nd at high pressure, the evolution of the deep magma ocean-mantle system naturally generates the observed ε143Nd in mantle derived rocks and explains the systematic of chondrites with all terrestrial samples in ε142Nd. The existence of melt in the lowermost mantle for most of Earth’s history, deduced from geophysical arguments offers a solution for some of the long-standing geochemical paradoxes of the Earth’s mantle.

3Department of Chemistry, Trent University, Canada

Mercury contamination is an environmental problem of increasing concern in the Amazon basin. In Bolivia, indigenous people have elevated methylmercury hair concentrations. This highly toxic molecule originates in the release of inorganic Hg from chemical and physical weathering and from human activities. The aim of our study is to trace the sources and the processes involved in the cycle of Hg, in the Beni River watershed, through variations in Hg isotopic compositions. Three types of samples are studied: sediments, liquid Hg0 from gold mining and hair from gold miner and indigenous populations. Hg isotopic compositions were analyzed on a Thermo-Finnigan Neptune MC-ICP-MS at Trent Univ. and at the LMTG after sample digestion by aqua regia at 120°C (Foucher and Hintelmann, 2006).

The δ202/198Hg values (relative to NIST 3133) are significantly different with respect to the external precision of 0.05-0.2 ‰ (2σ): -0.34 ± 0.02 ‰ for liquid mercury, -1.05 ± 0.14 ‰ for sediments, -0.44 ± 0.20 ‰ for miner hair (n=9), +1.18 ± 0.10 ‰ for indigenous people hair (n=12). Mass-independent isotope fractionation was observed for odd isotope ratios in all hair samples (Figure 1): ∆199Hg and ∆201Hg anomalies of up to 1.16 and 0.98 ‰ respectively were observed, and were more pronounced for miners than indigenous communities. Preliminary data on fresh and oxidized black shale samples show up to 2 ‰ variation.

Figure 1: Mass-independent fractionation observed for δ199/198Hg for gold-miner and indigenous people hair samples. Lines represent mass dependent fractionation.

First steps in the feasibility study of CO2 geological storages monitoring through noble gas geochemistry

S. LAFORTUNE1, M. MOREIRA1, P. AGRINIER1,
H. SCHNEIDER2 AND H. CATALETTE2

1Institut de Physique du Globe de Paris (IPGP), France
Research Program on CO2 underground sequestration
(lafortune@ipgp.jussieu.fr)
2Electricité de France (EDF), R & D, France

Since noble gases are relatively inert, and for some of them lighter than CO2, they migrate faster. Thus they are potential precursors to survey the integrity of CO2 storages. By monitoring the surrounding aquifers, it could be possible to detect these precursors (e.g.: Helium (He) or Argon form spikes or air-pollution), and then to properly survey the trapping efficiency of a storage. In order to study the noble gases dissolved in brines, we have developed a new fully automated line, linked to a quadrupole mass spectrometer QMS200 by Balzers. We extract our water samples in gas phase, trap the water vapor on cold traps, and then purify the residual gas phase to analyze noble gases with our QMS. Gas aliquots can be sampled in order to analyze isotopic ratios using our glass-made mass spectrometers Aresibo.

As preliminary step, we chose to validate our new line with a simple analogue of CO2 storages: the Pavin lake, in the French Massif Central. Pavin lake is a crater lake (max. depth 90 m), aged of about 6 000 years and resulting from a magmato-phreatic eruption. The water column of this lake is stratified in two major layers, isolating the lower one which accumulates biogenic or magmatic gases like CO2 or He.

We collected water samples in mechanically sealed copper tubes, and analyzed them using our system. Our results enable to plot dissolved 4He concentration profiles. Whereas the upper layer presents 4He concentrations around 7.81e-6 cm3STP/g of water at -40 m, the lower layer presents higher 4He concentrations with 5.64e-5 cm3STP/g at -80 m.

We focused our study on the water layer with the highest 4He concentration gradient (between -60 m to -70 m) to compare our results with those obtained by Aeschbach-Hertig et al. (1999). Our results between 2.49e-7 cm3STP/g at -60 m and 1.77e-6 cm3STP/g at -70 m are in accordance with those published in 1999. Helium isotopic ratios are also similar to the value obtained by Aeschbach-Hertig et al. (1999), i.e. the subcontinental mantle ratio (6.5 Ra).

The accordance of our results with those published by Aeschbach-Hertig et al (1999) validates our new extracting-purifying-analyzing line and completes the preliminary step of our work. Our aim is now to test on a CO2 natural accumulation in France, the feasibility of the monitoring methodology we suggest.

The geochemical behaviour of Pb during core formation and accretion

M. LAGOS1,2, C. BALLHAUS1, C. MÜNKER1 AND J. BERNDT2

1Universität Bonn, Germany (lagos@uni-muenster.de; ballhaus@uni-bonn.de; muenker@uni-bonn.de)
2Institut für Mineralogie, Uni-Münster, Germany (jberndt@uni-muenster.de)

The lead isotope signature of the Bulk Silicate Earth (BSE) is not consistent with a simple single stage evolution model but requires an early process that has fractionated U from Pb. Core formation might be such a process, as previous studies suggested that significant amounts of Pb are sequestered in the Earth’s core. To examine the role of metal segregation, we have determined sulfide-silicate and metal-silicate partition coefficients (D) of Pb at upper mantle PT conditions. Our results indicate that Pb is incompatible in Fe melts but compatible in Fe-S melts at O2-fugacities representative for terrestrial core formation. Uranium on the other hand is incompatible in both iron melt and sulfide melt [1]. Modelling shows that Fe-dominated melts do not sufficiently fractionate U/Pb ratios whereas pure sulfide melt segregation could have formed a δBSE~8, assuming that the bulk Earth started with low initial μ~0.7 [2]. However, segregation of a pure sulfide melt is probably not consistent with mantle abundances of chalcophile elements.

It has been also assumed that U-Pb chronometry might date a late stage of core formation with a small amount of sulfide-dominated melt sequestered to the Earth’s core [3]. The late addition of oxidized impact material (~ 10 %) with a maximum CI-chondritic sulfur content after segregation of a Fe-rich melt would limit the amount of segregated sulfide melt to 2-3 %. Such a small amount of sulfide melt would require a D_{Pb}^{(sulf姊al)}~1000 assuming complete sulfide-silicate equilibration, much higher than measured. This indicates that Pb-model ages probably do not date a late stage of sulfide segregation to the Earth’s core but rather reflect a volatile depletion process.

A light lithium source for komatiites

Y. LAHAYE1, H.-M. SEITZ1, G.P. BREY1 AND N.T. ARNDT2

1Institut für Geowissenschaften, University Frankfurt, Germany (lahaye@em.uni-frankfurt.de)
2LGCA, Grenoble, France

Komatiites provide key information on melting processes and the geochemical composition of the Archean mantle. To gain more insight we have analysed the Li isotopic composition of komatiites of various ages and from different localities. Li was chosen because it has been shown that its isotopes can be used to study melting processes within the mantle and characterise mantle sources [1].

Care was taken to analyse only the least altered whole rock samples and, in addition, separates of olivine phenocrysts. The olivines from the Phanerozoic komatiites of Gorgona range in δLi from +6.9 to -7.5‰ (5 samples). Exceptionally well-preserved late Archean komatiites from the Abitibi greenstone belt have δLi from +1.9 to +6.0‰ (4 bulk rocks). Their primary olivines (3 samples) yield much lighter compositions from -0.8 to -4.3‰. Samples from several localities within the early Archean Barberton Greenstone belt yield δLi between +0.2 to +7.1‰. Although no primary minerals are available, it is noticeable that the best-preserved sample has the lightest δLi.

Li-isotopes of bulk rock komatiites roughly coincide with the value for Bulk Silicate Earth of δLi = 3.3 to 4.0‰ [1, 4], while fresh olivine phenocrysts give varying and strongly deviating negative values. Even the freshest komatiites have suffered some degree of low temperature alteration and metamorphism so that the olivines should reflect the original isotopic signature of the magma. However, such negative values have not been observed in any modern type basaltic magma. Komatiites must tap a source not accessible to present day magma genesis. We speculate, in conjunction with the high Helium isotopic ratios in these olivines [2, 3], that the source material once resided in the lower mantle.

Tracing of industrial emissions in an urban environment using Pb, Sr, Nd, and C isotopes (tree bark biomonitoring and aerosol sampling)

M. LAHD GEAGEA, P. STILLE, F. GAUTHIER-LAFAYE AND M. MILLET
EOST-Centre de Géochimie de la Surface, CNRS-UMR7517, 1 rue Blessig, 67084 Strasbourg, France.

The chemical composition of the atmosphere is affected especially in the northern hemisphere by increasing concentrations of heavy metals due to both natural and anthropogenic emissions. These pollutants are concentrated in submicrometer aerosols, which can be transported through the atmosphere over long distances before their deposition. Grousset and Biscaye (2005) showed in their review paper that combined Sr, Nd and Pb isotope ratios are most powerful tracers to identify natural dust sources and to identify their transport patterns. It has also been shown in many studies that Pb isotope ratios provide a very effective method of tracing anthropogenic atmospheric pollution. However Sr and Nd isotopes have very seldom been used for environmental studies. Only recently a first comprehensive study of trace metal pollution by a steel plant has successfully been performed using tree barks as biomonitors and Pb, Sr and Nd isotope ratios as environmental tracers and shows that the combination of the three isotope systems is extremely powerful for tracing of an anthropogenic pollution (Lahd Geagea et al. 2007).

In the present study we can show that the combination of the three isotopic systems is also extremely powerful for the distinction of different industrial atmospheric emissions sources in the same urban environment. This is of importance because Pb isotope ratios alone do not allow such distinction since industrial emissions like domestic waste incinerators, chemical waste incinerators or steel plant have very similar Pb isotopic compositions (206Pb/207Pb, 87Sr/86Sr, 143Nd/144Nd) as environmental tracers and shows that the combination of the three systems is extremely powerful for tracing of an anthropogenic pollution.

Re-Os systematics of Svecofennian Ni-Cu deposits in Finland

K. LÄHTEENMÄKI1, P. PELTONEN2 AND G. BRÜGMANN3

1University of Helsinki, P. O. Box 64, FI-00014 University of Helsinki, Finland
2Geological Survey of Finland, P. O. Box 96, FI-02151 Espoo, Finland
3Max-Planck-institut für Chemie, Postfach 3060, D-55020 Mainz, Germany

Svecofennian magmatic Ni-Cu deposits are hosted by mafic-ultramafic intrusions that emplaced close to the peak of the Svecofennian orogeny (~1.89 Ga). These orogenic intrusions have a high potential for magmatic Ni-Cu sulphides and have been the main source of nickel in Finland. One mine – Hitura – is in current production. The studied intrusions are located in different areas of the Svecofennian domain: Vammala and Hyvelä are a part of the Vammala nickel province in SW Finland, while Kotalalhti, Rytykyl and Hitura belong to the Kotalalhti Ni-belt close to the craton margin in eastern Finland. Previous studies have emphasized the significant role of crustal contamination, but the nature of the assimilant and timing of the magma-country rock interaction has remained controversial.

We report Re-Os results from these five deposits in order to constrain the origin of the ores in more detail. Eighteen whole-rock samples and five sulphide fractions were analyzed, all but one from the mineralized parts of the intrusions. Os and Re contents in the whole-rock samples range from 0.012 to 57 ppb and 0.24 to 654 ppb respectively, and in the sulphide fractions from 14.6 to 5580 ppb and 92.1 to 1187 ppb respectively. The Re/Os-ratio ranges between 1.4 and 37.3 with an average of 13.9. The Re-Os variation shows very little secondary disturbance and the samples from all intrusions define a Re-Os isochron giving an age of 1993± 29 Ma and an initial 187Os/188Os value of 0.32± 0.10. The radiogenic composition of the ores indicate crustal contamination, which is supported by low εNd (1900 Ma) values (-1.4 – 0.4) process, but occurred at deeper crustal levels. Sulphides have probably been transported in suspension to their present location.

Our results imply that crustal contamination led to the sulphide saturation in these Svecofennian orogenic magmas, and that this was not an in situ process, but occurred at deeper crustal levels. Sulphides have probably been transported in suspension to their present location.

Different sources of bacterial methane revealed by radiocarbon dating – Example from glacially deformed sediments, Denmark

T. LAIER1 and J. HEINEMEIER2

1Geological Survey of Denmark and Greenland (tl@geus.dk)
2University of Aarhus, Denmark (jh@phys.au.dk)

Methane is widespread in the Quaternary deposits, up to 200 m thick, of northern Denmark. Seabed sediments of the coastal seas are also rich in gas. Moreover, seeps and authigenic methane-derived carbonates are observed along the coast. Stable isotope data show that all of the methane is bacterial in origin, although radiocarbon datings of methane from different areas show a large variation, Fig. 1.

![Figure 1. Methane radiocarbon ages. Circles = Skagen-3 well; solid squares = shallow wells; open squares = submarine seeps; crosses = seabed sediments.](image)

In areas characterized by continuous deposition, the age of methane increases with the depth and age of the sediment: Skagen-3 well and piston cores [1]. However, methane from seeps [2] and some shallow wells is much older than would have been expected from its depth of occurrence. The shallow high-age methane is most likely derived from organic-rich interglacial marine deposits which were deformed and brought to shallower depths during the last ice-age, as is nicely illustrated in nearby coastal cliff exposures.

Nickel immobilization by coprecipitation with calcite

L.Z. LAKSHTANOV1,2 and S.L.S. STIPP1

1NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen O, Denmark (stipp@geol.ku.dk)
2Institute of Experimental Mineralogy RAS, 142432 Chernogolovka, Russia (leonid@iem.ac.ru)

Nickel contamination from industrial and mining activities can pose a serious risk to groundwater. Because Ni is toxic to plants and animals, data describing its behaviour and fate are required for valid assessment of risk and designing effective remediation strategies. Because the interaction of calcite with Ni controls its distribution in calcareous environments, better understanding of the mechanisms responsible for nickel uptake would improve modelling capabilities.

This work investigated calcite’s affinity for Ni and extent of partitioning into calcite precipitated from electrolyte solutions under strictly controlled conditions. Experimental conditions and all solution variables were held constant for each run and varied systematically in separate experiments.

Ni was moderately partitioned from solution into calcite. For dilute solid solutions (X_Ni < 0.001), $\lambda_{Ni}$ was estimated to be $\sim 1$ at $pCO_2 \sim 1$ atm and $10^{-3.5}$ atm and was weakly dependent on calcite precipitation rate in the range of 3-230 nmoles m$^{-2}$ s$^{-1}$. Changing $pCO_2$ does not imply any change in Ni incorporation mechanism, in spite of the significant impact of $pCO_2$ on calcite surface speciation. Ni molar fraction in the solid is directly proportional to Ni concentration in the solution. The fit of the data to such a model is good evidence that Ni is incorporated as a true solid solution, not simply by physical trapping.

Extrapolation of our experimental results to lower recrystallization rates ($\sim 10^{-2}$ nmoles m$^{-2}$ s$^{-1}$) gives $\lambda_{Ni} \sim 1.5$. It may be that this value is never exceeded in any natural or laboratory calcite (re)crystallization process so $\lambda_{Ni}$ may always lie within the limits of 1 – 1.5. Ni follows the behaviour of other elements with $\lambda > 1$ (Cd, Mn, Co) for which equilibrium $\lambda$ values are never achieved.

The effect of coprecipitation on nickel retardation in natural systems depends on $\lambda_{Ni}$ and on the thickness of a surface layer of solid solution equilibrated with the aqueous phase within a given period of interest. Coprecipitation will be important if large enough amounts of secondary calcite precipitate and if precipitation / recrystallization rates are high compared with transport rates in the solution. Considering a flow rate of $\sim 10$ m/year and Ni concentration $1\mu$M, Ni flux would be $0.3$ nmoles m$^{-2}$ s$^{-1}$, which is compatible with calcite recrystallization rates. With $\lambda_{Ni}$ obtained in this work, the mass distribution coefficient of Ni$^{2+}$ to calcite was calculated to be $K_d = 4$ at pH=8 and $K_d = 0.5$ at pH=6.5 for one (re)crystallized monolayer of calcite. This results in corresponding retardation factors R = 37 and 6. This means that solid solution partitioning to calcite can lead to a significant reduction in Ni mobility over a wide pH range.
**Genetic considerations in microbial silicification**

**Stefan Lalonde**¹, **George Ottrim**² and **Kurt Konhauser**¹

¹Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada (stefanw@ualberta.ca)
²Department of Biological Sciences, University of Alberta, Edmonton, Canada

The encrustation and entrapment of microbes in silica sinter is an inevitable outcome of life in some hydrothermal systems, where disequilibrium conditions lead to the spontaneous precipitation of amorphous silica. As some of the oldest evidence for life on Earth is found in >3.5 Gyr cherts, understanding factors that control the silicification process is critical to the study of life’s antiquity. Research to date has largely focused on the relative rates at which different microbes become encrusted with silica. These studies have generally demonstrated that microbes play a largely passive role in the silicification process, where their surface layers, or any other exposed surfaces for that matter, become encrusted with silica simply as a consequence of living in systems where its precipitation is inevitable. The influence of silica on the life of the microbe, however, has been given much less attention. In both the field and the laboratory, bacteria grow under conditions that are highly supersaturated with respect to amorphous silica, and in some cases, biological responses, such as sheath thickening for cyanobacteria, or increased EPS production in biofilms, have been noted. In order to better understand the dynamic interplay between microbe and mineral in these systems, we examined several relevant bacteria (i.e., a sheathed and unsheathed cyanobacteria, and a biofilm-forming thermophile) for biological responses to the silicification process that are manifest at the proteome level. Polyacrylamide gel electrophoresis was used to separate proteins that were regulated in response to the silicification process for identification via mass spectroscopy. Our results indicate that microbes are genetically equipped to respond to the silicification process, and although at present there is insufficient data to make any phylogenetic inferences, this study raises interesting questions regarding the role of silica in the survival of Earth’s earliest life forms.

**Lithogeochemical identification of Ni-Cu mineralised intrusions using fertility analysis**

**P. Lamberg**

Outokumpu Research, PO Box 60, 28101 Pori, Finland (pertti.lamberg@outokumputechnology.com)

**Nickel and cobalt numbers**

A novel lithogeochemical exploration methodology for nickel sulphide and PGE deposits utilising lithogeochemistry of barren cumulates was developed. The essential part of the fertility analysis is to identify whether target has experienced sulphide saturation and segregation. For that purpose two parameters, nickel and cobalt numbers, were introduced:

\[
\text{Ni#} = 100 \times \frac{\text{Ni}}{\text{Ni} + \text{Cu}} \\
\text{Co#} = 100 \times \frac{\text{Co}}{\text{Ni} + \text{Cu} + \text{Co}}
\]

Fractionation of olivine from ultrabasic-basic magma brings the Ni# down but Co# remains at the same level, whereas segregation of sulphides increases the Co# significantly in the residual melt and in sulphides equilibrium with it. Therefore the Ni# describes the primitiveness of the magma from which sulphides have segregated and the Co# indicates the nickel depletion. In primitive komatiitic and picritic systems the Ni# is greater than 75, in basaltic 50-75 and in more evolved flood basalts <50. The calculation is reliable if sulphides are a cumulus phase, i.e. >0.3 wt%.

In studied Ni-Cu ores Co# was low, at 1-5, but it increased in the stratigraphic units above the ore. In the ultramafic intrusions the range was quite narrow, at 2.9-15, but in differentiated mafic intrusions the range was as wide as 3-60. In depleted intrusions Co# was uniformly high, >10.

**Fertility analysis**

The parameters of the fertility analysis quantifying the requirements of the Ni-Cu sulphide ore formation are: 1) primitive character of the magma, 2) extent of sulphide saturation, 3) Ni-rich, chalcophile undepleted magma, 4) magmatic sulphides that are in equilibrated with a large amount of magma, 5) coeval primitiveness and sulphide segregation, 6) sulphide accumulation and 7) fractionation or mobilisation of sulphides. The values of the parameters and value of the overall discrimination index, OD, are calculated from the whole-rock analyses of the rock samples (Lamberg 2005). Mineralised samples are excluded from the analysis.

In the test with extensive lithogeochemical datasets of the Svecofennian intrusions of Finland (7517 samples / from 353 targets), Thompson Ni belt, Canada (287/27) and Cape Smith belt, Canada (287/27), the fertility analysis successfully discriminated between fertile and barren targets.

In low grade PGE deposits, Kevitsa and Duluth, Co# was found to correlate negatively with total PGE grades indicating that Co# may be a potential tool for identifying PGE potential intrusions and their parts and localising mineralised reefs.

Investigation of biominerals in the human knee of advanced osteoarthritis

L. LAMMERS¹, M. FUERST²,³ AND H.P. WIESMANN¹

¹Department of Cranio-Maxillofacial Surgery, University Hospital, Muenster, Germany (Lydia.Lammers@ukmuenster.de; Hanspeter.Wiesmann@ukmuenster.de)
²Department of Orthopaedics, University Medical Center, 22143 Hamburg-Eppendorf (mfuerst@uke.uni-hamburg.de)

Motivation

Osteoarthritis (OA) is a painful joint degeneration disease and in most cases leading to a complete surgical knee replacement. There is evidence that pathologic mineralisation contributes to OA (Swan et al., Pritzer et al.), but an actual distribution and composition of involved minerals, as well as the mechanisms of their generation still remain poorly understood.

Our intention was to find an effective and implementable way to analyse methodically the presence, nature and composition of minerals in the knee, to find out more about the physiological processes which lead to this special mineralisation.

Methods

Our studies were carried out on pieces of cartilage of medial femur condyle gained from over 30 different patients undergoing total knee replacement surgery. Additionally, chondrocytes obtained from these cartilage-specimens were cultured and investigated. We used several analytical methods in conjunction, including radiography, optical polarised light microscopy (LM), SEM, TEM, X-ray microdiffraction and Raman spectroscopy.

Results

Mineralisation was discovered in all specimens and analysed with the mentioned methods. Almost amorphous or polycrystalline hydroxyl-apatite was detected in huge amounts. In some cases idiomorphic calcium pyrophosphate was detected, but mostly associated with hydroxyl-apatite.

Discussion

Our data imply that mineralisation of articular cartilage seems to be a common event in end-stage OA. However, calcium pyrophosphate appears not to be the initiator of this disease. Instead, the mineralisation of apatite is a more likely cause, considering it was identified in all specimens. The production of pyrophosphate inside the cells perhaps functions as an inhibitor to reduce further mineralisation of apatite in cartilage.

**Geochemical constraints on Shaxi porphyry Cu-Au deposit: A possible link to adakitic genesis?**

**XIANGHUA LAN**\(^1\) AND **XIAOYONG YANG**\(^{1,2*}\)

\(^1\)CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University Science and Technology of China, Hefei 230026, China (*xyyang@ustc.edu.cn)\(^\dagger\)

\(^2\)State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

**Introduction**

The Shaxi porphyry Cu-Au deposit is located in the northwestern part of the Luzong volcanic basin, as one of important metallogenic belt in Yangtze valley. Tectonically, the Tan-Lu and Tongcheng-Fanshan faults cut and passes through the ore district. Former studies show that this deposit has a genetic link to the Yansha nian intrusive (c.a.130 Ma), consisting of quartz diorite porphyrite.

**Experiment and Results**

The total REE content of the Shaxi porphyry Cu-Au deposit ranges from 69.31×10\(^{-6}\) to 123.7×10\(^{-6}\), the ratio of \(\sum \text{Ce} / \sum \text{Y}\) is relatively high, ranging from 7.55 to 11.53, and the ratios of (Ce/Yb)\(_N\) and (La/Yb)\(_N\) range from 18 to 38, much higher than those of Shaxi, the ratios of (La/Sm)\(_N\) and (Gd/Lu)\(_N\) are all around 2 or so. The relative low \(\delta\text{Eu}\) anomaly was determined ranging from 0.8 to 0.95. The REE distribution pattern exhibits relatively large fractionation between LREE and HREE. The spider diagrams of trace elements such as Sc, Cr, Co and Ni and some transitional compatible elements such as Ti, V, Mn, Fe and Cu in the Shaxi Cu-Au porphyry deposit have have experienced strong fractionation as compared to the trace elements of crust rocks. The igeous rocks related to Cu-Au mineralization in this area have high concentrations of Al\(_2\)O\(_3\) and Sr, low contents of Y, with very high ratios of Sr/Y and La/Yb. All these geochemical characteristics resemble the distinct adakitic genesis. This study presents the fact that the Shaxi porphry Cu-Au deposits have possible link to the subduction of the Pacific Ocean to the east China continent edge from southeast to northwest in Mesozoic. This processing brought a large mount of oceanic crust to produce the adakitic rocks in Yangtze megalogenic region. During this oceanic-crustal collision and later magmatism, the Cu and Au and other uncompatiable elements enriched.

**Determination of SO\(_4^{2-}\) sources using stable S isotope for two karstic ground water systems, Guizhou Province, Southwest China**

**Y.-C. LANG, C.-Q. LIU, S.-L. LI, F. GU AND Z.-Q. ZHAO**

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (langyc822@163.com, liucongqiang@vip.skleg.cn, lisiliang@vip.skleg.cn, xgufux@126.com, zrzzhaozhiqi@163.com)

The objects of this study were to understand the sources of sulphate ion and its geochemical cycling in the karstic surface and ground water of the two largest cities, Guiyang and Zunyi, in Guizhou Province, China. The sulphur isotopic compositions of sulphate ions in different water samples largely vary, with a large variation of \(\delta^{34}\text{S}_{\text{SO}_4}\) values from -20‰ to +30.5‰, as shown the table blow.

The sulphate ions in the studied surface and ground water are of multiple sources, mainly derived from the dissolution of mineral and rocks, from rain water and anthropogenic inputs. Combined use of sulphur, carbon and strontium isotopes as tracers of sources and geochemical processes leads to a better understanding of water/rock interaction, oxidation of sulfide minerals and sulphur-containing organic matter. Sulphate ions of anthropogenic and natural sources show different isotopic composition, which allows identification of different contributions of various sources. Ground water of from city zone has much higher concentrations of sulphate ion as compared to that from outskirts of the city, suggesting that karstic ground water system is subject to pollution by human activities. Sulphur isotopic signatures and chemical composition of water show that carbonate rock was dissolved by both of sulphuric and carbonic acid, which needs further studies considering global carbon cycling.

ATEM-EELS study of diamond-like phases in the B-C-N system

F. LANGENHORST1,2 AND V.L. SOLOZHENKO3
1Institut für Geowissenschaften, Universität Jena, Burgweg 11, D-07749 Jena, Germany; Falko.Langenhorst@uni-jena.de
2Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany
3LPMT-CNRS, Université Paris Nord, F-93430 Villetaneuse, France; vls@lpmtm.univ-paris13.fr

Diamond is the hardest known material but its technical use as abrasive tool is limited by the finite thermal stability. On the other hand, cubic BN is thermally more stable and resistant to oxidation but is less hard than diamond. It is thus desirable to synthesize ternary diamond-like B-C-N phases that may combine the best properties of both materials.

To synthesize such B-C-N phases we have used static (multi-anvil, diamond anvil cell) and dynamic (shock) high-pressure techniques pressurizing nano-powdered graphite-like (BN)0.5C0.5 to 30 GPa at temperatures up to 3500 K [2]. The structures, compositions and properties were subsequently studied by analytical transmission electron microscopy, electron energy loss spectroscopy, and X-ray powder diffraction.

Analyses of recovered materials reveal the formation of nanocrystalline diamond-like B-C-N compounds of variable composition ranging from BC2N to BC8N. B, C and N are homogeneously distributed in nanocrystals; superstructures with ordered arrays of C and BN have not been observed. The lattice constant $a$ is a linear function of the composition. The variation in chemical compositions indicates however that there is no complete solid solution between diamond and cubic BN. Due to supersaturation of diamond in the BN component all ternary diamond-like B-C-N phases tend to decompose at high temperature into an diamond + cubic BC assemblage.

Ordering of the Al cation distribution in the octahedral sheets related to the ordering of Al in the tetrahedral sheets of phlogopite studied by $^1$H $^{29}$Si CPMAS NMR spectroscopy

R. LANGNER AND M. FECHTELKORD
Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität-Bochum, Universitätsstraße 150, 44780 Bochum, Germany (Ramona.Langner@ruhr-uni-bochum.de)

Our research project is part of the ORION-project (Ordering of Ions in Minerals) in the EuroMinSci programme of the ESF which aims the elucidation of ionic ordering in three exemplary systems by combining experimental investigations and theoretical calculations. One of the systems to be investigated is phlogopite, a trioctahedral 2:1 layer silicate.

Previous NMR solid state experiments of phlogopites indicated a non-statistical distribution of cations and anions in the octahedral sheets: F prefers sites coordinated by three Mg, whereas OH prefers sites with Al as next-nearest-neighbors (Fechtelkord et al. 2003). Further investigations will be carried out on phlogopites with various Al-contents and synthesized at different temperatures. In addition to that, cross-polarization (CP) experiments will be performed to clarify, whether the degree of ordering in the octahedral sheets is related to that in the tetrahedral layers.

The CP experiment is a double resonance experiment which allows the transfer of magnetization from a nucleus with a strong magnetic polarization due to its high natural abundance and high magnetogyric ratio, such as $^1$H, on a nucleus with a low spectral resolution such as $^{29}$Si via heteronuclear dipolar interaction. The increase of magnetization is a function of the cross polarization time, the number of proton spins, and the distance of these spins, $r_{ij}$, to the $^{29}$Si nucleus. Thus, direct neighborhoods of protons in the octahedral sheets to Si environments in the tetrahedral sheets can be correlated in one- and two dimensional CPMAS NMR experiments. Moreover, information on the position of Al in both sheets can be achieved indirectly.

Our first experiments clearly indicate a direct neighborhood of aluminum in the tetrahedral sheets to aluminum in the octahedral sheets and, thus, a relationship between the ordering of ions in both sheets.

Earthworm calcite production rates

GRAHAM LANGWORTHY1, MARK E. HODSON1 AND MATT CANTI2

1Department of Soil Science, School of Human and Environmental Sciences, University of Reading, RG6 6DW, UK (m.e.hodson@reading.ac.uk)
2Ancient Monuments Laboratory, Centre for Archaeology, Fort Cumberland, Eastney, PO4 9DL, UK (Matt.Canti@english-heritage.org.uk)

It is a little known fact that many species of earthworm excrete calcite granules. These comprise either individual or aggregates of calcite crystals that can reach up to 2.5 mm in diameter. Despite being described by Darwin (1881) relatively little work has been carried out on these granules. It is known that the granules form by the coalescence of CaCO3 spherulites in the calciferous glands but the function of the granules is unclear – possibilities include, Ca, CO2 and pH regulation though significant problems exist with each of these hypotheses.

Preliminary work by Canti indicated granule production rates by the earthworm *Lumbricus terrestris* of up to 76 mg calcite in 35 days (2.2 mg per day). Assuming an average earthworm density of 300 m^-2, this corresponds to a rate of production of 2.4 moles of calcite m^-2 year^-1. Calculated another way earthworm calcite granule production potentially retains c. 60 kgC ha^-1 yr^-1 in the soil. Typical CO2 soil fluxes are 5 – 315 mol CO2 m^-2 yr^-1 and typical soil C sequestration measures would remove 300 to 800 kgC ha^-1 yr^-1. Thus earthworm calcite granules are potentially highly significant in the terrestrial C cycle.

In this presentation we consider the influence of soil chemistry on granule production rates. *L. terrestris* were cultured in high Ca - high pH, high Ca – low pH, low Ca – high pH and low Ca – low pH soils for 70 days. After 35 and 70 days calcite granules were extracted from the soils and production rates were determined. The impact of soil chemistry on production rates and also the impact of the calcite granules on the final soil pH will be discussed.

Residence time of suspended particles in the Dordogne River: Indications derived from ^7^Be and ^210^Pb

AURELIE LANOUX1, SABINE SCHMIDT1, HENRY ETCHEBER1, THOMAS CONDOM2 AND HANNA-K. SAARI1

1UMR5805 EPOC, Université Bordeaux 1 - CNRS, Avenue des Facultés, F-33405 Talence (s.schmidt@epoc.u-bordeaux1.fr)
2EA 2957 – Institut EGID, Université Bordeaux 3, 33607 Pessac Cedex, France (thomas.condom@egid.u-bordeaux.fr)

Particulates that enter the ocean from rivers are the products of integrated basin-wide processes (soil erosion, sediment transport and deposition in watersheds). The fate of sediments in river is therefore challenging and generally analysed using hydrodynamics models. An alternative method relies on the use of fallout radioactive tracers, such as ^7^Be, ^210^Pb and ^137^Cs, to identify sediment source regions and/or to estimate suspended sediment age or the fraction of the suspended sediment recently eroded from the landscape (Dominik et al, 1987; Matisoff et al, 2005 and references herein).

This work presents the application of the two naturally occurring radionuclides ^7^Be (T1/2 = 53 days) and ^210^Pb (T1/2 = 22.3 years) to investigate residence times of particles in the Dordogne River (South-West France). The Dordogne River has a watershed of 24 500 km² with a mean discharge of 320 m³ s⁻¹ (max 12500 m³ s⁻¹). It flows westward about 500 km from the mountains of Auvergne, ending into the Gironde, its common estuary with the Garonne River, in the north of the city of Bordeaux. To characterize the suspended sediments of the Dordogne River, repeated samplings were performed from January through August 2007 at selected sites along this river system. Particulate and dissolved activities of radionuclides were determined using a low-background, well-shaped γ spectrometer. Additional examinations of river discharge, rain rate and particulate organic carbon were done to better interpret radioanuclide data. Particulate ^7^Be and ^210^Pb activities present marked spatio-temporal variations; dissolved fractions are always low. To derive sediment ages from the present dataset, two distinct modellings have been used: 1/ based on radionuclide budget (Dominik et al, 1987), and 2/ using ^7^Be/^210^Pb activity ratio (Matisoff et al, 2005). The age estimates will be compared in order to discuss the interest of each model in a large river system.

Lu-Hf age and isotope systematics of the Dora Maira nappe, western Alps

T.J. LAPEN¹, C.M. JOHNSON² AND B.L. BEARD³

¹Univ. Houston (tjlapen@uh.edu)
²Univ. Wisconsin - Madison (clarkj@geology.wisc.edu; beardb@geology.wisc.edu)

Lu-Hf garnet-whole rock geochronology applied to metamorphic rocks that contain old and unequilibrated zircon can effect both the isochron age and calculated initial Hf isotope composition. In order to better constrain the magnitude of these effects, we have performed Lu-Hf isotope analyses of the Dora Maira nappe because it contains zircons that are ~230 Ma older than the age of metamorphism.

The sample locality within the Dora Maira contains pyrope megacrysts within a matrix of mostly quartz and white mica. Evenly distributed throughout the major phases are zircon grains that contain ~275 Ma cores and ~35 Ma rims; locally, the 35 Ma zircons are unzoned (Gebauer et al., 1997; Lithos, 41:5-24). Preservation of old U-Pb zircon ages suggests that Hf within the zircons may have only partially equilibrated with the UHP metamorphic assemblage, producing two reservoirs of Hf: one in old zircon and another in UHP-equilibrated phases that crystallized at ~35 Ma. We have conducted Lu-Hf isotope analyses of garnet and matrix phases such that the entire sample was digested, including unequilibrated zircon. This approach contrasts with the digestion methods used by Duchêne et al. (1997; Nature, 387:586-589), which were designed to avoid dissolution of zircon. The Lu-Hf age and initial ¹⁷⁶Hf/¹⁷⁷Hf ratio determined using the complete dissolution method is 35.74±0.71 Ma (2σ) and 0.282580±7, respectively; this compares with 34.1±1.2 Ma and 0.282661±16 obtained by Duchêne et al.

The difference in age and initial Hf isotope compositions between our isochron and that of Duchêne et al. reflects a rotation of the isochron due to inherited zircon. The atypically high ‘whole rock’ ¹⁷⁶Lu/¹⁷⁷Hf ratio of 0.263 (Duchêne et al., 1997) is much higher than would be expected for any reasonable protolith and highlights the strong leverage that zircon has on the effective Lu/Hf ratio and Hf evolution of the zircon-free matrix reservoir between the time of protolith crystallization and Alpine meta-morphism. Based on the present data, we calculate that roughly 30-40% of the protolith zircon (by volume) equilibrated during metamorphism. This partial equilibration preserves significant differences in Hf isotope compositions between the two reservoirs and is coupled with a systematic, but subtle difference in the measured Lu-Hf ages which are within error of one another. Because some zircon will be dissolved during sample digestion regardless of technique employed, any liberated Hf that did not isotopically equilibrate during metamorphism will result in the rotation of an isochron. In order to obtain accurate Lu-Hf ages of rocks such as the Dora Maira, the difference in age between protolith zircon and metamorphism must be less than a few 10s of Ma or nearly all of the zircon must have equilibrated with its co-existing phases during metamorphism.

Geochemical characteristics of eclogites from the Eastern part of the Kokchetav complex (N. Kazakhstan)

T. LARIKOVA

Institute of Ore Deposits, Mineralogy, Petrology and Geochemistry of Russian Academy of Sciences, Moscow, Russia (larik@igem.ru)

Amphibolised eclogites were studied in the eastern part of the Kokchetav complex (Borovoe region). They consist mainly of garnet, omphacite, quartz, and rutile. During the retrogression, eclogites assemblages became unstable: omphacite was substituted by clinopyroxene-plagioclase symplectites. Garnet grains were surrounded by two coronas: an inner (adjoining to garnet) made of plagioclase (sometimes - of symplectites of Pl and Cpx), an outer – of hornblende. Rutile is surrounded by ilmenite, and by titanite rims. Borovoe eclogites show a P-T peak conditions (at T=670-690 C, P=16-19 kbar) of the metamorphism, its decompression stage with Cpx-Pl symplectite development at 9-12 kbar, and final transformation to garnet amphibolites. Host quartz-phengite schists show similar P-T parameters (up to 20 kbar).

Major and trace element study of the Borovoe eclogites provides an insight into their magmatic petrology, and also to the later metamorphic transformations: dehydration processes during the subduction of the basalts, and to the amphibolisation of the eclogites at the exhumation stage.

Geochemistry of the eclogites shows that their protolith composition probably corresponds to the MORB and/or island-arc basalts. Depletion in the light REE, that is observed in some samples, might be related to these elements loss during dehydration of the subducted oceanic crust.

Strong enrichment in large-ion-lithophile-elements (LILE) and U may be due to the amphibolisation of the eclogites during their exhumation stage. Moreover trace elements concentrations probably vary slightly depending on the extent of the retrograde changes of the eclogites.

Thermodynamic potential for the 
abiatic synthesis of nucleobases, 
ribose, and deoxyribose under 
submarine hydrothermal conditions

D.E. LAROWE¹ AND P. REGNIER²
¹Department of Earth Science – Geochemistry, Utrecht 
University, Utrecht, Netherlands (larowe@geo.uu.nl) 
²Department of Earth Science – Geochemistry, Utrecht 
University, Utrecht, Netherlands (p.regnier@geo.uu.nl)

Common to all organisms, ribose, deoxyribose, and the 
five common nucleobases (or, nucleic-acid bases) are 
constituent molecules of nucleotides, which are involved in 
the storage (DNA) and transmission (RNA) of genetic 
information. They serve as bioenergetic intermediates (ATP, 
GTP), oxidation-reduction couples (NAD and NADP) and are 
central to poly saccharide synthesis (UDP). Because these 
molecules are essential to so many basic metabolic functions, 
documenting the range of fluid compositions and chemical 
potentials required to generate and stabilize nucleobases and 
(deoxy)ribose is crucial to better understanding conditions that 
were conducive for the emergence and early evolution of life.

Due to the high chemosynthetic potential created by fluid 
mixing in extant hydrothermal systems and the relatively close 
phylogenetic relationship that many thermophilic organisms 
might have with the last common ancestor, numerous 
experimental and theoretical studies have explored the role 
that submarine hydrothermal environments may have had in 
hosting the origin of life. In this study, we have quantified the 
thermodynamic potential for the abiotic synthesis of 
nucleobases (adenine, cytosine, guanine, thymine, and uracil), 
ribose, and deoxyribose as a function of temperature, pressure, 
and bulk fluid composition using formaldehyde and HCN as 
precursor building-block molecules. Under low concentrations 
of these precursors and for a wide range of temperature and 
pressure conditions, favorable thermodynamic conditions are 
established for the abiotic synthesis of ribose, deoxyribose and 
all of the common nucleobases except thymine. A 
thermodynamic description and interpretation of the 
biogeochemical reactions involved in these pre-biotic 
processes can be used to design experimental investigation of 
the abiotic synthesis nucleic-acids and related biomolecules.

The Paleocene volcanic succession in 
West Greenland: Compositions, 
volumes, and mantle sources

L.M. LARSEN¹ AND A.K. PEDERSEN²
¹Geological Survey of Denmark and Greenland (GEUS), Øster 
Voldgade 10, DK-1350 Copenhagen K, Denmark 
(lml@geus.dk) 
²Geological Museum, Natural History Museum of Denmark, 
Øster Voldgade 5-7, DK-1350 Copenhagen K, Denmark 
(akp@snm.ku.dk)

The Paleocene volcanic succession on Disko and 
Nuussuaq in West Greenland consists of up to 2 km of of 
mainly picrites with on average 15.7 wt% MgO (the Vaigat 
Formation, VF) overlain by up to 2 km of tholeiitic flood 
basalts with on average 6.5 wt% MgO (the Maligât Formation, 
MF) (MgO in uncontaminated rocks). The whole succession 
has been dated at 62–60 Ma, with no measurable time lapse 
between the two formations.

The picrites of the VF represent unfractionated or slightly 
fractionated primary magmas, whereas the basalts of the MF 
are three-phase cotectic and distinctly fractionated. About 5% 
of the VF and 40% of the MF lavas are contaminated by 
sediments in high-level crustal magma chambers. Contamina-
ted rocks usually form separate volcanic units, and except for 
the upper part of the MF, uncontaminated rocks abound.

REE patterns for uncontaminated rocks of both formations 
are consistently convex-up with LaN/NdN= 0.6–1.1 and 
GdN/LuN = 1.3–2.7. Simple REE melting modelling suggests 
similar to slightly lower degrees of melting for the MF basalts 
compared to the VF picrites.

The magmas of both formations were derived from a 
uniform asthenospheric mantle source which was 
geochimically and isotopically depleted. Uncontaminated 
magmas have ⁸⁷Sr/⁸⁶Sr(i)= 0.70294–0.70344, ¹⁴³Nd/¹⁴⁴Nd(i)= 
0.51291–0.51308, and ²⁰⁶Pb/²⁰⁴Pb(i)= 17.51–17.99. Two units 
in the VF and some scattered lavas in both formations show 
various ‘enriched’ geochemical signatures and are considered 
to be contaminated during their passage through the 
lithospheric mantle with metasomatized areas there.

Based on the measured lava volumes on Disko and 
Nuussuaq, extrapolation to the whole region, and 
consideration of the amount of fractionation and estimated 
degrees of melting, the total volume of mantle involved in the 
generation of the Paleocene volcanic succession in West 
Greenland is 550,000 km³. With a ‘rift’ length of 300 km and 
a width of the productive areas of max. 50 km, the involved 
mandle prism was min. 37 km deep. This volume of uniform 
and hot mantle is best envisaged as part of a mantle plume.

Convex-up REE patterns are uncommon in LIPs. They 
would be produced by melting of a depleted mantle in garnet 
facies under a thick lithospheric lid and would occur on the 
broken-up margins of thick cratons such as Precambrian ones.
In the North Atlantic region they occur along the periphery of the 
suggested mantle plume but not in the centre.
H/D isotopic interpretation of hydration isotherms

A. LASSIN1, H. GAILHANOU1, T. RICHARD2 AND M. AZAROUAL1

1BRGM, 3 av. C. Guillemin, B.P. 36009, 45060 Orléans cedex 2, France (a.lassin@brgm.fr)
2UMR-CNRS 8148 ‘‘IDES’’, Université Paris-Sud, 91405 Orsay, France (thierry.richard@u-psud.fr)

Various methods have been developed since years for describing the poral distribution of porous materials from hydration isotherms measurements. The most well known is the BJH method, which relies on a model of cylindric pores. More recently, methods (e.g. Or and Tuller, 1999) consider pores with various geometries (slit pores, pores with polygonal section), providing great improvements in the description of hydration isothers and/or retention curves.

However, these approaches are based on a series of assumptions (constant molar volume of hydration water, a priori geometrical characteristics of pores, no contact angle between adsorption film and capillary meniscus, etc). As a result, determination of the amount of water available for chemical reactions remains qualitative in such systems.

Richard et al. (2007) have measured the H/D isotopic fractionation factor (α) between hydration water and water vapor as a function of relative humidity (RH). Two main types of water were identified and interpreted as 2D (low RH) and 3D (high RH) water networks. The 3D-water is considered as the location where aqueous reactions occur.

Based on this work and without any a priori assumption on the pore space geometry, we propose a new approach aiming at quantifying the amount of "reactive" (capillary) water in a porous medium as a function of water saturation.

We have developed a new approach for the determination of hydration isotherms and the amount of "reactive" water (capillary water). This approach is based on the measurement of the H/D isotopic fractionation factor (α) between hydration water and water vapor as a function of relative humidity (RH). Two main types of water were identified and interpreted as 2D (low RH) and 3D (high RH) water networks. The 3D-water is considered as the location where aqueous reactions occur.

Figure 1: schematic representations of a) H/D fractionation factors and b) amounts of film and capillary water along a hydration isotherm, as a function of RH.

A new version of the Fe-Ti-oxide thermo-oxybarometer relevant to basic magmatic rocks

D. LATTARD, U. SAUERZAPF, M. BURCHARD AND R. ENGELMANN

Mineralogisches Institut, Universität Heidelberg, INF 236, D-69120 Heidelberg (dlattard@min.uni-heidelberg.de)

The Fe-Ti-oxide thermo-oxybarometer, which is based on equilibrium between coexisting Ilm (ilmenite-hematite solid solution) and Tmt (magnetite-ulvöspinel solid solution) has been widely used to retrieval information on temperature and oxygen fugacity (O2) during magmatic and metamorphic processes. However, the two available formulations (Andersen & Lindsley, 1988; Ghiorso & Sack, 1991) yield unsatisfactory results at high temperature and low to moderate O2, i.e. in conditions relevant to crystallisation in basic rocks.

To contribute to a re-calibration of the Fe-Ti oxide thermo-oxybarometer, we have carried out synthesis and re-equilibration experiments in the systems Fe-Ti-O (Lattard et al. 2005) and Fe-Ti-Mg-Al-O at 1000 to 1300°C and a large variety of O2. The compositions of coexisting Tmt and Ilm were derived by EMP analysis.

Our results show that the addition of Mg and/or Al in the concentration ranges that are usual in Fe-Ti oxides from basic magmatic rocks can be accommodated by simple projections in the range 800-1300°C under low to moderate O2 conditions. To generate an empirical formulation of the Tmt-Ilm thermometer-oxybarometer for this T-O2 range we have performed numerical fits on an experimental data set comprising our results and those of selected literature studies (e.g. Evans et al. 2006). With the resulting expressions we can retrieve temperature values from X'usp and X'ilm (projected mole fractions) of Tmt-Ilm pairs and O2 values from X'usp and T.

We have tested our numerical formulations by using the compositions of Tmt-Ilm pairs in products of liquidus experiments conducted at known T- O2 conditions in the frame of several literature studies (e.g. Toplis & Carroll, 1995). In most cases, the calculated values reproduce the experimental ones within ± 50°C and ± 0.4 log O2. This is a significant improvement compared to the previous models.

Time span of Malani Igneous Suite, NW India: Constraints from mineral and wholerock Sm-Nd isotope studies

VIVEK LAUL AND S. BALAKRISHNAN

Department of Earth Sciences, Pondicherry University, Pondicherry 605 014, India (vivek_l@yahoo.com)

Malani is an important Neoproterozoic igneous suite, covering an area of approximately 51,000 sq km in Northwestern Indian shield which shows Bimodal volcanism. The Malani consists mainly of volcanic, granite and dyke phases. Crawford and Compston (1970) determined Rb-Sr age of ~ 745 Ma for the volcanics and granites. Rathore et al. (1996, 1999) on the basis of whole-rock Rb-Sr and Ar-Ar studies suggested that Jalore and Siwana granites, which are part of Malani Igneous Suite, were emplaced at 727 ± 8 Ma and 698 ± 10 Ma, respectively and affected by later thermal event ~ 550 Ma ago.

In order to reliably determine age of magmatism of Malani suite of rocks we have initiated Rb-Sr and Sm-Nd isotope studies on mineral separates and wholerock. Amphibole and K-feldspar were separated from a sample of Siwana granite, a major granite phase of the Malani suite. These minerals along with the whole-rock define a collinear array in Sm-Nd isotope evolution diagram (Figure 1) whose age corresponds to 813 ± 13 Ma (MSWD = 0.57). We interpret that this as the age of crystallization of the Siwana granite, near Mokalsar, Rajasthan, India.

Figure 1: Sm-Nd Mineral isochron on a sample of Siwana granite, near Mokalsar, Rajasthan, India

Experimental determination of the Iridium solubility in silicate melts

V. LAURENZ1,2, C. WOHLGEMUTH-UEBERWASSER1,2 AND C. BALLHAUS2

1Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Germany (veral@uni-muenster.de)
2Mineralogisch-Petrologisches Institut, Rheinische Friedrich-Wilhelms-Universität Bonn, Germany

To understand the fractionation of Os, Ir, and Ru during partial anatexis in the Earth's mantle, we investigate experimentally the solubility of Ir in silicate melt and the partitioning of Ir between chromite and melt at high pressure as a function of oxygen fugacity (fO2). Starting material is a natural picrite doped with 15 wt.% FeCr2O4 component and 5 wt.% Ir as Ir2O3. Run conditions are 1700°C and 2.5 GPa. Liquidus phases are silicate melt, chromite, and (Ir,Fe) alloy. To promote chromite grain sizes sufficiently large for LA-ICPMS analysis we add several percent Li teraborate. fO2 at run conditions are derived from Fe activities in the alloys. fO2 is varied between FMQ-4 and FMQ+3 using different capsule materials and pressure assemblies. Reduced conditions are imposed with talc-pyrex assemblies and graphite capsules, oxidized conditions are generated with anhydrous materials and olivine capsules embedded in hematite.

It is found that Cr2+ is about ten times more soluble in silicate melts than Cr3+. Based on Cr concentration in silicate glasses, the switch from predominantly trivalent to predominantly divalent chromium is observed at an fO2 of around FMQ-2.5. Chromite compositions appear to be less sensitive to the valence state of Cr, in that Cr/(Cr+Al) ratios show little variation with fO2. Apparently, Cr2+ is rather incompatible with the chromite lattice.

The combination of high temperature, chromite oversaturation, and Li tetraborate flux in the silicate melt allows to grow chromite up to 200 µm in diameter, appropriate in size for quantitative LA-ICPMS analysis. Iridium analyses of glasses and chromites are carried out with an ArF excimer laser coupled to a single-collector magnetic sector ICPMS. Isotopes recorded in addition to 191Ir and 193Ir are 58,59,60Cr, 57Fe, and 57Fe. Count rates are normalized to the isotope 57Fe and the FeO content of each phase.

Preliminary results of two charges synthesized at FMQ-2 show that under reduced conditions, Ir concentrations in the chromites and the picritic melts are below detection of the laser probe, i.e. around 15 ppb. Hence, it is not possible to calculate partitioning coefficients for Ir between chromite and melt. The low Ir solubility, even at 1700°C, in the picrite melt suggests that sulfide-undersaturated primitive basalts are generally saturated with the refractory PGE (Os, Ir, Ru), hence capable of crystallizing discrete PGE-Fe alloys. It is expected though that, as more oxidized experiments become available, Ir solubilities will turn out higher in silicate melts more oxidized than FMQ-2. Refractory Os-Ir-Ru-alloys exhibit strong epitactic preferences to chromite surfaces. Hence, the refractory PGE may be fractionated relative to Pt and Pd whenever a silicate melt is saturated with chromite.
Yellow Mn-rich elbaite from the Canary mining area, Zambia

BRENDAN M. LAURS1, WILLIAM B. SIMMONS2, BJÖRN ANCKAR3 AND ALEXANDER U. FALSTER2

1 Gemological Institute of America (GIA), 5345 Armada Drive, Carlsbad, CA, 92008, USA (blaurs@gia.edu)
2 University of New Orleans, 2000 Lakeshore Drive, New Orleans, LA, 70148, USA (wsimmons@uno.edu)
3 GeoloGem Consulting, Driveslättvägen 102, Alingsås 44191, Sweden (bjorn.anckar@geologem.com)

The only commercial source of yellow gem tourmaline is the Canary mining area, located 32 km west-southwest of Lundazi in eastern Zambia. Since 1983, tourmaline has been mined in colors typically ranging from yellow-green to yellow to orange and brown; much of the orange-to-brown material is heated to attain a “golden” or “canary” yellow color. Significant production has come from eluvial and alluvial deposits, but the largest find (~3 tonnes) occurred at a nearby granitic pegmatite, in a large cavity that also contained abundant quartz crystals and “cleavelandite” feldspar. The pegmatite is lens-shaped and discordantly intrudes biotite schist; it strikes east-west (~100°) and dips moderately south.

By the time of the authors’ visit in 2004, most of the pegmatite had been removed via a large open pit that was partially filled with water. Visible portions of the footwall showed a medium-grained border zone (~15 cm thick) and in places a discontinuous aplitic zone that abruptly transitioned into a coarse-grained intermediate zone consisting mainly of K-feldspar and subordinate sodic plagioclase. Quartz was leached from the rock, resulting in vugs containing black tourmaline and local albite (An0-1.5, as clear overgrowths on K-feldspar). Conspicuous veins (up to 10 cm thick) of black tourmaline ± K-feldspar + albite cross-cut the pegmatite.

Electron-microprobe analysis of 23 samples of yellow-to-brown and yellow-green tourmaline from the associated secondary deposits showed they were elbaite with 1.14-7.59 wt.% MnO and 0.04-0.54 wt.% TiO2; iron was typically absent but exceptionally ranged up to only 0.21 wt.% FeO. Previous studies have recorded up to 9.18 wt.% MnO in this elbaite (e.g., J. E. Shigley et al., Am. Min., 71, 1986, pp. 1214-1216), approaching the tsilaisite end member.

Gem tourmaline typically consists of pink, green, or blue elbaite that is mined from the lepidolite-bearing inner zones of complex LCT pegmatites. In contrast, Mn-rich (and Ti-bearing) yellow-to-brown elbaite from the Canary mining area appears to have formed in a relatively simple pegmatite that was enriched in B and H2O, but not Li. Early crystallization of abundant schorl consumed the available Fe, inhibiting subsequent crystallization of garnet and biotite; this allowed Mn to be conserved until the late-stage formation of gem tourmaline. Following pegmatite crystallization, the influx of an unusual B-, Fe-, K-and Na-rich fluid (apparently from an external source) resulted in local tourmaline ± K-feldspar + albite veining and quartz dissolution; the same event also brecciated some of the yellow elbaite with black tourmaline ± K-feldspar + albite assemblages.

Bixbyite in bixbyite – Precipitates as indication for fast diffusion pathways

STEFAN LAUTERBACH AND HANS-JOACHIM KLEEBE

Technical University of Darmstadt, Institute for Applied Geosciences, Geomaternal Science, Schnittspahnstr. 9. D-64287 Darmstadt, Germany

Large Bixbyite crystals (Mn,Fe)2O3, space group Ia3, occur only at one location in the Thomas Range (Utah), where crystals up to 4 cm have been discovered.

In contrast to the commonly small isomorphic crystals, most of the larger Bixbyite crystals show distinct re-entrant facets at halfway of every edge of the cube, linked by a band of parallel linear features. The structure of these linear features was studied using high-resolution transmission electron microscopy (HRTEM). HRTEM revealed atomically sharp interfaces between lamellae running along {100} of the Bixbyite structure and the matrix.

Regular formed precipitates aligned parallel to these lamellae show the same chemical composition by EDS as the host crystal and electron diffraction indicates that the precipitates have the same crystal structure as the host crystal.

We present a model explaining the formation of small ‘child crystals’ with identical structure and composition in the host Bixbyite matrix, which makes use of the assumption that the observed lamellae act as fast diffusion highways.
Chemistry of a Swedish groundwater affected by oxidising alum shale

U. LAVERGREN, B. BERGBÄCK AND M. ÅSTRÖM

Kalmar University, School of Pure and Applied Natural Sciences, SE-391 82 Kalmar, Sweden
(ulf.lavergren@hik.se; bo.bergback@hik.se; mats.astrom@hik.se)

Background
Alum shale (black shale) is a rock rich in sulphides as well as in many trace elements. The shale is readily weathered when exposed to air and water and since many of its elements have toxic properties such weathering can constitute a contamination source for soils and waters, a process analogous to metal leaching from acid sulphate soils and acid mine drainage. This study aims at assessing the mobilisation of a number of elements to the groundwater phase in an old mining area with outcropping alum shale and deposits of burnt shale. The chemistry of the local groundwater, both originating from the mining deposits and the natural bedrock, was monitored for a period of eight months.

Results
The variations existing in groundwater chemistry between nearby sampling points were large, while the temporal variations generally were marginal. At some sampling points the groundwater was acidic (pH 4), while at others it was circumneutral (pH 6-8). All the groundwater samples were, however, clearly affected by the shale material, as shown by elevated metal concentrations.

The acidic groundwater was found in an area covered by extensive deposits of burnt shale where the conditions for sulphide oxidation were especially favourable, and the water was strongly elevated in the metals Al, Cd, Co, Cu, Ni, U and Zn. Uranium and Cd were, however, also abundant in many of the circumneutral water samples only affected by the natural bedrock. Another metal that was enriched in the circumneutral waters was Mo, which appears to be particularly easy mobilised from this type of shale.

Conclusion
The mobilisation of metals from the alum shale in the investigated area has clearly been enhanced by the historical mining activities, but also weathering of the natural alum shale bedrock is a considerable source for groundwater metal contamination.

Ra and Rn enrichment in the water column of the Gulf of Aqaba (Northern Red Sea)

B. LAZAR AND Y. KOLODNY

Institute of Earth Sciences, The Hebrew University of Jerusalem, Israel (boaz.lazar@huji.ac.il; kolodny@vms.huji.ac.il)

The Gulf of Aqaba is a pull-apart basin along the Dead-Sea-Red-Sea Transform (RST). It is about 180 km long, 20 km wide and on the average 800 m deep (maximum depth reaches ~1800 m). The gulf is bordered by active faults on which numerous earthquakes (magnitude up to 7.4) occur. The gulf is connected to the main Red Sea via the narrow Straits of Tiran. Due to large excess of evaporation, its average salinity is high (40.7 ‰) and larger than that of the northern Red Sea. Residence time of water in the gulf is about 1.5 y. The water column fluctuates seasonally between deep mixing in the winter and intensive summer stratification.

The activities of $^{226}$Ra and $^{222}$Rn were measured in several transects, a depth profile and a well dug on the beach. The gulf's water column contains exceptionally high levels of $^{226}$Ra (up to 60 dpm·100 L$^{-1}$) and unsupported $^{222}$Rn (up to 700 dpm·100 L$^{-1}$). The temporal fluctuations of both nuclides are very high even in the center of this deep-water gulf. The activity of the long lived $^{226}$Ra in the gulf is about twice as high as that in the northern Red Sea. Considering the short residence time of water in the gulf, this indicates an intra-gulf source of the Ra, which supplies Ra (and Rn) rather rapidly. The depth profiles show that the high values are near the bottom (flux from the sediments) and in the upper 200 m (Fig. 1).

We propose that both the temporal and spatial variability of Ra and Rn in the gulf are related to their release from the major faults that border the RST, especially during and following earthquakes. For example, after the Nov. 19, 1998 earthquake (Mag. 4.4) we observed a sharp peak in both Ra and Rn in the open water column.

Figure 1: Depth profiles of $^{222}$Rn and $^{226}$Ra (dpm·100 L$^{-1}$) at stations A1 (ca. 4 km off shore), R2 (ca. 1.5 km), R3 (ca. 0.7 km) and R4 (ca. 0.2 km).
Ra and Th adsorption coefficients in lakes – Estimate based on a whole ecosystem study in Lake Kinneret (Sea of Galilee)

B. LAZAR1, Y. WEINSTEIN2 AND Y. KOLODNY1

1Institute of Earth Sciences, The Hebrew University of Jerusalem, Israel (boaz.lazar@huji.ac.il; kolodny@vms.huji.ac.il)
2Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel (weinsty@mail.biu.ac.il)

A whole ecosystem balance of Ra isotopes that enter with saline springs into the freshwater Lake Kinneret provided a unique opportunity to constrain the Ra and Th adsorption characteristics in the lake. We suggest that preferential adsorption of Ra on particles in the lake is responsible for the decrease of 226Ra activity from a range of 7·103 - 250·103 dpm·m-3 in the springs to about 5·102 dpm·m-3 in the lake. Similarly, the adsorption of 228Th results in the reduction of the 224Ra/228Ra and 224Ra/223Ra activity ratios correspondingly from 1.5 and 8 in the springs to about 0.1 and 4 in the lake. Solving simultaneously the mass balance equations for 223Ra, 224Ra, 226Ra, 228Ra and 228Th in Lake Kinneret (using the accepted water exchange constants for the lake) yield the time scales required to reach steady state, the residence time and the steady state values for each nuclide as a function of the adsorption coefficients for Ra and Th. The model predicted very well the steady state values of 226Ra and the 224Ra/228Ra and 224Ra/223Ra ratios in the lake (the solid circles in Fig. 1). The estimated adsorption rate constants in the lake are: 0.005 to 0.02 d-1 and 0.5 to 1 d-1 for Ra and Th, respectively. The Ra desorption rate coefficient was estimated to be about 100 times larger than its adsorption rate constant. The observed activity ratios of the Ra nuclides in the lake are all steady state ratios that are achieved after a rather short time. They depend only on the rate constants and the activity ratios in the saline springs, and are independent of the flow rate of the saline springs. Thus, the estimated constants should apply for any productive, meromictic lake.

Leaching bench – scale experiments to model aquifer storage and recovery (ASR) operations in laboratory conditions: Central Florida case studies

O. LAZAREVA AND T. PICHLER

Department of Geology, University of South Florida, 4202 East Fowler Avenue, Tampa, Fl 33620 United States (olazarev@mail.usf.edu; pichler@shell.cas.usf.edu)

Arsenic (As) is found in the Floridan Aquifer mostly associated with pyrite. Pyrite is thought to dissolve and release As during aquifer storage and recovery (ASR) due to the injection of ozone-treated surface waters. As a result concentrations of As of up to 100 µg/L were observed in recovered water. To simulate the release of As during ASR in the laboratory we conducted a series of leaching experiments using different water compositions and aquifer matrices. These experiments were performed in standing PVC columns of 0.019 m in diameter in different lengths using native ground water from the Floridan Aquifer and drinking water from the City of Tampa, Florida. Water was pumped from the bottom through the columns by peristaltic pump to ensure complete saturation of the sediment. Leachate samples were taken at certain intervals, monitored for T, pH, ORP, S2-, and Fe2+, and analyzed for major anions, major cations, and total As. Our study showed: (1) Low As concentrations (<6 µg/L) and negative ORP values for leaching test using the native ground water from the deep Floridan well; (2) Mobilization of As during injection of drinking water with concentrations up to 42 µg/L; (4) Consecutive injection tests for a period of four months at two weeks interval indicated the decrease of As concentrations from 42 µg/L to <10 µg/L; (5) Distributions of As from leaching experiments were comparable to those of sulfate concentrations, confirming the dissolution of pyrite.

Timing of mantle depletion and enrichment from single subcalcic garnet grains (Finsch mine, SA)

M. Lazarov\textsuperscript{1,}, G.P. Brey\textsuperscript{1,}, J.W. Harris\textsuperscript{2} and S. Weyer\textsuperscript{1}

\textsuperscript{1}Institut fuer Geowissenschaften, Johann Wolfgang Goethe-Universität, Frankfurt, Germany (marina@em.uni-frankfurt.de)
\textsuperscript{2}Earth Sciences, University of Glasgow, Glasgow, UK

Subcalcic garnets are characteristic for the peridotitic inclusion suite in diamonds and constituents of clinopyroxene free harzburgites and dunites. The latter rock types are rare among the xenolith suite in kimberlites. The subcalcic garnets, however, are index minerals for diamonds in heavy mineral concentrates. In the absence of clinopyroxene, garnet is the main carrier of many trace elements and thus reflect the bulk composition. With this assumption we have identified and selected 21 subcalcic garnets out of 700 garnets from a heavy mineral concentrate from the Finsch Mine in South Africa (Kaapvaal craton). The grains were 3-5 mm sized. We have analysed major and trace elements by EPMA and LA ICP MS and Lu-Hf and Sm-Nd isotopes on the single grains by MC-ICP-MS.

The garnets have low CaO (1-6 wt\%) compared to their respective Cr\textsubscript{2}O\textsubscript{3} of 2-12 wt\% and high Mg-values (Mg\textsuperscript{#}=85-90). Their depleted nature is also shown by low Zr, Ti and LILE. The REE mostly show the sigmoidal pattern commonly observed in subarthonic peridotite mantle lithologies. The HREE have a positive slope reflecting the original depletion event which must have occurred in the uppermost mantle \cite{1}. Light to middle REE are bow shaped and enriched relative to primitive mantle. The range of Hf and Nd isotope signature is large in these low-Ca garnets. They have mostly radiogenic Hf isotope compositions with $\varepsilon$Hf up to 640. Nd displays mainly unradiogenic $\varepsilon$Nd down to -36 and only few have radiogenic $\varepsilon$Nd up to +25.

The results for the Lu-Hf isotopic system yield an isochron age of 2.529 ± 130 Ga. Since garnet is the major host for Lu and Hf in the clinopyroxene free harzburgites this garnet isochron should provide a similar age to that of a whole rock isochron. A minor correction for Lu-Hf in opx would slightly increase the whole rock age. We thus consider our Lu-Hf results on garnets as a minimum age for the timing of the final depletion of the subcratonic mantle which coincides with the final cratonization of the Kaapvaal craton.

The Sm-Nd system displays a large range of isotopic compositions with only weak correlations of $\varepsilon$Nd with Sm/Nd. However, corresponding ages are always younger than Lu-Hf ages, which may indicate various enrichment events during orogenic cycles within the Kaapvaal craton.

Reduction of hematite nanoparticles by \textit{Shewanella oneidensis} MR-1

D.R. Learm\textsuperscript{1,}, S. Bose\textsuperscript{1,2,}, N.S. Wigginton\textsuperscript{1,}, S.D. Brown\textsuperscript{3} and M.F. Hochella, Jr.\textsuperscript{1}

\textsuperscript{1}NanoBioEarth Group, Virginia Tech, Blacksburg, VA 24061, USA
\textsuperscript{2}Plant and Microbial Biology, University of California, Berkeley, CA 94720-3102, USA
\textsuperscript{3}Biosciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831, USA

The ability of \textit{Shewanella oneidensis} MR-1 to reduce hematite (α-Fe\textsubscript{2}O\textsubscript{3}) nanoparticles of different sizes was examined under anaerobic conditions. Hematite nanoparticles used in these experiments had a size range between approximately 11 nm and 99 nm. Particle surface area was determined by BET and size distribution, aggregation, and morphology was determined by TEM. \textit{S. oneidensis} was grown in a defined anaerobic media and the different sized nanoparticles were added as the sole electron acceptor. Reduction of the nanoparticles was verified by analyzing the cell supernatant for Fe\textsuperscript{2+}. Experiments have shown that the reduction rates of the larger 99 nm particles are faster than the smaller particles when normalized to surface area. The greatest difference in surface area normalized reduction rates (one order of magnitude) were seen between the 11 and 99 nm particles. The two particles have similar morphologies (pseudo-hexagonal to irregular shaped) and they aggregate very similarly when suspended in the media. The variation in reduction rates are likely caused by differences either in size-specific particle properties or the bacteria’s cellular response to the two particle sizes. Internal and surface structural differences, exposed crystal faces, Fe\textsuperscript{2+} surface passivation, or decreased solubility of the smaller nanoparticles are potential size-dependent properties that could influence reduction rates, but evidence for the influence of these properties on nanomaterials in this system remains elusive. Testing whether actual cellular differences are evident between cells grown on the two particle sizes, however, can be done within the framework of a detailed knowledge of the genome of \textit{S. oneidensis}. Ongoing work focuses on examining the genetic and proteomic response of \textit{S. oneidensis} to the different sized hematite nanoparticles in hopes of elucidating the primary factors that influence size-dependent reduction rates.
**Experimental kinetic study of carbonaceous material maturation: An appraisal of pressure and time effects on vitrinite reflectance at 400°C**

R. Le Bayon, G.P. Brey, W.G. Ernst and R. Ferreiro Mählmann

1Institut für Angewandte Geowissenschaften, Technische Universität Darmstadt, Darmstadt, Germany (rlebayon@geo.tu-darmstadt.de)
2Institut für Mineralogie, Abt. Petrologie und Geochemie, J.W. Goethe University, Frankfurt am Main, Germany
3Department of Geological and Environmental Sciences, Stanford University, Stanford, USA

Vitrinite reflectance ($R_0$) measurement in organic carbonaceous material-bearing rocks is of great interest in metamorphic petrology. This stems from the ability of $R_0$ to constrain paleotemperature conditions and maturity degree of organic matter in very low- to low-grade metamorphic terranes where recrystallization is not obvious. However, considerable discrepancy still exists concerning the role of pressure and time on $R_0$ evolution.

Consequently, the goal of this laboratory rate study is to understand and estimate the effects of pressure and time on the development and kinetic evolution of $R_0$. We conducted a series of maturation experiments at 400°C in a closed system at pressures of 2, 10 and 20 kbar employing a high-pressure piston-cylinder apparatus and cold-seal pressure vessels. Experiments were performed on dry (no water added) xylite of swamp cypress and involved run lengths from 0 second to 80 days.

The experimental results demonstrate for the first time that a kinetic equation of the form

$$R_0(P, t) = R_0(P, 0) + k(P) t^n(P)$$

where, in contrast to the initial $R_0$ at $t = 0$ [$R_0(P, 0)$], the rate constant $k(P)$ is found to decrease with $P$. This kinetic equation supports all our qualitative observations. With the exponent $n(P)$ increasing regularly with $P$ and $0 < n(P) < 1$, our parabolic equation calls for a larger increase in $R_0$ and a lesser deceleration with $t$ of the $R_0$ isothermal kinetic evolution with increasing $P$. We regard our kinetic formulation as providing a step toward a general equation describing the $R_0$ evolution as a function of pressure, time and temperature.

**Directed proteomics applied to the detection and characterization of arsenic-transforming enzymes in complex communities from the Alvord Basin hydrothermal system**

R.N. Ledbetter, L.A. Deobald, A.J. Paszczynski and T.S. Magnuson

1Idaho State University, Pocatello, ID (ledbrhes@isu.edu, magntimo@isu.edu)
2University of Idaho, Moscow, ID (andrzej@uidaho.edu, deobaldl@uidaho.edu)

Microorganisms have the ability to transform over forty elements on the periodic table including major, minor, and trace elements. Microbial enzymes carry out a wide variety of these transformation reactions, any of which can potentially be measured. The primary goal of this research was to apply directed proteomics to the detection and characterization of arsenic-transforming enzymes in multi-species microbial systems inhabiting a hydrothermal environment.

Microbial mat samples were collected from the Alvord Basin in southeast Oregon, USA. One laboratory isolate (Thermus Strain A03C), cultivated from the Alvord Basin, was used as a positive control as it is has been shown to oxidize arsenite and respire on arsenate. Proteins were sequentially extracted using detergent-aided lysis of biomass and then mechanically extracted using a vigorous glass bead-beating procedure. Microbial arsenite oxidase and arsenate reductase activities were successfully detected and resolved using zymography, an approach that allows the detection of enzyme activities among proteins and enzymes resolved by electrophoretic methods. Activity stains specific for arsenite oxidase and arsenate reductase activities were used to visualize enzymes involved in arsenic transformation. Several activity bands were effectively resolved in individual mat samples and suggest distinctive isoforms of the enzymes. Activity bands were excised from the gel, processed, and analyzed using Liquid Chromatography-Mass Spectrometry (LC/MS). The majority of peptides obtained from the LC/MS analysis had corresponding database matches for the enzyme of interest, and functional gene analysis confirmed the presence of corresponding genes. However, some samples had no peptides related to the specific activity. These sequences could signify new unidentified enzymes involved in the transformation of arsenic and can be compared to sequences in the metagenome to potentially assign a defined biological function to ‘hypothetical’ or unidentified proteins and their associated genes.

By combining tools commonly used in the study of microbial ecology with the most contemporary proteomic separation and analysis techniques, great strides can be made in achieving a greater understanding of microbial enzymes and their ecophysiological roles.
**Effect of carbonates on the sorption of U(VI) onto granite: Correlation with aqueous speciation**

J.K. LEE AND M.H. BAIK

HLW Management Research Center, Korea Atomic Energy Research Institute, Daejeon, Rep. of Korea (jklee1@kaeri.re.kr, mbbaik@kaeri.re.kr)

The mobilization of metal contaminants through geological media is strongly influenced by the reaction between metals and the surrounding rocks and mineral phases. In this study, the effect of carbonates on the sorption of U(VI) onto a Korean crushed granite was investigated by performing batch sorption experiments. A correlation between the uranium sorption behavior and the aqueous speciation of U(VI) in the solution was also analyzed. The chemical speciation of uranium was calculated by MINTEQA2 at different geochemical conditions.

**Figure 1:** The Carbonate effect on U(VI) sorption onto granite

The distribution coefficients ($K_d$) of U(VI) onto granite were found to be highly dependent on the solution pH and the aqueous carbonate concentration. As shown in Figure 1, the maximum $K_d$ was significantly decreased and the peak was shifted to a lower pH side as the carbonate concentration increased. Thus the concentration of carbonate can be directly related to the distribution of the aqueous U(VI) speciation. The $K_d$ values were decreased even in the absence of carbonate which was correspondent with the formation of anionic uranyl hydroxo complexes.

Based upon the calculations at $10^{-6}$ M of U(VI) and acidic pH, free uranyl ion $(\text{UO}_2^{2+})$ was the dominant species sorbed onto crushed granite in the absence of carbonate. However, the uranyl carbonates such as $\text{UO}_2\text{CO}_3(\text{aq})$ and $\text{UO}_2(\text{CO}_3)_2^{2-}$ were dominant in $10^{-4}$ and $10^{-2}$ M of carbonate concentrations, respectively. This reveals that U(VI) sorption on granite is inhibited by forming uranyl carbonate complexes, resulting in a lower sorption affinity to the granite at a neutral pH region. Thus the formation of uranyl carbonates is one of the most important factors in the prediction of the uranium migration in natural environments.

Analysis of water movement through an unsaturated soil zone in a volcanic island using oxygen and hydrogen isotopes

KWANG-SIK LEE¹, JUN-MO KIM², DONG-RIM LEE³ AND YONGJE KIM⁴

¹Division of Isotope Geoscience, Korea Basic Science Institute, Daejeon 305-333, Korea (kslee@kbsi.re.kr)
²School of Earth and Environmental Sciences, Seoul National University, Seoul 151-742, Korea
³Jeju-Do Branch, Korea Rural Community and Agriculture Corporation, Jeju-Do 690-072, Korea
⁴Division of Groundwater and Geothermal Resources, Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350, Korea

In order to analyze water movement through an unsaturated soil zone in Jeju Island, soil waters were collected biweekly at three different soil depths using suction lysimeters. For comparison, precipitation was collected monthly using a plastic bottle. Temporal variations in the oxygen-18 and deuterium isotopes of the precipitation and soil waters were then monitored for about one year. The stable oxygen and hydrogen isotopic compositions of the soil waters are plotted between or near the two local meteoric water lines for summer and winter precipitation indicating that the soil waters were recharged from the year-around precipitation, and evaporation was negligible even during hot summer season in the study area. Finally, mean residence times of the soil waters were estimated from the δ¹⁸O, δD, and deuterium excess or d-values of the precipitation and soil waters using two well-mixed or exponential models (EM) and one exponential piston-flow model (EPM). The regression results show that the combination of the exponential piston-flow model and the d-values of the precipitation and soil waters gives the most reasonable estimation of the mean residence times of the soil waters in the study area: 74 days (2.5 months) and 198 days (6.6 months) to depths of 30 cm and 60–80 cm, respectively, in the unsaturated soil zone from the ground surface. The estimated low moisture contents and hydraulic diffusivities of the soils at the three different depths also suggest that the boundary between the upper fine-grained soil and the lower coarse-grained soil may act as a capillary barrier, and the soil waters probably flow slowly through micropores rather than rapidly through macropores in the unsaturated soil zone.

Revealing the composition and crystallinity of weathered alkali feldspar surfaces by XPS, FIB and TEM techniques

MARTIN R. LEE¹, DAVID J. BROWN² AND MARK E. HODSON³

¹Dept. of Geographical and Earth Sciences, University of Glasgow, UK (Martin.Lee@ges.gla.ac.uk)
²Dept. of Civil & Structural Engineering, Kroto Research Institute, University of Sheffield, UK (d.j.brown@sheffield.ac.uk)
³Dept. of Soil Science, The University of Reading, Reading, RG6 6DW, UK (m.e.hodson@reading.ac.uk)

How does the composition and structure of silicate mineral surfaces change during their reaction with acidic solutions in the field? Recently, Zhu et al. 2006 (Geochimica et Cosmochimica Acta 70, 4600-4616) have described ~10 nm thick amorphous layers on naturally weathered alkali feldspars, which supports the experimentally derived ‘leached layer’ model for silicate dissolution. We have tested this model further by comparing the chemical composition and crystallinity of the near-surface regions of alkali feldspars used in pH1 laboratory dissolution experiments with minerals from the same parent rock that had been naturally weathered. Angle-resolved X-ray photoelectron spectroscopy (AR-XPS) provided the compositional data whereas information on crystallinity and structure was obtained by cutting cross-sections of grain surfaces using the focused ion beam (FIB) instrument for high-resolution TEM imaging.

AR-XPS data confirm that the outermost ~9 nm of alkali feldspars reacted with pH 1 HCl are non-stoichiometric (i.e. enriched in Si and O relative to Al and alkalis). Analyses acquired at the shallowest take-off angle are most Si-rich, indicating that the ‘layer’ is likely to be considerably thinner than the maximum ~9 nm XPS sampling depth. TEM images of FIB-produced cross-sections of the etched grain surfaces show that they are crystalline throughout; if the non-stoichiometric layer is amorphous it must be thinner than can be resolved by the FIB-TEM technique (i.e. <~2.5 nm), or if thicker than 2.5 nm it must be very irregularly distributed over the grain surface and so has not been sampled.

AR-XPS data from naturally weathered grain surfaces are more difficult to interpret. Most analyses show enrichment in Al and depletion in Si relative to the unweathered grain interior, with data for the alkalis showing no clear trend. These data are inconsistent with the presence of a silica-rich layer equivalent to that formed experimentally but may indicate that aluminosilicate weathering products have been produced. However, secondary minerals could not be found by SEM, and FIB-TEM work has again demonstrated that the feldspars are crystalline to within <~2.5 nm of their outer surface. These results indicate that any chemical and structural modification is restricted to the outermost <2 nm of these alkali feldspars and so thick ‘leached layers’ are absent.
Use of CaCO$_3$ as an amendment to immobilize heavy metals from the contaminated farmland soil around abandoned mines

MINHEE LEE, HYUNMIN KANG AND AEJUNG CHOI
Department of Environmental Geosciences, Pukyong National University, Daeyongdong, Namgu, Busan, 608-737, Korea

Experimental method
This research focused on the soil stabilization process by using limestone (CaCO$_3$) to decrease the leaching of arsenic and other heavy metals from contaminated farmland soils around abandoned mines, Korea. Pilot scale column experiments were performed to investigate the efficiency of limestone as the immobilizing amendment to reduce the heavy metal leaching from the contaminated soil. A physical model for the genuine contaminated soil environment was designed and heavy metal leaching rates by artificial rainfall were measured in diverse treatment conditions.

An acrylic column (19cm in diameter and 30cm in height), which of the upper and lower part consist of dense lattice screen plates and the drain system for injection and extraction of artificial rainfall, was used for the column experiments. As the amendment, granulated limestone (4 ~ 6mm in diameter) was used for the “mixing treatment” experiment. Two or 5 w.t.% of granulated limestone was well mixed with the farmland soil. At every 12 hr, 817 ml of artificial rain (33% of average monthly rainfall) was uniformly sprayed on the top of the column at the constant rate of 200 ml/min for thirty days, representing 5 year of soil leaching in the real farmland field. Discharged water was sampled from the bottom of the column at different time interval. The pH of discharged water was measured and its heavy metal leaching concentrations were analyzed on ICP/OES to calculate the accumulative mass of each heavy metal leached from the soil for 5 year.

Results and discussion
With only 2% of granulated limestone, As, Cd, and Zn leaching concentrations decreased by 53%, 97%, and 98%, respectively, compared to that without the amendment mixing and they maintained much below Korean Drinking Water Limit (KDWL) for 5 year leaching. Although 5 w.t.% of limestone was added as an amendment in the column experiments, the pH of the leaching solution slightly increased and maintained lower than 9 (mostly lower than 8), but its efficiency immobilizing heavy metals in the soil was potent. Because of low pH change, less adverse effects, and economical consideration, limestone could be more available to immobilize heavy metals from the farmland soil than lime(CaO) in the real contaminated site.

Conclusion
From the pilot scale continuous column experiments, it was investigated that the “mixing treatment” using limestone will become one of major processes to immobilize heavy metals from the contaminated soils around abandoned mines.

Influence of organics on microbial reductive dissolution of synthetic Fe-Cr oxides

SANGHOON LEE$^1$, SANG-WOO LEE$^2$, SA-HO CHUN$^1$, SUNG-HYUN JI$^1$ AND SANG-YUN LEE$^4$

$^1$Environmental Engineering Section, Division of Biotechnology, Catholic University, Buchun, Gyounggi, 420-743, Korea (slee@catholic.ac.kr)

$^2$Department of Environmental Science and Engineering, Chungbuk National University, Cheongju, Chungbuk 361-763, Korea (lswenv@hanmail.net)

Cr speciation either as Cr(III) or Cr(VI) in subsurface environment is corresponding to its chemical state; reducing or oxidising, which is again controlled by microbial activities. Cr speciation is of environmental concern due to their different behaviour in mobility and toxicity. Amorphous and crystalline Fe-Cr oxides were synthesized using the method of Sugimoto (1992). Firstly, three different experimental settings were established using the Fe-Cr oxides under anaerobic condition; 1) Oxides + 2,6-anthrahydroquinone disulphonate (AQDS) + Iron reducing bacteria (Shewanella sp.). 2) Oxides + Iron reducing bacteria and 3) without the microbe and AQDS. The Shewanella sp. used in the experiment has been isolated and cultured from the sea clay collected in western coast in Korea. The mixture was placed in vials and were run for up to 40 days. In the experimental set mixing the synthetic oxides and the microbe, more Cr was been released from amorphous Fe-Cr oxides, compared to crystalline oxides (45.4 and 30.8mg/Kg). Addition of AQDS enhanced the mobility of Cr to 57.6 mg/kg (amorphous oxides) and 35.4 mg/kg (crystalline iron oxides), respectively. Cr concentrations increase with days but reached rather constant values in 10 (crystalline) to 20 (amorphous) days, whereas the Cr in the samples without bacteria and AQDS increase to a certain level (10 and 5 mg/Kg for amorphous and crystalline) and then decrease to 0 in 40 days. Fe(II) and Fe$_{total}$ concentrations are corresponding to the changes in Cr released from the synthetic oxides, as well as Eh. Little Cr(VI) has been detected in all samples and the Cr speciation in the experiment is believed to exist nealy as Cr(III). Both Fe(II) and Fe$_{total}$ were more released from amorphous oxides, compared to crystallin oxides. Humic acids are utilised as an electron shuttle in the metal-microbe-organic system. Namely, the Fe-Cr oxides are dissolved under reducing condition through interactive chains of electron shutting involving iron reducing bacteria, AQDS and metals (Fe, Cr) in subsurface environment. This geochemical process is instrumental in remediating metal contaminated soils.

Geochemical implications of Sr isotopic compositions in hot springs, Korea

S.G. LEE, T.K. KIM, J.S. LEE, Y. SONG AND T.J. LEE
KIGAM, Daejeon 305-350, Korea (sgl@kigam.re.kr; tkkim@kigam.re.kr; jsly@kigam.re.kr; song@kigam.re.kr; megi@kigam.re.kr)

Though, at present, there is no volcanic activity, high temperature hot springs with more than 40°C water temperature occur near to Jurassic and Cretaceous granite area in South Korea. In order to clarify the heat source of the hot springs in the South Korea, we carried out a geochemical study using Sr isotope compositions of the hot spring water being collected from the fourteen area for 5 years. In this report, we discuss some relationship between the distribution of granites and geochemical characteristics of Sr isotope ratios from the high temperature hot springs.

The hot springs in the Jurassic granite area are mainly of Na-HCO₃ type, whereas those of the Cretaceous granite area are Na-Cl(-SO₄) type. In Sr isotope ratios, $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the hot springs in the Jurassic granite area range in 0.710 to 0.730, whereas those in the Cretaceous granite area range 0.700 to 0.710. In addition, $^{87}\text{Sr}/^{86}\text{Sr}$ ratio from each hot spring is constant for five years, respectively. Another interesting characteristic of $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the hot springs from the South Korea is that each $^{87}\text{Sr}/^{86}\text{Sr}$ ratio from the hot springs corresponds well to the initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the granite itself at the area that the hot spring occurs. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the hot springs is divided into also three groups according to geographical classification of South Korea such as eastern, western and southern part.

The correspondence between the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the hot springs and the initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the hot spring-bearing granite indicates that the high temperature hot springs in South Korea may be derived from the heat source related with the Mesozoic granite though it is difficult to think that the Mesozoic granite itself is the heat source of the hot spring.

Mineralogical study on the uranium sorbed biotite

S. Y. LEE, M.H. BAIK AND J.W. CHOI
Korea Atomic Energy Research Institute, Daejeon 305-353, South Korea (seungylee@kaeri.re.kr)

Experimental

Large books of biotite were cushed to less than 3 mm. Some biotite samples were oxidized with $\text{H}_2\text{O}_2$ solution (34%) for 2 weeks. The biotite was characterized by a series of techniques, including XRD, SEM, TEM, and chemical analysis. A range of experimental reactions with biotite were conducted at a solid to solution ratio of 1:100 in 50 mL centrifuge tubes. $\text{U}^{\text{VI}}$ solutions were prepared by adding $\text{UO}_2(\text{NO}_3)_2\cdot6\text{H}_2\text{O}$ (Reagent grade) to deionized water (electrical resistivity at 25°C $> 16.6 \text{ mol/Ωcm}$). Solution compositions covered pH 3.0-9.0, and $\text{U}^{\text{VI}} = 0.2 \text{ mM}$.

Results and interpretation

The XRD patterns of biotite changed by the effect of oxidation treatment: a lowering of peak height, a broadening of peak width, a low-angle shift of the (001) peak, and a high-angle shift of the (060) peak. Iron oxidation and cation loss from the biotite were occurred and caused a decrease in the $b$-dimension with the formation of discontinuities, resulting in partial hydrous interlayers (<10%).

U sorption was higher on the fresh biotite rather than on the one treated with $\text{H}_2\text{O}_2$. At low pH (pH 3), U was mainly sorbed onto the biotite interlayer, replacing K elements from the interlayer sites. In addition, U sorption was affected by the surficial condition of the biotite such as its morphology and edge types.

TEM recorded nano-scale U-rich zones in the interlayer region for those samples with relatively high uranium sorption.

Reduction of Chromium(VI) by *Cellulomonas* sp. and *Propionibacterium* sp. in anaerobic soil microcosms

S.E. LEE¹, A. KONOPKA¹ AND H.T. CHON²

¹Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907, USA (slee@purdue.edu)
²School of Civil, Urban, and Geosystem Engineering, Seoul National University, Seoul, 151-744, Korea (chon@smu.ac.kr)

**Introduction**

Chromium is considered as one of the priority pollutants in the USA and elsewhere (Hedgecott, 1994). A number of biological treatment methods which use microorganisms for the chromium(VI) removal have been investigated and developed to remediate chromium contaminated soil. While the chromium(VI) reduction in aerobic soil microcosms has been extensively studied, there is little information in anaerobic soil community (Turick and Apel, 1997; Kourtev et al., 2006).

In this study, we used *Cellulomonas* sp. and *Propionibacterium* sp. to study the effect of various initial concentrations of Cr(VI) on chromium reduction rate in anaerobic soil microcosms and to examine the effect of various oxygen concentrations on Cr(VI) reduction rate.

**Results and Discussion**

The reduction rates of Cr(VI) decreased with an increase of Cr(VI) concentrations. When the second dose of Cr(VI) added after the onset of Cr(VI) reduction, the reduction rate of Cr(VI) decreased, indicating that the developing Cr-resistant communities had a relatively low tolerance threshold.

The oxygen was added from 2 % to 20 %, with 2 % interval, in anaerobic enrichment culture mediums. The reduction rates of Cr(VI) by *Cellulomonas* sp. decreased with an increase of oxygen concentrations. When the 20 % of oxygen added, which is the oxygen concentration in the atmosphere, the Cr(VI) did not reduce. The addition of oxygen can inhibit the reduction of Cr(VI). However, the concentrations of Cr(VI) was reduced by *Propionibacterium* sp. with the additions of oxygen continuously. Therefore, the reduction of Cr(VI) by *Propionibacterium* sp. was not affected by the presence of oxygen.

U-series comminution ages: Depositional age and transport times for non-marine sediments

Victoria E. Lee, Donald J. DePaolo, and John N. Christensen

1 Dept. of Earth and Planetary Science, University of California, Berkeley, 307 McConic Hall, Berkeley, CA 94720-4767 USA (vlee@eps.berkeley.edu)
2 Center for Isotope Geochemistry, Lawrence Berkeley National Laboratory, 1 Cyclotron Road, MS70A4418, Berkeley, CA 94720 USA

An important timescale in sedimentary cycling is the elapsed time between formation and deposition of sediment grains. This timescale is critical for assessing sediment residence and transport times, and may equate with depositional age in some environments. U-series isotopes may provide a way to determine this timescale, referred to as the “comminution age” (DePaolo et al. 2006). The approach is based on the decrease in the $^{234}\text{U}/^{238}\text{U}$ activity ratio resulting from alpha-recoil loss of the $^{234}\text{U}$ isotope from a grain once it is reduced below a threshold grain size.

We have investigated the relationships between the $^{234}\text{U}/^{238}\text{U}$ activity ratio and sediment characteristics for a core from the Kings River alluvial fan to determine if this method can be applied to non-marine deposits. This fan is a large Pleistocene-age feature whose deposits originate from a glacially-influenced drainage basin on the western side of the Sierra Nevada, California (Weissmann et al. 2002). We confirm a decreasing $^{234}\text{U}/^{238}\text{U}$ ratio with decreasing grain size and with increasing sediment age, consistent with a model where recoil loss of $^{234}\text{U}$ is the dominant process controlling the $^{234}\text{U}/^{238}\text{U}$ ratio in the detrital fraction. Various leaching procedures to remove non-detrital phases were investigated; the U isotope signature of the residue can be sensitive to this leaching. Parallel studies of sediments from Owens Lake, CA (USGS core OL-92) do not show a strong correlation between grain size and $^{234}\text{U}/^{238}\text{U}$ activity ratio, likely due to relatively high concentrations of U in non-detrital components that are not easily removed by leaching.

These initial results indicate that the $^{234}\text{U}/^{238}\text{U}$ comminution age method may indeed be a valuable tool for understanding sedimentary timescales, but methods for sampling and treating the sediments need refinement. Combining this approach with Nd and Sr isotopes to assess provenance, studies of sediment composition and physical characteristics, and modeling of recoil effects will also be discussed.

Integrated air quality assessment – Accumulation, transport, and source recognition of PAH

E. Lehndorff, M. Urban and L. Schwark

Department for Geology and Mineralogy, University of Cologne, Germany (e.lehndorff@uni-koeln.de, lorenz.schwark@uni-koeln.de)

In a multidisciplinary approach atmospheric quality in the Greater Cologne Area (GCA) was studied using pine needles as bioreceptors. Here we report accumulation behaviour, transport fractionation, source allocation and the spatial distribution of polycyclic aromatic hydrocarbons (PAH). The organic pollutant load is compared and interpreted in concert with major and trace elements, $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ isotopes, and environmental magnetic data.

The GCA comprises a complex mixture of various PAH emission sources, mainly lignite fueled power plants, highly trafficked regions, domestic heating and large industrial complexes along the Rhine Valley. Our previous studies demonstrated a systematic accumulation of PAH in/on pine needles and a statistically significant variability in the PAH concentrations between different sampling locations. In this study we focus on the discussion of PAH distribution maps based on data from 71 locations that are equally distributed on 3000 km² in the GCA.

In addition to the parent PAH listed in the EPA priority list we analyzed the dispersal of alkylated 3/4-ring PAH, increasing the number of PAH to >50 and thus improving their source diagnostic potential. In the GCA the dominant emitters of PAH are lignite-fueled power plants, followed by traffic in urban regions, and petrochemical plants along the river Rhine. Power plant emissions are characterized by elevated concentrations of phenanthrene, dibenzoanthracene and benzo[a]pyrene and reduced amounts of methyl- and dimethylphenanthrenes (MP, DMP). Traffic derived combustion PAH are recognized by high abundances of anthracene, 9-MP, 1,7-DMP and cyclopenta[def]-phenanthrene (CPP). Emissions of thioaromatics from vehicular engines are small due to the recent introduction of low-sulfur diesel. Release of uncombusted PAH from refineries and petrochemical industry is indicated by a high level of alkylated PAH and specific alkylation patterns. The ratio of 2/1-MP or 1,3+2,10+3,9+3,10-DMP/CPP are particularly high in refinery areas. Wood combustion is recognized by specific distribution patterns of 1,7-DMP (gymnosperms), 1,8-DMP (angiosperms) and retene.

Transportation distance and fractionation are assessed by investigating the relative proportions of 4-, 5-, and 6-ring PAH. Concentrations of particle phase bound PAH correlate well with those of magnetic combustion particles and are dominated by short transportation distance. Traffic indicator PAH show a perfect spatial distribution match to trace element indicators like Sb, Fe and Cu. Multiproxy air quality analyses allow for very reliable and independent source allocation especially in areas with multiple emission sources.
EarthChem – A geochemistry data network

KERSTIN LEHNERT1, DOUGLAS WALKER2 AND BAERBEL SARBAS3

1 Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, 10964, USA (lehnert@ldeo.columbia.edu)
2 University of Kansas, Lawrence, KS, 66045, USA (jdwalker@ku.edu)
3 Max-Planck-Institut fuer Chemie, Mainz, Germany (sarbas@mpch-mainz.mpg.de)

EarthChem is a collaborative effort to create an advanced and integrated network of geochemical data collections, to make a greatly expanded range and number of data collections discoverable and accessible for the broad Earth Science community through a single portal (‘One-stop-Shop for Geochemical Data’), and facilitate the analysis and integration of geochemical data with other geological, geochronological, geophysical, and geodetic information, and incorporate new legacy and future data. Current partners of the EarthChem project include SedDB, PaleoStrat, EarthRef, MetPetDB, CZEN (Critical Zone Experiment Network), MexDB (Mexican Volcanic database), the IODP US, the USGS, and GEON. EarthChem focuses on three areas:

1. Operation of a data portal (‘One-stop-shop for geochemical data’) that provides search capabilities across federated databases and tools for data quality assessment, data analysis, and visualization including plotting methods and an information-rich map interface. As part of the portal development, EarthChem has created an XML schema for geochemical data that allows all partner databases to communicate their data in a common format.

2. Expansion of available digital data collections for geochemistry. EarthChem is building tools to facilitate data submission from users, and contribution of focused projects, and compiles new critical datasets as identified by the community. Over the past year, a new data collection for the Petrology of the Deep Lithosphere has been created. A new geochronological data collection is being developed to provide a home for EarthTime and GeoEarthScope geochronology data.

3. EarthChem addresses user concerns, and responds to broad scientific and educational needs. EarthChem hosts workshops, holds exhibits, and works with scientific societies to address community issues related to data management and data use such as citation of original data contributors/authors versus citation of databases or standards for reporting data and analytical metadata in publications. Examples include: (a) Implementation of a ‘Data Usage Index’ on the EarthChem portal to track the number of times that data from a specific publication has been downloaded by users of the EarthChem portal. Ensuring credit to the author(s) of original data publications is fundamental for the broad geochemical community to support digital data collections. (b) Through several community workshops, EarthChem has defined recommendations for the reporting of analytical and sample information in geochemistry data publications.

Lithium isotope systematics in the Strengbach catchment (Vosges, France)

E. LEMARCHAND1, F. CHABAUX1, N. VIGIER2, R. MILLOT3 AND M.C. PIERRET1

1 CGS-CNRS/ULP, UMR 7517, 1 rue Blessig, 67084 Strasbourg Cedex, France
2 CRPG-CNRS, 15 rue N-D des pauvres, 54501 Vandoeuvre-les-Nancy Cedex, France
3 BRGM, 3 avenue Claude-Guillemin, 45060 Orléans Cedex 2, France

Lithium isotopic compositions of rocks, soils and continental waters are proposed to be proxies of continental weathering processes, but the reason of isotopic fractionation is not entirely known. The aim of this study is to better constrain Li isotope fractionation processes during weathering by studying variations of Li concentrations and isotopic compositions at the scale of a small granitic watershed (Strengbach catchment, Vosges, France, http://ohge.unistra.fr). Samples of precipitations, spring and stream waters and soil solutions have been collected during 2 years for Li concentration and isotopic measurements. Some of the principal results are compiled below:

- Based on the Li concentrations and isotopic compositions of rainwaters, soil solutions, spring and stream waters, it can be shown that the Li isotopic composition of the waters collected at the outlet of the Strengbach catchment results from mixing between two different fluxes: a “deep” one corresponding to rock weathering and a surface one, more significant at high discharge, corresponding to waters that interacted with soils. Due to solid/solution interactions, the δ7Li of these two fluxes are significantly variable.

- At low discharge, δ7Li of spring and stream waters increases with decreasing altitude. This should signify that waters sampled at the bottom of the catchment drained less weathered rocks than at the top. Isotopic signatures of the weathering flux seem to depend of the weathering degree of the drained rocks.

- Isotopic ratios (δ7Li) display also a great range of variations in soil solutions. In the first horizons of soil, [Li] and δ7Li in solution results from the combination of vegetation recycling and Li release from mineral. At the opposite, in deeper horizons, Li concentration and isotopic composition of soil solutions are driven by adsorption and/or coprecipitation processes.

This study particularly shows the interest of lithium isotopes to trace water circulations at the scale of a little catchment.
Solvation processes in steam: *Ab initio* calculations of ion-solvent structures and clustering equilibria

K. H. LEMKE AND T.M. SEWARD

Geochemistry Group, Institute of Mineralogy and Petrology, ETH-Zürich, Universitätstrasse 16, CH-8092, Zürich, Switzerland (kono@erdw.ethz.ch)

Reports of the high ion content of steam and low-density supercritical fluids date back to the work of Carlon [1], who invoked ion and neutral water clustering as a mechanism to explain why ions partition into the low-density aqueous phase. Mass spectrometric, vibrational spectroscopic measurements and quantum chemical calculations have refined this concept by proposing strongly bound ion-solvent aggregates and water clusters, e.g. Eigen and Zundel-type proton clusters \(H_2O^+\) and the more weakly bound water oligomers \(H_2O_m\). The extent to which these clusters affect fluid chemistry is determined by their abundance, however, little is known regarding the stability of such moieties in natural low-density high temperature fluids. Here we report, building on our recent report of the structures and energetics of protonated water clusters [2], results from quantum chemical calculations using high-accuracy multi-level G3 [2], and CBS-Q [4] theory to address this question. In particular, we have investigated the cluster structures and clustering equilibria for the ions \(H_2O^+\)(\(H_2O\))\(_m\)(\(H_2S\))\(_n\), \(NH_4^+\)(\(H_2O\))\(_m\)(\(H_2S\))\(_n\), and \(H_3S^+\)(\(H_2O\))\(_m\)(\(H_2S\))\(_n\), where \(m\leq6\) and \(n\leq4\), at 300 to 1000K and 1bar as well as under vapour-liquid equilibrium conditions between 300 and 646K. We find that incremental hydration enthalpies and entropies derived from van’t Hoff analyses for the attachment of \(H_2O\) and \(H_2S\) onto \(H_2O^+\), \(NH_4^+\) and \(H_3S^+\) are in excellent agreement with experimental values and that the addition of water to all three ions is energetically more favourable than solvation by \(H_2S\). As clusters grow in size, the energetic trends of cluster hydration begin to reflect those for bulk \(H_2O\) liquids, i.e. calculated hydration enthalpies and entropies approach values characteristic of the condensation of bulk water (\(\Delta H=44.0\ \text{kJ mol}^{-1}\), \(\Delta S=-118.8\ \text{J K}^{-1}\text{mol}^{-1}\)). Water and hydrogen sulphide cluster calculations at higher temperatures indicate that a significant fraction of \(H_2O^+, NH_4^+\) and \(H_3S^+\) ions exists as solvated moieties.

Constraints on the Earth’s mantle heat budget from mantle plumes

WEI LENG AND SHIJIE ZHONG

Department of Physics, University of Colorado, Boulder, Colorado 80309, USA (szhong@colorado.edu)

Mantle plumes may be derived from thermal boundary instabilities in the bottom thermal boundary layer (e.g., the core-mantle boundary) of the convective mantle and may contain important information on the heat transfer across the bottom thermal boundary layer. Plume heat flux and plume excess temperature for the upper mantle can be used to constrain the heat flux from the core to be ~35%-40% of the total surface convective heat flux and internal heating rate for the mantle to be ~60%-65%, depending on whether mantle convection is layered or whole-mantle convection. Here, we extended this study by computing models for a large parameter space (particularly different mantle rheology) and a much improved resolution and also by considering different criteria for detecting plumes. The new results confirmed that ~30-35% of the surface convective heat flux or ~10-12 TW needs to be derived from the core. We demonstrated that plume heat flux may account for ~90% of the core heat flux when plumes are generated above the CMB but plume heat flux decreases significantly as plumes ascend from the lower mantle to the upper mantle by a factor of ~2. More importantly, we demonstrated that the reduction of plume heat flux as plumes ascend is mainly caused by the large adiabatic cooling of plumes due to their excess temperature, while subadiabatic temperature only contributes less than 30% towards the plume heat flux reduction. We also showed that the plume temperature follows the adiabat for the plumes, and this provides a new approach to constrain the CMB temperature or the averaged dissipation number for the mantle from plume temperature in the upper mantle. Our results again suggest that for cooling rates less than 70K/Ga, the radiogenic heat generation rate for the MORB source regions needs to be more than 4 times higher than that for the depleted mantle.
Iron oxyhydroxide nanomaterials play important roles in the mobility of aqueous metal species through sorption and desorption processes. The growth of such nanophases leads to changes in their structure and reactivity and may additionally modify the mechanisms by which metal ions are adsorbed and retained. In this study, macroscopic and microscopic techniques were used to elucidate the sorption, desorption and incorporation mechanism of metals onto and within nanoscale iron oxyhydroxides during their aging and growth.

The retention of Zn(II) and Cu(II) to iron oxyhydroxide nanoparticles aged at 25 – 75°C for 0 – 96 hours was demonstrated through macroscopic uptake and desorption experiments. While uptake of Zn(II) (Fig. a) and Cu(II) (data not shown) was rapid and complete within an hour, desorption was found to be partially irreversible (Fig. b) and showed a clear relationship with both nanoparticle aging time and temperature. Less Zn was desorbed from material aged at either higher temperature or for longer time periods, indicating stronger adsorption or the role of physical incorporation mechanisms in these cases. X-ray absorption spectroscopy (XAS) of selected sorption and desorption samples supports the hypothesis that the retained metals are present as structurally incorporated sorption complexes. This is evident by the higher metal-Fe coordination observed in samples from which the readily desorbed material has been removed.

Used together such techniques provide information about how these and possibly other metals are 1) complexed on the surface of iron oxyhydroxides or 2) are incorporated into the iron oxyhydroxide structure. These findings have implications for the long-term removal of hazardous metals from the aqueous phase and the development of possible remediation strategies targeting contaminated environments.

Nano-carbonate clustering in organic globules supports a biogenic origin of 2.7 Gyr old stomatolites

K. LEPOT¹, K. BENZERARA¹,² AND P. PHILIPPOT¹

¹Institut de Physique du Globe de Paris, Equipe Geobiosphère Actuelle et Primitive (lepot@ipgp.jussieu.fr, philippo@ipgp.jussieu.fr)
²Institut de Minéralogie et de Physique des Milieux Condensés (benzerar@impmc.jussieu.fr)

The macroscale morphology of Archean stromatolites has been used as evidence of early microbial ecosystems. But as Archean stromatolites only rarely contain fossil microbes, their biogenicity is tacitly assumed on the basis of macroscopic morphological comparisons with modern structures. Biogenetic definitions, however, require microscopic examination of suspected stromatolites.

We obtained an unique collection of pristine samples from a diamond drillhole that intersected the 2.7 Ga Tumbiana Formation, Australia (Pilbara Drilling Project, Van Kranendonk et al., 2006). We report the occurrence of micron-sized globules of organic carbon intimately associated with the host micritic carbonate. Scanning Transmission X-ray Microscopy (STXM) analysis revealed that these organic globules are composed of organic carbon with aromatic, aliphatic and carboxyl functional groups. High Resolution Transmission Electron Microscopy (HRTEM) analysis revealed that the organic material occurs in intimate association with clustered, 50-200nm rounded bodies of aragonite. These nano-aragonite aggregates show striking similarities with nano-carbonate spheroids associated with microbial cells and polymers in modern microbialites.

Our results indicate that Tumbiana stromatolites were likely formed via in-situ microbial lithification. They also extend the geologic record of aragonite back more than 2,300 million years, with profound implications on the environmental conditions prevailing on Early Earth.

⁷Be, excess ²¹⁰Pb and artificial radionuclides as tracers of orographic deposition of aerosols

G. LE ROUX¹, L. BOURCIER¹,² AND O. MASSON¹

¹Institut de Radioprotection et Sûreté Nucléaire, St Paul lez Durance, France (Gael.le-roux@irsn.fr)
²Laboratoire de Météorologie Physique, Université Clermont Ferrand, France

Aerosols play a significant role in global biogeochemical cycles and climate system. In mountainous sites, atmospheric deposition of pollutants and nutrients is enhanced by different mechanisms including feeder-seeder effect or cloud-interception. Understanding these mechanisms is necessary to improve deposition models and evaluate the sensitivity of these fragile ecosystems.

We use inventories of ²¹⁰Pb, ⁷Be, both natural aerosol-bound radionuclides and artificial radionuclides (¹³⁷Cs and Pu) in undisturbed soils to quantify mechanisms influencing aerosol deposition along the different slopes of the Puy de Dôme (1465m asl), an unactive volcano in Massif Central. We combine these results with 2-years measurements of aerosols and atmospheric deposition at the top and the base of Puy de Dôme.

The figure 1 shows that ²¹⁰Pb inventories are increasing with altitude. Using also ⁷Be and ¹³⁷Cs inventories, we are able to demonstrate that this increase of ²¹⁰Pb and therefore aerosol deposition is due to orographic effects. It seems that NO and NE slopes are more affected by orographic deposition. Other mechanisms increasing the deposition of "surface air" enriched in ²¹⁰Pb like the feeder-seeder mechanism can also explain these results. ⁷Be gives us insights of aerosol origin from the free troposphere and the stratosphere. Despite shorter representativity of ⁷Be values (¹/₂life: 50d), measured flux ratios of ²¹⁰Pb/⁷Be (0.04-0.016) in soils are in good agreement with ²¹⁰Pb/⁷Be ratio measured in aerosol and precipitations (0.1-0.16).

It will be discussed how the use of both radionuclides can offer a way to quantify wet deposition mechanisms and validate 3-D conceptual models of atmospheric deposition.

![Figure 1: ²¹⁰Pb inventories in soils vs. altitude along different slopes of the Puy de Dôme](image-url)
Insights into refertilization processes in lithospheric mantle from integrated isotopic studies in the Lherz Massif

V. LE ROUX1,2, J.-L. BODINIER1, O. ALARD1,2, P. WIELAND2 AND S.Y. O’REILLY2

1Géosciences Montpellier, UMR 5243 - CC 60, Université Montpellier 2, Place E. Bataillon, 34095 Montpellier cedex 5 France
2GEMOC, Department of Earth & Planetary Sciences, Macquarie University NSW 2109, Australia

Differentiation of the Earth’s mantle occurs principally through partial melting and extraction of basaltic melt. Among the mantle rocks occurring at the Earth’s surface, harzburgites are widely considered as refractory mantle residues left after extraction of a basaltic component. In contrast, fertile lherzolites are generally regarded as pristine mantle, only weakly affected by partial melting. However in the Lherz Massif (France), structural mapping shows that the lherzolites are secondary rocks formed at the expense of the harzburgites. Variations of major, minor and trace elements across the harzburgite-lherzolite contacts indicate that the lherzolites were formed through a refertilization process involving interaction of refractory, lithospheric mantle with upwelling asthenospheric partial melts. Rare-earth elements (REE) in clinopyroxenes display variable chondrite-normalized REE patterns. Massive harzburgite bodies show U-shaped REE patterns whereas lherzolites have classic N-MORB REE patterns as observed in orogenic lherzolites worldwide. However at the contact, both lherzolite and harzburgite show more LREE-enriched clinopyroxenes than their distal counterparts. These REE enrichments also cannot be explained by partial melting model and provide further evidence for refertilization.

In order to further constrain the mechanisms involved in the refertilization process, we investigated Sr, Nd and Hf isotopic compositions of over 15 samples across a harzburgite-lherzolite contact, as well as “distal” samples. Sr isotopes were measured in whole-rocks and clinopyroxene separates (TIMS and MC-ICP-MS), combined with the Sr in-situ method on clinopyroxenes (LA-MC-ICP-MS). Al2O3 is negatively correlated with 87Sr/86Sr and positively correlated with 143Nd/144Nd. These correlations are consistent with REE patterns. Distal harzburgites have 87Sr/86Sr = 0.703638(6), while distal lherzolites have 87Sr/86Sr between 0.7020 and 0.7025. Towards the contact, the lherzolites show a steady increase in 87Sr/86Sr up to 0.7032. The harzburgites within the contact radiogenic compositions up to 0.7055. The highly radiogenic composition of the contact zone is not compatible with melting models. Further investigations are in progress to characterise the scale and range of isotopic variations across the transition from harzburgite and lherzolite.

P-V-T equation of state of glasses and melts by X-ray microtomography and absorption

C.E. LESHER1, Y. WANG2, S. GAUDIO1, A. CLARK1, AND M. RIVERS2

1Dept. of Geology, UC Davis, Davis, CA 95616 (celesher@ucdavis.edu)
2GSECARS, ANL, Argonne, IL 60439

The new high-pressure X-ray tomographic microscope installed on 13-BM-D at GSECARS-APS/ANL is being refined to measure the volumetric properties of glasses and melts. Bulk moduli are constrained through direct measurements of volume changes by X-ray computed tomography and density is determined from X-ray absorption. The tomographic microscope consists of two opposing anvils compressed within an X-ray-transparent containment ring supported by thrust bearings driven by a 250-ton hydraulic press. This system permits the pressure cell to rotate under a load, while collecting radiographs through 180 degrees of rotation. Individual radiographs are recorded by a CCD camera after conversion to visible light by a YAG scintillator and are combined to render the volume using a back-projection algorithm and standard flat/dark field corrections with minimal filtering, following by image processing. The 13-BM-D beamline configuration permits switching between a monochromatic beam to produce high-quality radiographs and a white beam to measure pressure through energy dispersive diffraction of a standard. Density is recovered from the linear attenuation coefficient calibrated against internal pressure standarts. Preliminary results are reported for refractory magnesium silicate glasses compressed to ~11 GPa and heated to glass transition temperatures using a modified toroidal anvil cell. Strategies to reach the melting interval for in situ studies of compositions relevant to the Earth’s mantle and core will be discussed.
Tectonothermal evolution of Helanshan Complex, westernmost part of the Khondalite belt in the Western Block of North China Craton

WINGHANG LEUNG, GUOCHUN ZHAO, MIN SUN AND CHANGQING YIN

Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong (h0327799@hkusua.hku.hk)

New data show that the Western Block of the North China Craton formed by the amalgamation of the Yinshan Terrane in the north and the Ordos Terrane in the south along a Paleoproterozoic collisional belt, named the Khondalite Belt [1-6]. However, the timing and tectonic nature of this collisional event remains unclear. More and more studies show that the metamorphic P-T evolution can be successfully used to constrain the tectonic nature and processes of orogenic belts. In this study, we present petrological and thermobarometric data for the Helanshan Complex at the westernmost segment of the Khondalite Belt, which provide important insights into the tectonic history of the belt.

The Helanshan Complex consists mainly of Al-rich gneisses, quartzites, marbles and calc-silicate rocks, called khondalite series in the Chinese literature, and S-type granites. Microstructural analysis and metamorphic reaction relations show that the Al-rich gneisses underwent four major metamorphic stages. The M1 assemblage is represented by inclusions found in the garnet poikiloblast, which includes quartz, plagioclase, biotite and kyanite. The M2 stage is defined by growths of matrix minerals quartz, plagioclase, K-feldspar, biotite, cordierite and sillimanite and garnet porphyroblasts. M3 is represented by the reaction rim of cordierite formed around the garnet porphyroblast. The final stage, M4, is represented by muscovite and sericite, and occasionally, andalusite, overprinting the major foliation in the rock.

These mineral assemblages and their P-T estimates define a clockwise P-T path involving decompression, which indicates that the Helanshan Complex underwent initial crustal thickening and subsequent exhumation, accommodating a collisional environment, supporting the recently-proposed model that the Khondalite Belt represents a collisional belt along which the Yinshan and Ordos Terranes amalgamated to form the Western Block in the Paleoproterozoic.

This study was financially supported by the Hong Kong CERG grants (7055/05P, 7058/04P, and 7063/06P) and a Chinese NSFC Grant (40429001).

Role of natural nanoparticles (imogolite and allophane) on the mobility of trace metals in soils from La Reunion island

C. LEVARD1, J. ROSE1*, A, MASION1, E. DOELSCH2, I. BASILE-DOELSCH1 AND J.-Y. BOTTERO1

1CEREGE, CNRS-UPCAM UMR6635 13545 Aix en Pce Cedex 04-France (*rose@cerege.fr)
2CIRAD, Saint-Denis Messagerie Cedex 9, La Réunion, F-97408 France

This research adresses the sensitive field of waste management in an insular context. The case of the Reunion Island bears some aggravating factors making the waste management an even more sensitive subject: 1) it is a small island with a fast growing population and associated activities 2) the agricultural soils (mostly andosols) have an elevated natural concentration of trace metals. An inexpensive form of waste management is to reuse agricultural- waste (especially pig manure) as fertilizer. However, reuse of waste, may modify physico-chemical conditions and trace elements can be released from the soils. The accuracy of the prediction of metal fluxes in soils will be greatly enhanced by a detailed knowledge of the pollutants' speciation, which controls their mobility, toxicity and ultimately their bioavailability. Although the trace metals Cu, Ni, Zn selected for this study because of their occurrence in the soils and wastes, may bind to numerous components of the soils (clays, Fe and Al oxides, organics), we chose to focus on 2 types of nanosized aluminosilicates: the tubular imogolites (2nm diameter) and the spherical allophane (3-5nm). The choice of these phases is justified by their high abundance in the andosols of the Reunion, and their suspected high reactivity arising from the presence of -SiOH and -AlOH at the surface of structures whose specific surface area can reach 700m²/g. Here we detail using a molecular approach the types of the binding mechanisms between pollutants and natural occurring nanoparticles.
Unveiling the origin and evolution of dust in comets

A.C. LEVASSEUR-REGOURD1, J. LASUE1, E. HADAMCIK1 AND W. KOFMAN2

1Univ. Pierre et Marie Curie-Paris6, UMR 7620, Aéronomie (aclr@aerov.jussieu.fr, jeremie.lasue@aerov.jussieu.fr, edith.hadamcik@aerov.jussieu.fr)
2LPG, Grenoble (wlodek.kofman@obs.ujf-grenoble.fr)

Investigating the properties of dust released by comets is of major interest to constrain their formation models. Instruments flying-by comet Halley had discovered the presence of organics, and pointed out the low albedo and extremely low density of the dust. Analyses of IDPs and remote spectroscopic observations have indicated that cometary dust consists of an un-equilibrated heterogeneous mixture of organic refractory materials and of amorphous and crystalline silicate minerals, as recently confirmed by Stardust. Observations of the solar scattered light, together with elaborate simulations, have revealed physical properties of the dust. For a well-documented comet, the mass ratio between silicates and absorbing organics, the size distribution and the structure of the dust particles, can be estimated, suggesting that a fair amount consists in fluffy aggregates built up from submicronic grains [1,2], as recently confirmed by Stardust. A detailed analysis of the waves passing through the nucleus of the propagation delay of long wavelength radio waves [3]. On board the Rosetta probe, MIDAS experiment will provide unique information on the dust texture, shape, size and flux, during the rendezvous with comet Churyumov-Gerasimenko. Moreover, the CONSERT experiment will investigate the deep interior of the nucleus from measurements of the propagation delay of long wavelength radio waves [3]. A detailed analysis of the waves passing through the nucleus will put constraints on the materials and on the heterogeneities within the nucleus. While it is now established that nuclei have low densities and are significantly fragile, it will then be possible to better constrain their formation process and their origin.

Partial melting of eclogite to form high-pressure granitic rock: A case from the Erzgebirge, Southeast Germany

B.J. LEVAY1, M.D. FEINEMAN1, T. ZACK2 AND D.M. KERRICK1

1Department of Geosciences, Penn State University, University Park, PA, 16802, USA
2Mineralogisches Institut, Universität Heidelberg, INF 236, 69120 Heidelberg, Germany

We describe an eclogite body from the shore of the Saidenbach reservoir in the Erzgebirge, Germany, that appears to have partially melted to produce a high-pressure granite. The primary eclogite assemblage is omphacite (commonly altered to jd-poor cpx + plag (An10 – An17) symplectites) + garnet + quartz + phengite + rutile. Within these rocks are numerous veins (1 mm to 5 cm wide) and pockets of potassium feldspar + quartz + plagioclase (An11) + phengite + garnet + rutile. This coarse-grained leucocratic material also occurs somewhat diffusely throughout portions of the eclogite matrix, in direct contact with unaltered omphacite.

Textural evidence leads us to believe that the leucocratic material is derived from fluid-fluxed partial melting of the host eclogite. Anatectic of metabasalt compositions typically leads to the formation of tonalites and trondhjemites, but at high pressures partial melting of potassium-enriched eclogites can produce granite over a significant range of melt fractions (Schmidt et al., 2004). The major element composition of the granitic veins in the Saidenbach eclogites is very similar to experimentally generated, basalt-derived granitic melt compositions, with K:Na ratios of ~1.4 (Schmidt et al., 2004). The granitic melt generated by partial melting of the Saidenbach eclogite may also be related to diamoniferous quartzofeldspathic rocks outcropping on the shore of the same reservoir. These kyanite-bearing rocks have been interpreted as high-pressure metasediment melts due to their high aluminum content (Massonne, 2003). However, experiments have shown that high-pressure eclogite melts can also be aluminous (Schmidt et al., 2004). Mineral assemblages of the eclogite leucosomes and the nearby quartzofeldspathic rocks are extremely similar, except for occurrence of kyanite and a higher abundance of carbon (in form of graphite and/or diamond) in the latter. By comparing the geochemistry of the two rock types, we have the rare opportunity to work out the similarities and differences of possibly sediment-derived and clearly eclogite-derived melts, allowing more precise statements about the metasomatic capacity of high pressure melts.

Water delivery from the outer planetary system: The role of dynamical instabilities

H. F. LEVISON
Southwest Research Institute, Boulder, CO, USA
(hal@boulder.swri.edu)

Water abounds in the outer regions of planetary systems. Indeed, comets, which are the leftover building blocks of the giant planets, are roughly 40% water by mass. Thus, these regions can furnish a significant amount of water to terrestrial planets provided a dynamical mechanism exists that can transport enough material inward.

In recent years it has become recognized that planetary systems can become dynamically unstable, leading to a violent redistribution of the planetary orbits. Indeed, we see evidence of such instabilities in some of the extra-solar planetary systems thus far discovered (Rasio & Ford 1996). These events, which can occur quite late in the history of a planetary system, can liberate a large amount of water rich objects and deliver them to the inner planetary system where they can strike the terrestrial planets.

Such an event may have occurred in our own Solar System. Many of the large basins on the Moon formed ~700Myr after the beginning of the Solar System – much too late for the impactors to be the leftovers of terrestrial planet formation (Bottke et al. 2007). The model that has been the most successful at reproducing the characteristics of these basins is one where the orbits of Uranus and Neptune became unstable, sending a large amount of icy material into the inner Solar System (Gomes et al. 2005). Such an event would have contributed roughly 5% of Earth oceans. Also, it would have contributed enough icy material to Mars to explain its putative early massive atmosphere (Levison et al. 2001).

More details on this talk can be found at www.boulder.swri.edu/~hal/talks.html

Volatiles and Boron isotopes analysis in olivine-hosted melt inclusions from Vulcano (Italy) and Pichincha (Ecuador) lavas

M. LE VOYER1, E.F. ROSE-KOGA AND P. SCHIANO
LMV, 5 rue Kessler, 63000 Clermont Ferrand, France
(M.Levoyer@opgc.univ-bpclermont.fr)

We have analysed in-situ major and trace elements (electron probe, LMV, Clermont Ferrand, France), as well as volatiles and boron isotopic compositions (ion probe, 1280 WHOI, MA, USA) in olivine-hosted primitive melt inclusions (MI) in basic lavas of two volcanoes from two different subduction settings:

1- The Ecuadorian subduction zone is controlled by the subduction of the Nazca plate beneath South America. The collision of the Carnegie aseismic ridge disturbs the subduction, flattens the slab (small dip from 20 to 30°) and controls the surface expression of active volcanism. Slab melt takes part in the formation of these lavas and some adakite occurrences have been described.

2- The Aeolian arc lavas are thought to represent typical examples of island-arc calc-alkaline magmatism. The tectonic setting of the Tyrrenhian Sea is dominated by the convergence between the European and African plates. The Aeolian arc is related to the subduction of the oceanic Ionian plate beneath the Tyrrenhian Sea (strong dip around 50 and 60°), actually in eastward migration.

Primary MI are at equilibrium with their host minerals, so they preserve information on the composition of intermediate steps in the formation of magmas. In particular, MI in the early-formed olivine phenocrysts have been proposed to be pristine samples of mantle-derived melts that were trapped prior to mixing at shallower levels. Moreover, unlike lavas, MI keep their primitive volatile content.

The MI from these two different settings are CaO-rich and nepheline-normative. These compositions have been interpreted as the result of melting of a lower crust clinopyroxene-rich lithology (Schiano et al., 2000)

$^{11}$B in MI range from –5.0±1.0‰ to +3.0±1.0‰ for Vulcano, and from –18.8±1.0‰ to +9.5±1.0‰ for Pichincha) which suggest heterogeneous sources for the two volcanoes. MI from Vulcano are enriched in H2O and Cl, and those from Pichincha are enriched in CO2, F and S (Vulcano: 0.95 to 3.50% H2O, 80 to 170 ppm CO2, 805 to 910 ppm F, 3000 to 3500 ppm Cl and 2000 to 2400 ppm S; Pichincha: 0.1 to 1.5 % H2O, 130 to 800 ppm CO2, 100 to 400 ppm F, 200 to 700 ppm Cl, 500 to 2500 ppm S; relative errors are equal to or less than 5%). We will discuss the results in terms of source variation and input from the slab.

Low temperature nucleation of ferric arsenate using microorganisms

R.A. LEWIS, A.J. MONHEMIUS AND J.A. PLANT

Department of Earth Science and Engineering, Imperial College London, SW7 2AZ, UK.
(robert.lewis@imperial.ac.uk; john.monhemius@imperial.ac.uk ; jane.plant@imperial.ac.uk)

Introduction
The safe disposal of arsenic is important for the metal extraction industry worldwide. Previous work has shown that crystalline ferric arsenate (FeAsO$_4$·2H$_2$O), which is a synthetic version of the natural mineral scorodite, fulfils most of the criteria for safe disposal. Presently, this requires the use of expensive pressurised equipment in industrial applications. There is increasing evidence that microorganisms play an important part in the geochemical cycle of As. In environmental samples, bacteria are often closely associated with mineral precipitates, as well as in bioleaching samples.

Method
Strains of acidophillic bacteria (Acidithiobacillus spp., Sulfobacillus spp. and Thiomonas spp.) have been enriched and isolated in liquid and on solid media from rock samples from former mine sites in the Czech Republic and the UK, and experiments carried out to determine whether the bacteria can catalyse the formation of ferric arsenate.

Results
No distinct mineral phases have been identified by XRD, and there is no variation in crystallinity with varying concentrations or valences of arsenic species. FTIR analyses of precipitates have identified no crystalline mineral phases, and there is no increase in crystallinity with age over the months during which the precipitates have been studied.

Conclusions
To date we have no evidence that the selected bacteria can precipitate ferric arsenate on solid media, despite varying concentrations of As added as As$^{3+}$ or As$^{5+}$. Material formed has been x-ray amorphous due to rapid formation, and FTIR analyses have shown no increase in crystallinity with age over the months in which the precipitates have been studied.

FT-IR investigation of the uranium S-layer interaction in aqueous solutions

B. LI, H. FOERSTENDORF, J. RAFF AND G. BERNHARD

Forschungszentrum Dresden-Rossendorf, Institut für Radiochemie, Postfach 510119, 01314 Dresden, Germany (b.li@fzd.de)

Many bacteria possess so-called surface layer (S-layer) proteins, forming paracrystalline lattice structures on the cell wall [1]. Beside its ecological relevance for the retention of toxic metals, they are a good model system for investigations of the interaction of bio-ligands, e.g. proteins, with uranium in aqueous solutions. Several S-layers from different Bacillus strains were proved to have high binding capacity to uranium. But there is still little knowledge of the interactions between the functional groups of the protein with the actinyl ions at a molecular level [2].

In this work we present results of batch experiments where the uranium binding capacities of different S-layer protein from different Bacilllus strains were determined. The experiments were carried out at different pH values (pH 4, 6, and 8) for each isolated S-layer protein. It was found that the uranium binding capacities of each gram S-layer range from 5.0 mg and 63.9 mg, from 11.1 mg and 561.1 mg, and from 14.2 mg and 33.5 mg at pH 4, 6, and 8, respectively, depending on the respective S-layer.

For a deeper understanding of the molecular binding of the uranyl ion to the protein we used Attenuated Total Reflectance Fourier-transform Infrared spectroscopy (ATR-FTIR) which allows vibrational spectroscopic investigations of aqueous solutions containing actinide ions and dissolved proteins as well [3, 4]. The spectra clearly demonstrate carboxyl groups are the major functional groups which interact with the uranyl ions at pH 4. Additionally, the infrared spectra suggest the formation of different uraniu m-protein complexes depending on the incubation period (1 h vs. 48 h) which can be observed by a peak shift of the absorption band representing the antisymetric uranyl stretch to lower wavenumbers.

This spectroscopic approach constitutes the foundation of more detailed investigations on the impact of the pH value and of other functional groups (e.g. phosphate or amino groups) on the uranium complexation by bio-systems.

Experimental study on liquid immiscibility of lamprophyre – Sulfide melt at high temperature and high pressure

BO LI¹, ZHILONG HUANG²* AND CHENMING ZHU²

¹Land and Mineral resource Engineering College of Kunming University of Science and Technology, Kunming 650093, China
² The Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (* huangzhilong@vip.gyig.ac.cn)

The liquid immiscibility of silicate-sulfide melt is a common geological phenomenon in magmatic processes (Naldrett, 1989; Roedder, 1992). This phenomenon is often used to explain the zonal distribution of ore layers in basic-ultrabasic rocks and the formation of magmatic Cu-Ni sulfide deposits (Naldrett, 1989, 2005). At present, the experimental investigation of liquid immiscibility of the silicate-sulfide melt in synthetic FeO-SiO₂-FeS system has accumulated a lot of data (Fleet and Pan, 1994). But the investigation in the system of natural rocks is hardly conducted.

By taking lamprophyres and pyrites from the Laowangzhai orefield, Yunnan Province, China as starting materials, at 1.5 GPa to 3.0 GPa and 1160 °C to 1560 °C, this paper carry out experimental study on liquid immiscibility of lamprophyre-sulfide melt at high temperature and high pressure in the DS-29A cubic 3600t/6 type high pressure apparatus.

The results show that the liquid immiscibility of silicate-sulfide melt is a common geological phenomenon in magmatic processes (Naldrett, 1989; Roedder, 1992). This phenomenon is often used to explain the zonal distribution of ore layers in basic-ultrabasic rocks and the formation of magmatic Cu-Ni sulfide deposits (Naldrett, 1989, 2005). At present, the experimental investigation of liquid immiscibility of the silicate-sulfide melt in synthetic FeO-SiO₂-FeS system has accumulated a lot of data (Fleet and Pan, 1994). But the investigation in the system of natural rocks is hardly conducted.

By taking lamprophyres and pyrites from the Laowangzhai orefield, Yunnan Province, China as starting materials, at 1.5 GPa to 3.0 GPa and 1160 °C to 1560 °C, this paper carry out experimental study on liquid immiscibility of lamprophyre-sulfide melt at high temperature and high pressure in the DS-29A cubic 3600t/6 type high pressure apparatus.

The results show that the liquid immiscibility of lamprophyre-sulfide melt in magmatic processes will happen during the early magmatic evolution (high-pressure condition), and this process should also occur in every stage of the magmatic evolution (from high-pressure to low-pressure condition) if sulfur exists. The sulfide melt which separated from the silicate melt will make directional movement in temperature and pressure field and assemble in the low-temperature and low-pressure region. Because the density of sulfide melt is higher than that of silicate melt, the former would gather together in the bottom of magma chamber and there would exist a striking boundary between the two melts.

A new genetic model for the Noril’sk-Talnakh Ni-Cu-PGE sulphide deposits

CHUSI LI, EDWARD M. RIPLEY AND CRAIG H. MOORE
Department of Geological Sciences, Indiana University, Bloomington, IN 47401, USA (cli@indiana.edu)

A popular genetic model for the Ni-Cu-PGE sulphide ores in the Noril’sk-Talnakh intrusions in Siberia which emphasizes a direct link between the sulphide-bearing intrusions and the overlying PGE-depleted basaltic lavas has been criticized because of differences between the intrusions and lavas such as trace element ratios and S-Sr-Nd isotope compositions. In addition, the unusual combination of high PGE concentrations and high δ³⁴S values (~11‰) in the sulphide ores has not been explained adequately. Based on our new S isotopic data and mass balance calculations, we suggest that such an unusual combination resulted from anhydrite dissolution in sulphide under-saturated, PGE-enriched magma. We propose that the PGE-enriched magma was generated by complete resorption of early immiscible sulphide liquids in new pulses of mantle-derived, sulphide under-saturated magma in a deep staging chamber. The magma became sulphide saturation again after subsequent assimilation of anhydrite country rocks at shallower levels. Abundant anhydrite xenoliths with δ³⁴S values of ~16‰ in the intrusions provide direct evidence for anhydrite-magma interaction during magma ascent and final emplacement. The PGE-depleted lavas which may have contributed chalcophile elements to the early sulphide liquids in the deep staging chamber directly erupted to the surface without interacting with anhydrite-bearing country rocks; thereby they did not acquire anhydrite S isotopic signatures.
New carbon isotope stratigraphy of an old section in southwest China: Implications for placement of PC-C boundary on Yangtze Platform

DA LI, HONG-FEI LING*, YONG-QUAN CHEN, JIA-YONG PAN, SHAO-YONG JIANG and HONG-ZHEN FENG

State Key Laboratory for Mineral Deposit Research, Dept. of Earth Sci., Nanjing University, Nanjing 210093, China

We report a high-resolution carbon isotope profile from Laolin section on Yangtze Platform, in northeastern Yunnan Province, southwest of China. The Laolin section, located east to the Dianchi Fault, has more continuous strata around the Precambrian-Cambrian (hereafter PC-C) boundary than the Meishucun section located west to the Dianchi Fault, where exist depositional hiatuses between Batianshao member (including the Xiaowaitoushan member) and Zhongyicun member, and between Dahai member and Qiongzhusi Formation (Qian et al., 1996). Thus the Laolin succession has great value for placement of PC-C boundary on the Yangtze Platform and global correlations. Shen & Schidlowski (2000) studied the carbon isotope chemostratigraphy for the Laolin section, though their strata frame was doubted by Zhu et al. in 2001. Our study on carbon isotope stratigraphy of the Laolin succession based on careful stratum frame work yielded two negative excursions (L1´ and L3´) and a positive excursion (L4). The first negative δ¹³C excursion (L1´) in upward order around the PC-C boundary occurs just below the first appearance data (FAD) of small shelly fossil (SSF) which was found at the base of the Zhongyicun member (Luo et al., 1991). Such combination of negative δ¹³C and FAD of SSF is the same as the situation of eastern Siberia PC-C boundary. We correlate the Laolin succession with those in Mongolia, eastern Siberia, northern Siberia, Iran and Canada, where similar situations that the first negative δ¹³C excursion occurs closely beneath or over the FAD of SSF, and provide a better PC-C boundary on the Yangtze Platform than the Meishucun succession. This study is supported by NSFC grant 40572017.

ISODUST: A Nd-Sr isotopic database to trace the source regions of Asian dust

GAOJUN LI AND JUN CHEN

Department of Earth Sciences, Nanjing University, Nanjing, China (ligaojun@nju.org.cn; chenjun@nju.edu.cn)

Mineral dust emitted from Asian Interior has broadly environmental impacts as it is spreading in the atmosphere. The knowledge on the source regions of Asian dust and their temporal variations is critical for predicting the overall dust impacts and understanding the paleo-environmental proxies in the dust deposits. Radiogenic Nd-Sr isotopes have been proven to been reliable source tracers, but this method needs long-term accumulation of data. This database is designed to solve this problem. It contains more than 400 pairs of Nd-Sr isotopic data which belong to the following three sub-databases mainly based on our own measurements.

ISODUST1: Potential Source Regions
It covers all of the potential source regions in North China and Mongolia, including the deserts, sandy lands, Gobi, fluvial fans, dry riverbeds and dry lake basins. Most of the data are based on the fine (< 75 µm and < 5 µm) silicate fractions of the samples, which enable the direct comparison between the dust and their potential sources without the influences of weathering and transportation. It is shown that different source regions have distinct Nd-Sr isotopic compositions controlled by their tectonic settings. The tectonic control suggests that the Nd-Sr isotopic signatures of these sources could be quite stable on the sub-tectonic time scales, which enable the use of this database to trace the provenances of the ancient dust.

ISODUST 2: Ancient Dust Deposits
Silicate Nd-Sr isotopes of ancient dust deposited in North China, North Pacific and Greenland are collected. It shows that the vast distributed loess in North China is transported from their adjacent regions by the prevailing near-surface wind. The provenance of the eolian deposits in Chinese Loess Plateau is quite stable in the most times of past 7 Myrs. However, rapid changes in source regions have been detected, probably reflects some abnormal monsoon conditions. The Asian end members of the ancient dust in North Pacific and Greenland are mainly the deserts on the margin of Tibetan Plateau, where the westerly jet passes by.

ISODUST 3: Modern Dust
It consists of the silicate Nd-Sr isotopic data of the atmospheric particles collected in the past years. The Nd-Sr isotopes provide a method to trace the sources of modern dust in addition to other observational techniques. Anthropogenic influence on the dust sources in Beijing has been detected by comparing the Nd-Sr isotopic compositions of the modern dust to those of the ancient dust deposits (loess) in this region. Dust emitted from the locally dry riverbeds caused by water management can explain the observed anthropogenic influence.
Microbial uranium mineralization and hydrocarbon oxidation in the Qianjia-dian deposit, NE China

HONGTAO LI, CHUNFANG CAI, HONG HE AND LI KAIKAI
Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, P. R. China

Braided rive facies sandstone - hosted tabular uranium deposit has recently been found in the Lower Cretaceous Yaqia Formation in the Qianjadian deposit, the Kailu basin, NE China. The mineralization consists mainly of pitchblende (UO₂, x=2.16 to 2.7) and small amount of brannerite (UTi₂O₆). U-Pb dating shows the main U-mineralization took place at about 53±3Ma during the early Himalayan orogeny, when the basin was uplifted and petroleum was up-migrated from the Upper Jurassic lacustrine source rock through faults. Subsequently, part of the U ore was re-mobilized and re-precipitated at about 7±0 Ma during the late Himalayan orogeny. Uranium ore occurs as cement or adsorbed on plant debris, but no correlation occurs between TOC and U content. Some of the pitchblende is intimately intergrown with ore-stage pyrite, Fe dolomite and calcite, indicating part of carbon was derived from petroleum oxidation. The host sandstone contains adsorbed petroleum and oil inclusions with adsorbed methane up to 5530µl/kg. GC data from oil inclusions and adsorbed oils show the existence of unresolved complex mixtures, and significant amounts of demethylated hopanes and tricyclic terpanes. These lines of evidence indicate petroleum was likely oxidized by sulfate reducing bacteria (SRB) simultaneously with reduction of U(VI) to U(IV) and thus supplying some of the carbon in the carbonates. This suggestion is partially supported by the low-temperature diagenetic environment (<50°C). However, U(VI) pre-concentration by adsorption and subsequent inorganic reduction is likely to be less significant than direct reduction of U(VI) by SRB in the Qianjadian deposit. This is because ore-stage solution is non-acidic, as indicated by digenetic mineral assemblage pyrite, Fe-dolomite, calcite and pitchblende and lack of marcasite precipitation and carbonate dissolution in the host sandstone. The proposal that direct reduction of U(VI) to U(IV) by SRB is supported by recent finding of mineralized microorganisms in the Dongsheng deposit, NW China (Cai et al., 2007).

This work is financially supported by NSFC 40573034 and China’s 973 project 2006CB202304.

Sm-Nd and Rb-Sr isotopic ages of adamellite body from the Longquan in the south of Zhejiang, China

HUIMING LI¹ AND YINXI WANG¹²*

¹Center of Modern Analysis, Nanjing University , Nanjing 210093, China (*yxwang@nju.edu.cn)
²State Key Laboratory of Mineral Deposit Research, Nanjing University,Nanjing 210093, P.R. China

The adamellite body lies in the south of Zhejiang Province, China. The sampling location lie at Badou Group of Lower Proterozoic of Longquan area.

Analytical Method
Analysis of Rb-Sr abundances and their isotope compositions were performed on an automated multi-channel mass spectrometer VG 354 at Center of Modern Analysis, Nanjing University. $^{87}\text{Sr}/^{86}\text{Sr}$ = 0.710224±6 (2σ) for NBS987 standard. $^{43}\text{Nd}/^{144}\text{Nd}$ = 0.512465±6 (2σ) for BCR-1 standard.

Discussion of Results
The age of Rb-Sr isochron for the adamellite body from Badou Group area. is 665.5±21Ma and initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is 0.74175±92. Sm-Nd isotope age of the whole rock-mineral internal for the adamellite body rock is 2059± 52Ma. The isotopic age of the whole rock-mineral internal Sm-Nd isochron for the adamellite body from Badou Group of Lower Proterozoic of Longquan area is 2059±52Ma and initial εNd(t) is -1.97~2.46.

Conclusion
Rb-Sr age of the the adamellite body whole-rock and mineral samples reflects the age of this intrusion after the disturbance of the subsequent geological processes. Sm-Nd age of the the adamellite body whole-rock and mineral samples is consided as the emplacement age of the adamellite body and indicates that the earliest activity of granitic-magma in Zhejiang. In combination with the geological evidence and geochemical date,it is believed that the adamellite body belong to a S-type [1] or transformation-type granite. It was formed by partial melting of the crustal materials mainly of sedimentary constituents. $^{187}\text{Os}/^{187}\text{Os}$ of 5 whole rock-mineral samples is about 2600-2700Ma.

Analysis of Rb-Sr isotopic mass spectrometer and dating for bauxite deposits in Shanxi Province

HUIMING LI1, YINXI WANG1* AND DONHAO CHAI2

1Center of Modern Analysis, Nnjing University, Nanjing 210093 (*yxwang@nju.edu.cn)

Introduction
The Carboniferous bauxite deposits are diasporic bauxite deposits in Shanxi, China. Carboniferous bauxite in Shanxi massif is considered the combination of BED G bauxite and Shanxi-type iron deposit, which joint together and are called Ferrallite Formation (Wang Y. et al., 2000).

Analytical Method
Analysis of Rb-Sr abundances and their isotope compositions were performed on an automated multi-channel mass spectrometer VG 354 at Center of Modern Analysis, Nanjing University. Isotope dilution method was used for determination of the abundances. All Sr isotopic data are corrected for mass fractionation to $^{86}\text{Sr}/^{88}\text{Sr} = 0.1194$ and reported relative to a value of $^{87}\text{Sr}/^{86}\text{Sr} = 0.710224 \pm 6 (2\sigma)$ for NBS987 standard.

Discussion of Results
Isotopic age of the whole rock-mineral internal Rb-Sr isochron for Bauxite Clayrock from Wu Tai In Shanxi is $316.9 \pm 1.2 \text{ Ma}$ and initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is $0.71054 \pm 14$; Isotope age of the whole rock-mineral internal Rb-Sr isochron for Bauxite Clayrock from Linxian In Shanxi is $315.5 \pm 1.3 \text{ Ma}$ and initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is $0.71086 \pm 18$; Isotope age of the whole rock-mineral internal Rb-Sr isochron for Bauxite Clayrock from Xiaoyi In Shanxi is $317.3 \pm 1.1 \text{ Ma}$ and initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is $0.71050 \pm 14$.

Conclusion
We have been obtained for the bauxite whole-rock and clay mineral samples from Wu Tai (RS01), Linxian. We have been obtained for the bauxite whole-rock and clay mineral samples from Wu Tai (RS01), Linxian (RS02) and Xiaoyi (RS03), Shanxi Province respectively. These ages indicate that bauxite and the ore-hosting sedimentary sequence in Shanxi were deposited in the time interval between 315-317 Ma, corresponding to the Late Carboniferous Epoch.

Chemical weathering in Yangtze River: Evidence from water chemistry and $\delta^{13}C$ of dissolved inorganic carbon

J. Li, C.-Q. LIU AND S.-L. LI

State key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (lijun5931@163.com, liucongqiang@vip.skleg.cn, lisiliang@vip.skleg.cn)

Dissolved inorganic carbon (DIC) of river water from the mainstream and major tributaries of Yangtze River were measured with a main purpose to understand the chemical weathering. The equivalent ratios of $[\text{Ca}^{2+} + \text{Mg}^{2+}]/[\text{HCO}_3^- + \text{SO}_4^{2-}]$ of most samples are around unit, indicating a relatively large part of Ca$^{2+}$ and Mg$^{2+}$ need to be balanced by SO$_4^{2-}$, which may be from the gypsum dissolution and/or dissolution of carbonate minerals by H$_2$SO$_4$. Based on chemical budget and stoichiometry analyses, the estimation resulted in that carbonate weathering, on average, accounts for ~67%, and silicate weathering and evaporite dissolution for ~22% and ~11%, respectively.

The $\delta^{13}\text{C}_{\text{DIC}}$ values range from -8.9‰ to -3.4‰, which represents a mixture of DIC produced by the following weathering pathways: (i) carbonate weathering by carbonic acid (-8.5‰); (ii) silicate weathering by carbonic acid (-17‰); (iii) carbonate weathering by H$_2$SO$_4$ (0‰) derived from the oxidation of sulfide and/or anthropogenic SO$_2$ emission. A positive relationship exists between the SO$_4^{2-}$ and the $\delta^{13}\text{C}_{\text{DIC}}$, which further supports the hypothesis that H$_2$SO$_4$ is primarily neutralized by carbonates.

Fe isotope fractionation during Fe(III) hydrolysis in Cl\textsuperscript{-} medium at low temperatures

J. Li, X.K. Zhu and S.H. Tang
Lab isotope Geol., MLR, Inst. Geol., CAGS, Beijing, China (lijin80119@hotmail.com)

Realisation of the potential offered by stable isotope systems requires an adequate understanding of the factors controlling their isotope fractionation. Various processes such as reduction-oxidation, dissolution-precipitation, and biological utilisation, have been documented to be important controlling factors for Fe isotope fractionation. Here we extend this kind of study to Fe(III) hydrolysis in Cl\textsuperscript{-} medium at low temperature conditions.

A solution of 1mg/mL Fe(III) in milli-Q water was prepared from ferric chloride, and 9 mL- aliquots of the solution were loaded into 9 microcentrifuge tubes that were tightly stopped. 5 centrifugal tubes were put in water-bath solution were loaded into 9 microcentrifuge tubes that were prepared from ferric chloride, and 9 mL-aliquots of the low temperature conditions.

Duration of the experiments was 95 days. Ferric oxyhydroxide precipitation began after about a day for the experiments at 46\degree C, whereas it only started after about a month for those at room-temperature. After 95 days, the precipitates and residual solution were separated by centrifuging, and the precipitates were washed with Milli-Q water twice. Both supernates and precipitates were purified through anion exchange chromatography, before Fe isotope measurement using a Nu Plasma HR MC-ICPMS at high-resolution mode. The results are expressed in \(\varepsilon\) unit which is deviations in parts per 10\(^4\) from the same isotope ratios of the original FeCl\(_3\) used in the experiments. It is observed that the Fe isotope compositions in precipitates are systematically lighter than those of the corresponding supernates, which is consistent with a previous study (Skulan et al., 2002). The differences between precipitates and supernates in \(\varepsilon\)\(^{57}/54\)Fe are 17.0 \(\pm\) 0.8 and 20.2 \(\pm\) 1.8 for experiments performed at 20\degree C and 46\degree C, respectively.

It has been noticed that the measured Fe concentrations in the supernates are three orders of magnitude higher than those predicted from the solubility constant product for experiments performed at room temperature, whereas the measured and predicted Fe concentrations are similar in the residual solutions for those conducted at 46\degree C. This suggests that significant amount of ferric oxyhydroxide colloid has not flocculated, but remained in those supernates. Assuming isotopic equilibrium has been reached between the solid and liquid phases for experiments conducted at both temperatures, the Fe isotope composition of the ferric oxyhydroxide colloid must be lighter than that of the solution by at least 3 \(\varepsilon\) units in \(^{57}/54\)Fe ratio.

Origin of ore-forming fluids of the Dajiangping pyrite deposit, South China: Evidence from He-Ar isotopes

K. Li, K. Hu and S.M. Song
Department of Earth Sciences, Nanjing University, Nanjing 210093, China (kaihu@nju.edu.cn)

The ore genesis model for the Dajiangping ultra-large pyrite deposit in the South China has long been in dispute, and the major debate focuses on whether the pyrite orebodies were formed by a vapour-liquid superimposition event during hydrothermal alteration, or whether formation of ores was the products of hot-water sedimentation. He and Ar isotopes have been widely applied in tracing the origins and water-rock interactions of contemporary crustal fluids. Recently, these isotope systematics have also been successfully applied to the study of the origin of ancient ore-forming fluids and mineralization. In this work, we report He and Ar isotopic data for the Dajiangping ore deposit for the first time, and discuss the origin and evolution of the hydrothermal fluid.

He and Ar isotope were measured in fluid inclusions from six pyrites in the Dajiangping Deposit. These pyrite samples were collected from different ore types or places: orebody III (banded ores), orebody IV (massive ores), CK36 drill core and wall rocks. The results of helium and argon isotope data are shown that the fluid inclusions from pyrite have \(^{3}He/^{4}He\) ratios of 0.18~3.55\(\times\)10\(^{-6}\)(0.13~2.55Ra). The values of \(^{40}Ar/^{36}Ar\) ratios show slight variation between 348~443, which is higher than air-saturated water’s \(^{40}Ar/^{36}Ar\) ratios of 295.5(ASW). As shown in the plot of \(^{3}He/^{4}He\) vs. \(^{40}Ar/^{36}Ar\) ratios, the data fall among three sources district, which indicates that the hydrothermal fluid did not originate from the single source, and instead may be a product of crust-mantle mixture. The six pyrite samples come from two orebody IV, two orebody III, one CK36 drill core (depth 133 m), and one wall-rock in study area. We find that the data of fluid inclusion of two pyrites from orebody IV fall in between mantle-derived fluids and ASW. In contrast, the others lie lower on the graph; the CK-36 and DP-11 even lie between ASW and crust fluids.

These data indicate that mantle-derived fluids contributed to the ore-forming fluids. This study suggests that the hot fluids from the mantle intruded into the places of orebody along the thrust faults, and hydrothermed the orebody. This caused differentiation of the two typies orebody to result in the formation of the banded orebody III and the massive orebody IV.

Nitrogen and oxygen isotopes in phengite from UHP metamorphic rocks in the Sulu orogen, China

LONG LI1,2, YONG-FEI ZHENG2 AND PIERRE CARTIGNY1

1Laboratoire de Géochimie des Isotopes Stables, Institut de Physique du Globe de Paris, Université Paris 7, 2 place Jussieu, T54-64 E1, 75251 Paris, Cedex 05, France (longli@ipgp.jussieu.fr)
2School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

Ultrahigh-pressure (UHP) metamorphic rocks in the Dabie-Sulu orogenic belt of east-central China are documented to be remnant of the Neoproterozoic supercrustal materials that were subducted into the upper mantle in the Triassic. Previous studies of O, H and Ar isotopes show that these UHP rocks experienced limited fluid-rock interaction during subduction and exhumation, and thus have preserved the stable isotope features of their protoliths that underwent extensive meteoric-hydrothermal alteration during magma emplacement. Here, ammonium-N contents and isotopes, combined with oxygen isotopes, of phengites in UHP eclogite and gneiss from the Donghai area in the Sulu orogen were investigated in an attempt to understand the behavior of this volatile element during continental subduction-zone metamorphism and the potential effect of the recycling of the continental crust on the mantle N reservoir.

The phengites show low δ18O values of –11.9 to +3.3‰ as a result of different degrees of Neoproterozoic meteoric-hydrothermal alteration. The phengites also contain very low N from 6.5 to 34.4 ppm with a wide range of δ15N from –4.5 to +8.9‰. Samples from Qinglongshan show a negative relationship between N concentrations and δ15N values but no clear relationship between δ15N and δ18O. However, a positively correlated trend between δ15N and δ18O was observed at a larger spatial scale. The low N concentrations of phengites in these rocks might be inherited from their igneous protoliths. However, the negative δ15N are not consistent with an igneous origin, but indicate a significant negative shift by a 15N-depleted N source or N-isotope fractionation during the Neoproterozoic water-rock interaction. The negative relationship between N concentration and δ15N for the Qinglongshan samples could be caused by either Triassic subduction devolatilization or Neoproterozoic alteration. Further study of trace elements (Rb, Cs, etc.) may better constrain these possibilities. In either case, the presence of unnegligible amounts of N in phengites, which together with other K-rich minerals (e.g., muscovite, K-feldspar) may constitute of as much as 20 vol.% of the eclogites and 60 vol.% of the gneiss/schist, implies that considerable amounts of N could have been conveyed into the mantle due to breakoff of the subducted continental slab. Because the continental material is more 15N-enriched than the mantle, this deeply subducted N may have potential to increase mantle δ15N at a certain scale.

Two Mesozoic volcanic activities in Fujian Province, China: constraints on the transformation of tectonic domain in Southeastern China

LONGMING LI1, MIN SUN1, GUANGFU XING2, GUOCHUN ZHAO1, RONG CHEN2, JEAN WONG1, CHANGQING YIN1 AND KENNY WONG1

1Department of earth sciences, The University of Hong Kong, Hong Kong, P.R. China
2Nanjing institute of Geology and Mineral Resources, Nanjing, P.R. China

Two representative geologic sections of the late Mesozoic “Nanyuan Formation” volcanic rocks in eastern Fujian Province have been dated by zircon SHRIMP U-Pb technique. Two volcanic activities have been identified, i.e. the earlier at 162-150 Ma and the latter at 142-130 Ma. Basaltic rocks of the earlier period have geochemical features similar to those of OIB with significant crustal contamination and fractional crystallization of olivine and clinopyroxene, while the counterpart of the latter period are rich in Al, Fe, LILE and LREE and depleted in HFSE. It seems that the two volcanic activities should not be grouped into the same Formation and the magmas may have been generated in different tectonic settings. The above data may indicate a transfromation of Mesozoic tectonic domain in Southeastern China in a period of 150-142 Ma.

It is suggested that the earlier volcanic activity was generated by local extension resulted from the combining action of Tethyan tectonic dynamic system and Paleo-Pacific tectonic system whereas the latter was attributed to the regional extension induced by high-angle subduction of the Paleo-Pacific plate.

Evolution of carbon in the karst groundwater, Zunyi, China

The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (lisiliang@vip.skleg.cn, liucongqiang@vip.skleg.cn, langyc822@163.com, zrzzhaozhiqi@163.com, basalin@sina.com.cn)

The carbonate system evolves with weathering reactions driven by CO₂ dissolved from the soil and subsequent organic/inorganic reactions in soils and aquifers. This study focuses on the carbon evolution of karst groundwater, Zunyi, China.

The studied area is mainly characterized by karst landforms in Southwest China. The mean values of DIC in winter and summer are 4.54 and 3.82 mmol C/L respectively, reflecting the dilution effects of the heavy monsoon rains; The average δ¹³C_DIC values of ground water are -10.3‰ in winter and -11.1‰ in summer, which suggests that soil CO₂ makes a larger contribution to the DIC in summer than in winter. The concentration of DOC and POC in most of ground water samples are lower than 2.00 mg C/L and 0.50 mg C/L but some contaminated waters, respectively. There is a larger range of δ¹³C_POC in summer than that in winter. P₇_CO₂ of the waters generally is higher than 10⁻³.₅, and P₇_CO₂ in ground water is generally higher than that in surface water, showing deep soil CO₂ makes a greater contribution to ground water. The seasonal difference of contents and isotopic composition of carbon species reflect that the carbon evolution of karst groundwater is easily affected by the monsoon rains.

Cu isotope signature of granites

WEIQIANG LI, SIMON E. JACKSON, BRUCE W. CHAPPELL, OLIVIER ALARD AND NORMAN J. PEARSON

GEMOC ARC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia (wli@els.mq.edu.au)

The Cu isotope signature of bulk earth is proposed to be homogeneous (δ⁶⁵Cu=0) based on measurements of sulphides from mafic intrusions (e.g. Larson et al., 2003) and a limited numbers of mantle-driven rocks (e.g. Archer and Vance, 2004). However, it has been reported that highly evolved granite can have a Fe isotope signature remarkably different (about 0.5‰ δ⁵⁷Fe) from bulk earth values (Poitrasson and Freydier, 2005). As Cu is a trace element in most common rocks, and is also multivalent, its isotopes are more likely to be fractionated by Rayleigh (magma evolution) and redox (weathering / sedimentation) processes than Fe isotopes. Here we report our preliminary work to determine baseline values of δ⁶⁵Cu for various granite rocks and examine the Cu isotope homogeneity of crust.

A chemical procedure, modified from Maréchal (1999), was used to separate Cu from rock matrix. Quantitative recovery (100.9±1.2%) with a low total procedural background (2.65±0.66ng) for Cu has been achieved, allowing Cu isotopic measurements on samples with as little as 10 ppm Cu. Elution curves for peridotite, basalt and granodiorite indicate that elution of Cu is not affected by the bulk composition of rocks. Cu isotope ratios were measured with a Nu Plasma MC-ICP-MS using solution nebulisation sample introduction. Mass bias was corrected by both the sample-standard bracketing and the Ni-doping methods. The long-term external reproducibility of the measurements was 0.09‰ (2 sigma).

S-type and I-type granites from southeastern Australia have been analysed. The S-type granites have a large range of δ⁶⁵Cu, varying from -0.40‰ to 0.37‰, while the δ⁶⁵Cu values of I type granites are less variable (from -0.05‰ to 0.26‰), generally overlapping each other within error around zero (the bulk earth value). However, samples of the mafic end member (SiO₂<55wt%) of an I-type granite suite show remarkable heavy Cu isotope signatures (δ⁶⁵Cu up to 1.56‰).

The distinguishable variation in Cu isotopic composition of the S-type granite may reflect isotopic heterogeneity in the sedimentary source region as a result of redox processes. However, the possibility of Cu isotope fractionation during magmatic and magmatic-hydrothermal processes cannot be ruled out.

Zircon ages and Hf isotopic composition of gneisses from the Sulu UHP terrain, China

XIAOCHUN LI1,2, WANG XI-MING1,2 AND CHAOFEI LI1,2
1State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China (lixianghui@163.com)
2Laboratory for Radiogenic Isotope Geochemistry, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China

Identification of coesite and micro-diamond inclusions in eclogites of the Dabie-Sulu terranes in east-central China [1-2] demonstrates that supracrustal material was subducted to mantle depth of >120 km and underwent UHP metamorphism. Time of this collision was constrained at ca. 230-220 Ma by radiometric studies [3-4]. UHP eclogites occur as lenses in dominant gneisses of different types.

This study presents zircon U-Pb ages and Hf isotopic composition of gneisses in the Sulu UHP terrain for origin and provenance of the protoliths. Zircon grains from three samples of gneiss yield SHRIMP U-Pb ages of 710-770 Ma, consistent with protolith ages of eclogites and orthogneisses in other regions of the Dabie-Sulu orogen, interpreted as formation time of magmatic protoliths of the gneisses, which were contemporaneous with the magmatism during the breakup of the supercontinent Rodinia. Initial εHf values at (750 Ma) and Hf modal ages of zircon grains from the fourteen gneiss samples are variable. Zircon grains from two gneiss samples commonly give very low initial εHf values (average -16.4) and a mean Hf modal age of about 2.70 Ga. Seven gneiss samples contian zircon grains that yield a mean initial εHf value of -7.7 and Hf modal age of 2.15 Ga. These results suggest that part of protoliths were formed in Neoproterozoic by remelting Archean to Paleoproterozoic crustal material and further indicate existence of Archean crustal section probably of the Yangtze affinity beneath the Sulu UHP terrain. Other six gneiss samples mostly contain young zircon grains, having mean initial εHf values of -56 to 6.6. Part of them give Hf modal ages of 0.81 to 0.94 Ga. This suggests magmatic activity of mantle origin, new crustal formation and coeval crust-mantle interaction probably during breakup of supercontinent Rodinia in Neoproterozoic. Underplating of magmas of mantle origin caused remelting of the overlying Archean - Paleoproterozoic crustal section to form granitic magma along rift zones or marginal regimes of the Yangtze block.

This study is supported by the NSFC (No. 40525007).

Ca. 850 Ma intraplate magmatism in South China: implications for onset of the breakup of Rodinia

X.H. Li1,2, W.X. Li1 AND Z.X. Li3
1Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China (lixh@gig.ac.cn; liwx@gig.ac.cn)
2Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China
3Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia (z.li@exchange.curtin.edu.au)

Early to middle Neoproterozoic igneous rocks are widespread throughout South China, and their genesis and tectonic affilliations are important for understanding the geological evolution of South China with direct bearing on the Rodinia reconstruction. There are two main competitive models regarding their genesis. One is that the ≥900 Ma rocks were formed prior to or during the Sibao Orogeny related to the Rodinia assembly, whereas the 830-740 Ma rocks were anogenic products related to mantle plume activities during the breakup of Rodinia. An alternative model is that all these rocks were formed in active continental margins and/or during the amalgamation between the Yangtze and Cathaysia Blocks, and the coherent South China could not have formed until ca. 800 Ma.

We report here geochronological and geochemical data for the Shenwu dolerite dykes and Gangbian syenite intrusion from SE Yangtze Block. These rocks were dated at ca. 850 Ma by SHRIMP U-Pb zircon method. The Shenwu dolerites are tholeiitic in compositions, and exhibit overall moderate enrichment in most incompatible trace elements resembling intraplate basaltic rocks. They have relatively restricted range of εNd(T) value between 0.4 and 2.1, suggesting derivation from a metasomatized lithosphere mantle. The Gangbian syenites show a wide range of SiO2 = 46-67% and Mg# = 4.8% and K2O/Na2O = 0.4-1.2. They are enriched in LIL and depleited in Nb and Ta with εNd(T) = 0 to -6. The syenites were likely derived from the common metasomatized mantle source by small degrees of partial melting followed by varying degrees of crystal fractionation associated with minor crustal contamination. These ca. 850 Ma dolerites and syenites share close affinities with the intraplate basaltic and alkaline rocks, indicative of an intraplate origin, rather than products of arc magmatism.

The studied dolerites and syenites postdate the ca. 1.1-0.9 Ga Sibao Orogeny, and predate the formation of ca. 820-650 Ma Nanhu rift basin, providing an important petrological constraint on the tectonic transformation from ca. 1.1-0.9 Ga orogenesis to ca. 850 Ma intraplate rifting in South China. These rocks are synchronous with some reported ca. 850 Ma anogenic igneous rocks in other Rodinian contonents, possibly pointing to ontset of the breakup of Rodinia supercontinent.
An ecological explanation for high resolution stable carbon isotope stratigraphy approaching the Permian/Triassic boundary in Meishan area, South China

YUCHENG LI1,2 AND WANGCHUN WANG3

1Laboratory of Biogeochemistry and Eco-environmental management, Anhui University, 230039, Hefei
2Nanjing Institute of Geology and Paleontology, Academia Sinica, 210008, Nanjing
3Lanzhou Institute of Geology, Academia Sinica, 730000, Lanzhou

High resolution carbon isotope stratigraphy has been generated from marine carbonate and organic carbon during the Changhsingian at the end of Permian and earliest Triassic from Meishan in south China. The result reproduces a gradual decline in δ13C_carb during the Changhsingian, but this decrease trends is superimposed by three large positive excursions in δ13C_carb at lower, middle and upper interval. This observation maybe reflect changes in the rate of organic matter burial during the late Permian. The large positive δ13C_carb excursions would present the enhanced organic carbon burial, presumably in response to episodic transgression-associated anoxia.

The δ13C_carb values indicate much more variable compared to the δ13C_carb, however the values of ∆13C (δ13C_carb - δ13C_org) have fallen in only two groups: (1) between 28~30.3‰ and indicative of maximal fractionation of carbon isotopes by phytoplanktonic producers; (2) greater than 30.5‰ (< 33.3‰), and apparently indicative of significant input from bacterial biomass in bottom water. The δ13C_org of each of these groups parallels (separately) the more detailed profile of δ13C_carb, strongly suggesting that differences in δ13C of both inorganic and organic carbon related to difference in δ13C of CO2(aq) in photic zone. The multiple coeval negative excursions in δ13C of both carbonate and organic carbon occurred before extinction intervals, suggesting that isotopically CO2 was recycled into the photic zone from stagnant water below. The pattern and magnitude of change in both δ13C_carb and δ13C_org are easy to reconcile with the gas hydrate hypothesis as the explanation for abrupt negative δ13C anomalies at extinction interval. The methane−consuming associations of sulfate−reducing bacteria may have contributed to this dramatic negative shift.

Geochemistry, Sm-Nd and Rb-Sr isotopic compositions of eclogite in the Lasha terrane, Tibet, and their geological significance

ZHAOLI LI, JINGSUI YANG, ZHIQIN XU, TIANFU LI, XIANGZHEN XU AND YUFENG REN
Key Laboratory for Continental Dynamics, Institute of Geology, Chinese Academy of Geological Sciences, Beijing, 100037

Eclogite was first discovered in the Lasha terrane, northeast to the Lasha city, Tibet, China. It is located in the north of the Gangdese island arc belt. The eclogite occurs as a 500-600 m thick belt, extending in EW for over 10 km. Most eclogites are massive, coarse-grained and fresh. Three types of eclogite have been recognized, which are rutile eclogite, quartz eclogite and phengite eclogite.

The major elements, trace elements, rare earth elements, Sr-Nd isotopic compositions and Sm-Nd isotopic chronology of some eclogites were obtained in this study. The major elemental compositions and relatively high \(\varepsilon_{\text{Nd}}\) (t) of about +7.9 for the eclogites suggest that the protoliths of eclogites were ancient basaltic rocks developed in ocean crust, similar with the typical N-MORB, and derived from the depleted mantle. The \(87\text{Sr}/86\text{Sr}\) of the eclogites vary over a wide range, from 0.70335~0.70457, which is not closely relevant with the \(\varepsilon_{\text{Nd}}\) (305 Ma) and trace elements. We favor that this irrelevant may be due to the ocean environment of these eclogites developed and the later aqueous alteration after its formation. The Sm-Nd age of 305.5±50 Ma defined by the whole rock is interpreted to represent a developed age, indicating that there was ancient Tethys and its deep subduction in northern Gangdese at early Carboniferous-lately Permian.

Fe isotopes of banded iron formation from Anshan, northeast China

Z.H. Li\(^1\), X.K. Zhu\(^1\), Y.H. Li\(^2\) AND S.H. Tang\(^1\)
\(^1\)Lab Isotope Geol., MLR, Inst. Geol., CAGS, Beijing, China (lizh1975@hotmail.com)
\(^2\)Lab Isotope Geol., MLR, Inst. Mineral Resources., CAGS, Beijing, China (lyh@mx.cei.gov.cn)

Fe is the most abundant element engaging in redox chemistry, and is one of the element has been used biologically at very early stage. Thus understand the geochemical cycling of Fe has great implications for the development of an oxygenated atmosphere and the origin of life. Banded iron formations (BIFs) are chemical deposits from oceans. They have potential to preserve paleoceanographic signatures. Here we report the results of an iron isotope study on BIFs from North China Craton.

The BIFs studied were formed at the Archean–Proterozoic transition period (2.5 Ga), and subjected to amphibolite-facies metamorphism. They consist of finely layered alternating beds dominated by magnetite and quartz respectively, with minor amounts of pyrite and hematite. The minerals of magnetite, hematite and pyrite were separated. After purification using anion exchange chromatography, Fe isotope ratios of the mineral separates were measured using a Nu Plasma HR MC-ICPMS in conjunction with a DSN 100 desolvating nebuliser. The results are expressed in \(\varepsilon\) units which are deviations in parts per 10\(^4\) from the same isotope ratios of the reference material IRMM-14. Fe isotope compositions of the mineral separates range in \(\varepsilon_{\text{57Fe/54Fe}}\) units from 1.1 to 20.9, 8.6 to 12.5, and 1.3 to 18.5, for pyrite, hematite and magnetite respectively. Another observation is that the Fe isotope compositions of pyrites are systematically heavier than corresponding magnetites in each samples.

The average Fe isotope compositions obtained from BIFs in this study for pyrite and magnetite are unusually high relative to the bulk silicate Earth, other BIFs in Transvall and Greenland, and MOR hydrothermal fluids. This suggests that only a small fraction of Fe(II) in sea water has been oxidised to Fe(III) to form the BIFs in Anshan area, which implies an atmosphere with low \(O_2\) contents at the time. Alternatively, this may imply that some fraction of Fe(II) has been precipitated as iron sulfide or carbonate, resulting relative enrichment of heavy isotopes in seawater, prior to the precipitation of BIF. Indeed, some archean pyrite deposits in North China exhibit very light Fe isotope signature.

As the contents of pyrite in the BIFs studied are <1%, the Fe isotope compositions of bulk rocks are predominated by magnetite. The fact that the Fe isotope compositions of pyrites are systematically heavier than corresponding magnetites in each samples suggests that these mineral pairs were re-equillibrated in terms of Fe isotopes during metamorphism.
Effects of source heterogeneity and upwelling rate on trace element distribution during mantle melting

Y. LIANG

Department of Geological Sciences, Brown University, Providence, RI 02912 (Yan_Liang@brown.edu)

Several lines of evidence suggest that the melt generation and segregation regions of the mantle are heterogeneous consisting of chemically (enrich vs. depleted) and lithologically (peridotite vs. pyroxenite) distinct domains of variable size and dimension. Partial melting of such heterogeneous mantle source regions give rise to a divers range of basaltic magmas erupted on the sea floor. Although significant progresses have been made in understanding the processes of mantle melting using simple (e.g., batch, fractional, dynamic, and fluxed) melting models, none of the models identified can be readily used to study the effects of source heterogeneity and melt and solid flows on the distribution and evolution of trace elements and isotopes in the melt and residual solid during partial melting in an upwelling mantle column.

In order to better assess the role of source heterogeneity during mantle melting, we have undertaken a theoretical study of trace element and isotop distribution during partial melting in an upwelling mantle column. The 1-D version of the advection-diffusion-melting equation of McKenzie (1984, his Eq. A42) was solved analytically for both uniform and distributed melting rates and under the assumption of constant and uniform partition coefficient, porosity, melt and solid velocities. For simplicity, we neglected diffusion in the melt. Source heterogeneities of various forms (e.g., pyroxenite vein) were introduced into the melting column through initial and boundary conditions. Main results of our analyses to date can be summarized as follows. (1) Since melt flows faster than the solid, heterogeneities introduced at the base of the melting column are decoupled during melting and upwelling: while being diluted during melting, the incompatible element signatures of the source travel with effective velocities that largely follow the flow of the melt, whereas heterogeneities recorded by compatible elements follow mostly the solid matrix. Hence the overlaying mantle (above the pyroxenite vein, say) is cryptically metasomatized by the percolating melt derived from the pyroxenite. (2) When melting happens only in the lower part of the column (distributed melting), significant extent of metasomatism occurs in the upper mantle column. A lack of chromatographic separation among trace elements in lavas may indicate additional means of melt migration: i.e., flow through porous channels or open fractures. (3) The simple analytical solutions obtained in this study make it possible to invert for mantle source compositions through systemat studies in the future.

Examples illustrating the distribution and evolution of selected trace elements and isotopic ratios during partial melting of a pyroxenite-veind lherzolitic mantle will be discussed.

Deciphering the time of igneous activity in the Lavrion ore province, Attica, Greece: Manifestation of Late Miocene and Triassic magmatism

A. LIATT1, N. SKARPELIS2 AND G. PE-PIPER3

1Department of Earth Sciences, ETH-Zürich (liati@erdw.ethz.ch)
2Department of Geology, University of Athens (skarpelis@geol.uoa.gr)
3Department of Geology, Saint Mary’s University, Halifax (pe-piper@smu.ca)

The Lavrion area, known as a 3000 years old mining district, is part of the Attico-Cycladic Belt (ACB). A detachment fault separates the Lower Mesozoic metamorphic Basal Unit from the overlying Cycladic Blueschist Unit (Skarpelis, 2007). 9.4±0.3 Ma old granodiorite dykes and a Late Miocene granodiorite stock intruded the footwall of the detachment in a roughly N-S directed regional extensional stress field. With the aim of assessing the Miocene metallogenic evolution in Lavrion area, in conjunction with the igneous activity in the ACB, we dated by U-Pb of zircon (SHRIMP; GSC Ottawa) slightly deformed, hydrothermally altered porphyritic S-type granitoids occurring as sills along or within the hangingwall, close to the detachment fault. The zircon in cathodoluminescence (CL) displays euhedral long-prismatic crystals consisting either of a single oscillatory zoned, igneous domain or of a round (resorbed) inner core with relatively homogeneous CL and an oscillatory zoned, igneous rim. The resorbed character of the core, in combination with its homogeneous CL, are typical for zircons recrystallized under granulate-facies conditions. The cores and the igneous domains yielded (Tera-Wasserburg) lower intercept 206Pb/238U ages of 11.93±0.41 Ma and 8.34±0.20 Ma, respectively (error: 95% c.l.), interpreted as the time of a granulate-facies metamorphism (for the first time reported in ACB) and the time of magmatic crystallization, respectively. Emplacement was facilitated by the detachment fault. The dated S-type rocks of Lavrion, interpreted as partial melts of lower crustal granulites, are ca. 7-1 Ma younger than S-type granitoids in the ACB, also associated with an extensional tectonic regime. Above zircon ages constrain the time interval of active ductile to ductile-brittle deformation of the detachment fault.

Orthogneiss lenses within the metaclastic part of the Basal Unit in Lavrion (Kaesarian schists), previously considered of Tertiary age, yielded a lower intercept 206Pb/238U zircon age of 240±4 Ma interpreted as the time of crystallisation of the magmatic protolith. Opposite to earlier ideas about only Tertiary felsic magmatic rocks in Lavrion, our data show that there is an age diversity of the magmatic activity. The resulting age is consistent with the regional pattern of Triassic magmatism in the Hellenides.

Cold seeps are often called oases of life in the deep sea for their rich chemosynthetic communities populating the seafloor. Many typical seep organisms like the giant tubeworms, diverse bivalves and mats of giant sulfide oxidizing bacteria have a considerable influence on the biogeochemistry of methane-laden seafloor e.g. by bioturbation, bioirrigation and by replenishing sulfate to the electronacceptor-limited sediments. Here we investigated the biogeochemistry of a gas-emitting cold seep system in permanently anoxic waters, where animal life is completely absent. At most cold seeps the methane rising from subsurface reservoirs is oxidized anaerobically with sulfate diffusing into the seafloor from the overlying bottom water. Normally the produced sulfide is further oxidized by chemical and microbiological processes with either Fe(III), nitrate or oxygen as terminal electron acceptor. In the Black Sea these electron acceptors are absent below the chemocline, thus the sulfide may be largely exported to the water column.

This study was carried out at the Dvurechenskii mud volcano (DMV, Sorokin Trough) during expedition M72/2 with RV METEOR and ROV QUEST (MARUM, Bremen) in the framework of the EU FP6 integrated project HERMES and the DFG/BMFB GEOTECHNOLOGIEN program MUMM.

The main questions of our investigation were 1) Where are the hotspots of methane emission and turnover at the DMV?, 2) How does the absence of bioturbation affect rates and distribution of anaerobic oxidation of methane?, 3) How does the absence of oxygen and nitrate in the bottom water affect pH gradients and sulfide fluxes?

To answer these questions, we carried out in situ microprofiler measurements of H2S, pH, redox, and temperature along a transect from the center of the mud volcano northwards to the outer rim. Methane-fueled sulfate reduction was measured in situ by using the INSINC incubator and methane fluxes were determined with a benthic chamber as well as by concentration measurements in gravity cores and bottom water. Our results show that fluid flow velocity strongly controls methane turnover and export at these anoxic cold seeps, suggesting that the absence of seep fauna reduces the efficiency of the benthic methane filter.

Stable Strontium (δ88/86 Sr) and U-Th systematics of cold-water corals as new proxy for Holocene changes of the Mediterranean outflow

V. LIEBETRAU, A. RÜGGEBERG, J. FIETZKE, A. EISENHAUER, S. FŁÓGEL, P. LINKE AND J. SCHÖNFELD

Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, Germany (vliebetr@ifm-geomar.de)

This study combines the stable strontium isotope method (δ88/86 Sr) after Fietzke and Eisenhauer (2006) as a potential paleotemperature proxy with MIC-ICP-MS (multi ion counting – inductively coupled plasma – mass spectrometry) U-Th geochronology on cold-water corals from the central Gulf of Cadiz. The sampled reef structure in 1325 m depth on top of the Captain Arutyunov Mud Volcano (MV) consists predominantly of dead Lophelia pertusa, accompanied rarely by living solitary corals (Flabellum sp., Dendrophyllium sp.). Potentially recorded environmental influences on these archives are significant water mass changes, e.g. variation of depth and intensity of the Mediterranean Outflow Water (MOW) due to climate changes, time intervals of marine methane emanation (surface-near gas-hydrate occurrence close to the coral site) and the mud volcano activity itself.

Assuming a temperature dependent strontium isotope fractionation during calcium carbonate precipitation temperatures were determined for the living solitary corals, ranging from 9 to 11.5 °C (typical error: ± 1°C). For comparison, during sampling the bottom water temperature was 8.96 °C and the lower MOW reached from 1075 to 1188 m depth with 10 to 10.5 °C. First U-Th age data reflect slow growth rates of 0.13 to 0.25 mm/year for the solitary corals.

However, the temperature correlation implies the stable strontium approach, which was originally deduced from reef building corals, as suitable for solitary species as well.

For the fossil Lophelia pertusa colonies the actual δ88/86 Sr data set indicates a range from 7.5 to 13 °C with a distinct U-Th age distribution over the last 10 ka, closely correlating with the water depth specific record of lower MOW published by Schönfeld and Zahn (2000). The implication of a lower MOW control on reef formation is supported by coincidence of its actual elevated position with the lack of living Lophelia pertusa at the sampling site.

The stable strontium isotope ratio δ88/86 Sr of biogenic carbonates may serve as a new paleo-temperature proxy for reef-building and solitary deep-sea corals and thus introduce new perspectives in paleoceanography, such as changes in intermediate and deep-sea temperature and ocean circulation.

Vapor-liquid fractionation of B, Li, and Cl stable isotopes: Experimental constraints at 400 and 450°C, 20 to 42 MPa

A. LIEBSCHER\(^1\), J. BARNES\(^3\), W. HEINRICH\(^2\), A. MEIXNER\(^2\), R. L. ROMER\(^2\) AND Z. SHARP\(^3\)

\(^1\)Technical University Berlin (axel.liebscher@tu-berlin.de)  
\(^2\)GeoForschungsZentrum Potsdam  
\(^3\)University of New Mexico

We experimentally determined the vapor-liquid fractionation of the B, Li, and Cl stable isotopes in the systems H\(_2\)O-NaCl-B\(_2\)O\(_3\) and H\(_2\)O-LiCl. Experiments were performed at 400 and 450°C / 20 to 42 MPa. Vapor and liquid samples were analyzed for Na, B, and Li by inductively coupled plasma emission spectrometry. Isotopic ratios were determined by positive thermal ionization mass spectrometry. 

No coherent vapor-liquid fractionation of the different stable isotope systems is apparent. \(^{11}\)B has a preference for the vapor and fractionation increases along the individual isotherms towards lower pressure. The data have been fitted with a logarithmic function of the form \(1000 \ln \alpha_{v,l} = a + b \ln[(P - P_{sat}) + e^{c+\text{cutoff}}]\) and extrapolated to salt saturated conditions: maximum stable isotope fractionation is 1000 \(\ln \alpha_{v,l}(^{11}\text{B}) = 0.94 \text{ ‰ at } 400\text{°C and } = 1.43 \text{ ‰ at } 450\text{°C. Mass balance calculations show that for high degrees of fractionation fluid phase separation in an open system significantly alters the boron isotope signature of low-salinity fluids in hydrothermal systems. Comparing the results with natural oceanic hydrothermal fluids, however, indicates that other processes than fluid phase separation dominate the boron geochemistry in oceanic hydrothermal fluids.}

Contrary to the boron system, the lithium system indicates a slight preference of the heavy \(^{7}\)Li for the liquid. Measured fractionation is, however, very small and the data do not allow extrapolation of 1000 \(\ln \alpha_{v,l}(^{7}\text{Li})\) to salt saturated conditions. The data nevertheless suggest 1000 \(\ln \alpha_{v,l}(^{7}\text{Li}) \leq -0.5 \text{ ‰ at all studied conditions. The very small isotope fractionation indicates that even for fractionation in an open system the Li isotopic signature of vapor, liquid, and bulk system will not be altered by more than 1 ‰. The lithium stable isotopes are conservative tracer during aqueous fluid phase separation and any lithium stable isotope fractionation in natural hydrothermal systems reflect the combined effects of source reservoir and fluid-mineral interactions.}

For the chlorine system, no trend is apparent: At all studied conditions 1000 \(\ln \alpha_{v,l}(^{37}\text{Cl})\) is < 0.2 ‰ and switch between positive and negative values. Our data suggest a lack of notable stable isotope fractionation between vapor and liquid in the H\(_2\)O-NaCl system. This is at variance to the H\(_2\)O-HCl system, where recent data indicate significant vapor-liquid fractionation of up to 9 ‰.

Can millennial-scale geomagnetic field models improve time-integrated predictions of cosmogenic nucleic production rate scaling models?

Preliminary results using \textit{in situ} cosmogenic \(^{14}\text{C}\)

NATHANIEL A. LIFTON

Geosciences Dept and Arizona AMS Facility, University of Arizona, Tucson, AZ USA (lifton@email.arizona.edu)

\textit{In situ} cosmogenic nuclide (CN) production rates are typically determined by measuring CN concentrations in surficial rocks with well-constrained exposure histories. Scaling these time-integrated production rates to other locations with different exposure durations, though, requires knowledge or assumptions of how temporal and spatial geomagnetic field variations have affected instantaneous production rates. Previous attempts to quantify geomagnetic effects on CN production rate scaling have relied on various geocentric dipolar approximations to the effective vertical cutoff rigidity (\(R_C\)), driven by separate records of geomagnetic pole position and paleointensity (e.g., Lifton et al., 2005). However, the CN production rate scaling models in those studies are parameterized using detailed modern geomagnetic field representations. Applying dipolar paleomagnetic records spanning millennial time scales to scaling models derived using the modern geomagnetic field may lead to systematic errors in any calculated results.

A new continuous geomagnetic model covering the last 7 kyr (CALS7K.2) (Korte and Constable, 2005) may allow reduction of such errors by bridging the gap between detailed modern geomagnetic and simplified paleomagnetic models. I have developed a new model describing temporal and spatial variation in \(R_C\) for 0-7 ka and earlier, based on CALS7K.2, which explicitly accounts for non-dipole field effects while attempting to mitigate systematic scaling biases.

Scaling factors derived using the new \(R_C\) model predict significant longitudinal variability in time-integrated CN production, while predictions using dipolar geomagnetic approximations do not. One can test these predictions using \textit{in situ} cosmogenic \(^{14}\text{C}\) (in \textit{in situ} \(^{13}\text{C}\)) in quartz. Due to its short half-life, \(^{14}\text{C}\) attains secular equilibrium between production and decay after approximately 25 ky of exposure, at which point its measured concentration is only a function of its integrated average production rate. Preliminary \textit{in situ} \(^{14}\text{C}\) results from samples at secular equilibrium from 38°N and 3.5 km in Tibet and eastern California are consistent with the longitudinal variability predicted by the new model.

The influence of a method of sample preparation on element content in pore waters of sediments of Lake Baikal

A.V. LIKHOSHVAY1 AND E.P. CHEBIKIN2

1Lab. of Microbiology, Limnological Institute, Irkutsk, Russia (likhoshvay@mail.ru)
2Lab. of Paleoclimate, Limnological Institute, Irkutsk, Russia (cheb@lin.irk.ru)

Pore waters always contain a certain quantity of suspensions which cannot be removed by means of usual centrifugation and filtrations. The content of some elements, partially or completely being in colloidal state in pore waters, will depend on quantity of fine dispersed matter. Our purpose was to find what elements are connected with colloidal particles in pore waters of the sediments of Lake Baikal and to estimate what effect will give ultracentrifugation in comparison with filtration. A core (20 cm, depth 1300 m) of Baikal bottom sediments was collected in Southern part of the Lake. Pore waters were separated from six horizons of sediments by centrifugation, filtered through 0.2 µm filters and subjected to ultracentrifugation (70000 rpm, 2h). Experiments were carried out in argon atmosphere to prevent change Red/Ox conditions. The solutions were analyzed by ICP-MS method. The content of Al, a measure of terrigenic matter, in filtered pore waters is significantly higher (in 7-140 times), than in solutions after ultracentrifugation. The content of other terrigenic elements (Be, Ti, Y, Zr, Nb, Pd, REE, Hf, Ta, Th, and Fe, Ga, Ge, Ag, Pb, Bi, U) in filtrates are also increased (2-1200 times). V, Cr, Cu, Se, Ba are less subjected to concentration on the particles – a degree of their enrichment is <2 times. The content of Li, B, C, Na, Mg, Si, P, S, Cl, K, Ca, Sc, Mn, Co, As, Br, Rb, Sr, Mo, Sn, Sb, I, Cs, W, Re, Ti does not change after ultracentrifugation.

Magmatic evolution and crustal accretion in the Northern Oman-U.A.E Ophiolite: New insights from LA-ICP-MS analysis of clinopyroxene

R.M. LILLY1, J.A. PEARCE1, C.J. MACLEOD1 AND M. STYLES2

1School of Earth, Ocean and Planetary Sciences, Cardiff University, CF10 3YE, UK.
2British Geological Survey, Keyworth, NG12 5GG, UK.

The exceptionally well preserved Cretaceous Oman-United Arab Emirates (U.A.E.) ophiolite offers an ideal opportunity to study the original structure and composition of oceanic crust constructed by MORB magmas that show an increased role for water in their evolution, more akin to magmas from island arc or back arc basins.

Fieldwork has been conducted in co-operation with the British Geological Survey on the ophiolite sections in the U.A.E. This has led to the generation of geochemical data on basalts, dolerites and gabbros from the crustal section. These data record a complex history for the northernmost sections of the ophiolite. Initial magmatic events exhibit a MORB-like composition, indicating that the early crust formed at a ‘normal’ mid-ocean ridge. These primary events were followed by successive periods of magmatic activity, localised predominantly along major extensional faults, with each subsequent event exhibiting an increase in the subduction-related component. The northern Oman-U.A.E. ophiolite thus provides geochemical evidence for the transition from spreading- to subduction-related volcanism.

The use of a new LA-ICP-MS analytical technique has enabled trace element analysis of clinopyroxene crystals from individual gabbro units. With these data it has been possible to unlock the signatures of crustal gabbros and match plutonic units to their extrusive counterparts, providing a detailed chronology of crustal accretion events. Specifically two intrusive gabbro units are described, which represent discrete off-axis magma chambers that fractionated to feed upper extrusive units after ‘normal’ mid-ocean ridge processes had ceased. Geochemical and field characteristics of these units provide important constraints on the influence subduction-related fluids have on the amount of melting, mechanisms of magma fractionation and methods of crustal accretion at a fast-spreading ridge.

With the growing database of clinopyroxene trace element data this new LA-ICP-MS technique also offers significant potential for the identification of the tectonic environment of formation for cumulate rocks.
Analysis of aqueous Sr concentration in groundwater of carbon aquifer of Moscow artesian basin

O.A. LIMANTSEVA
Russian State Geological Prospecting University, Moscow, Russia (ryzhenko@geokhi.ru)

Underground waters of Carbon of Moscow artesian basin are enriched in Sr due to high Sr content in carbonate rocks of the area. The certain part Sr is from clays of confining layers contiguous to carbonate rocks.

The limiting factor of aqueous Sr enrichment is the solubility of Sr minerals. The aqueous Sr concentration curve (Sr=3.607-lnS+5.828, where S is salinity; R^2=0.508) is shown in fig below. Two reactions (dissolution of Celestite and deposition of Strontianite) occur simultaneously. It results in usually up to 8 - 10 mg Sr/l. In two samples the Sr concentration is even more: 13.8 mg Sr/l (DUBNA borehole, g2 layer of Upper Carbon) and 27.7 mg Sr/l (KLEPIKI, pd-ks layer of Middle Carbon).

The process of Sr accumulation is influenced by two major factors: the hydrogeochemical type of groundwater alteration along groundwater flow and delay of a groundwater filtration into direction of plunge the water-bearing layers.

Using thermodynamic approach the process of accumulation Sr looks as follows:

- Gypsum and Celestite dissolution brings SO_4 and Sr.
- Strontianite formation limits the aqueous Sr concentration, thus it is the regulating factor of accumulation Sr in ground waters Moscow artesian basin.

This study was supported by the Russian Foundation for Basic Research (project no. 07-05-00030).

Formosa Ridge, A cold seep with densely populated chemosynthetic community in the passive margin, southwest of Taiwan

S. LIN1, Y. LIM1, C.-S. LIU1, T.F. YANG2, Y.-G. CHEN2, H. MACHIYAMA3, W. SOH3 and K. FUJIKURA3
1Inst. of Oceanography, National Taiwan University, Taipei, Taiwan (swlin@ntu.edu.tw)
2Dept. of Geosciences, National Taiwan University, Taipei, Taiwan (tyyang@ntu.edu.tw, ygchen@ntu.edu.tw)
3Kochi Inst. for Core Sample Research, Japan Agency for Marine-Earth Sci. & Tech., Kochi, Japan (bucci@jamstec.go.jp, soh@jamstec.go.jp, fujikurak@jamstec.go.jp)

Chemosynthetic community and massive hydrate are two typical features appeared at cold seep environment. Mussel, clams, bacterial mats, and tubeworms also frequently found in the cold seep environments. In order to understand mechanism driving the chemosynthetic community found in the study area, ROV and Towcam surveys as well as core sampling were conducted on board the r/v Natsushima and r/v OR-I at the Formosa Ridge.

ROV Hyperdolphin survey showed that unusually densely populated chemosynthetic community appeared at water depth of about 1200 m in the passive margin southwest of Taiwan. Bathymodiolus Platifrons and Shinkai cronieri are two predominant macro fauna, patchy distributed on top of a stratigraphy high with clear Bottom Simulating Reflector (BSR) at depth. Mussel attached on porous carbonate with partially cemented mudstone tubes and laminate acting as gas and fluid conduit. Vent fluids are high in dissolved sulfide and methane. Δ13C of the authigenic carbonate lamina and vent tubes are as low as -56. Mussel shells, however, showed typical sea water carbon composition. Lower concentrations of pore water chloride indicate hydrate dissociation near surface.

Unlike other cold seep environment, no massive hydrate and tubeworms were found on the sea floor. The chemosynthetic community of the study Formosa Ride is supported by unusually high concentrations of dissolved sulfide and methane seeping through sea floor.
Competitive adsorption between tricarboxylic acids and phosphate

M. LINDEGREN, D. TINGSTROM AND P. PERSSON
Dept. of Chemistry, Environmenal and Biogeochemistry, Umeå University, 901 87 Umeå, Sweden (malin.lindegren@chem.umu.se)

The mobility and bioavailability of organic and inorganic ligands in soils and aquifers are dependent on interactions with mineral surfaces. Carboxylic acids are a group of organic ligands that have been noticed to be excreted by roots as a response to several stressful conditions, i.e. phosphorus depletion, iron deficiency and toxic aluminium conditions.

Citrate, a hydroxyl-tri-carboxylic acid, is known to be excreted by various plant species under all of the above mentioned conditions. The phosphate acquisition is thought to take place through dissolution of phosphate-rich minerals and/or through competitive adsorption between the organic acid and the nutrient on mineral surfaces. The present work focuses on the comparison of the competitive adsorption between citrate and phosphate on goethite (α-FeOOH) with that of two other tricarboxylic acids; tricarballylic acid and 1,2,4-butanetricarboxylic acid. Tricarballylic acid is identical to citrate without the hydroxyl group and 1,2,4-butanetricarboxylic acid has the same molecular structure as tricarballylic acid with one extra CH₂-group between two of the carboxylic groups. The aim of this work is to elucidate what effect small differences in structure and composition of otherwise similar organic ligands has on the ability to compete with phosphate for mineral sites.

In order to meet the research objectives, a combination of quantitative adsorption data and molecular spectroscopic data were collected. The work was made in series of batch experiments, measuring ligand adsorption as a function of pH. In-situ ATR-FTIR spectroscopy was extensively used to evaluate the speciation and adsorption mechanisms of phosphate and the carboxylic acids. In addition, ionic chromatography and atomic absorption spectroscopy were used to gain quantitative adsorption and dissolution data. Adsorption data of the three organic acids and of phosphate will be presented to illustrate the competitive adsorption in these systems and ATR-FTIR spectra will be used to explain the mechanisms behind the competition.

Laser Raman-spectroscopy study on fluid inclusions of sandstone-type uranium deposits in the Ordos basin, Northwest China

M.X. LING¹ AND X.Y. YANG¹, ²*
¹CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University Science and Technology of China, Hefei 230026, China (*xyyang@ustc.edu.cn)
²State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

Introduction

The Ordos basin is the second largest sedimentary basin in China. With the deep-going ore exploration, in-situ leachable sandstone-type uranium deposits have been discovered in several localities in different parts of the basin (Liu, 2005; Ling et al., 2006). This study focus on the compositions of fluid inclusions bearing in sandstones of these uranium deposits as well as their genesis.

Experiment and Results

The chemical compositions of fluid inclusions are determined with RM-1000 laser Raman spectroscopy produced by Renishaw Company, at the State Key Lab of Geol. Proc. & Mineral Res., China University of Geosciences. The results show that most of the fluid inclusions are mainly composed of H₂O, CO₂ and CH₄. The fluid compositions existing in different phase manifest their distinct original fluid genesis. The relative high concentration CH₄ captured in fluid inclusions indicates that original fluids might come from the natural gases widely spreading in the Ordos basin. The fluid inclusions formed and their components accumulated in the reduced condition, whereas uranium minerals deposited later when the oxygenation was dominated caused by uplifting of the Ordos basin during Mesozoic-Cenozoic. This study is of significance for understanding the uranium formation with multi-energy resources and mineral deposits coexisting in the Ordos basin.

Acknowledgment

This study is supported by the Chinese 973 National Key Research and Development Program (2003CB214600).

Characterization of hydrous species in hydrous and nominally anhydrous minerals by $^1$H solid state NMR spectroscopy

L. LINGNER, M. FECHTELKORD AND R. DOHME

Institut für Geologie, Mineralogie, und Geophysik, Ruhr-Universität Bochum, 44780 Bochum, Germany,
(Michael.Fechtelkord@ruhr-uni-bochum.de)

Nominally H$_2$O-free minerals (NAMs) like olivine and pyroxenes are considered to be significant reservoirs for H$_2$O in the upper mantle (e.g., Bai and Kohlstedt), which would drastically influence a number of physical properties of the mantle and processes related to these. The presence of H in small amounts may dominate the point defect chemistry of these minerals. Thus, depending on the exact incorporation mechanism and structural environment, physical properties like electrical conductivity and strain rates change compared to the completely dry mineral. The coordination of H in NAMs has been inferred so far either indirectly from the measurement of transport properties (e.g., Kohlstedt and Mackwell, 1998) or by interpretation of IR spectra.

Here we present $^1$H-solid state NMR spectroscopy as an alternative way to study the structural arrangement of H in nominally anhydrous minerals. A number of gem quality single crystals of NAMs like diopside and olivine as well as hydrous minerals like hydrogроссular and analcime were selected and prepared for both IR and $^1$H-NMR spectroscopy. The NMR spectra of hydrous minerals, where the coordination of H is well known, are used as a reference for comparison with the NAMs (Yesinowski et al. 1988). The pure $^1$H NMR signals in NAMs were derived by suppressing the probehead proton and background signal with a special DEPTH pulse sequence (Corey and Ritchie 1988). It was possible to identify clear $^1$H-signals using this technique, despite the significant Fe-content and the small amounts of H (< 1000 ppm) of the samples.

Preliminary results show that protons in diopsides are located in the structure as isolated (no neighboring H present) hydroxyl groups of a single coordination type. The chemical shift of the very narrow single $^1$H-signal is at approximately 1.8 ppm, which excludes the formation of silanol groups, but implies an association with Al$^{12+}$ on a Si site, as was suggested by e.g., Stalder (2004).

The Deep Biosphere: Quantitative and taxonomic constraints through microbial lipids

JULIUS S. LIPP AND KAI-UWE HINRICHS

Organic Geochemistry Group, Dept. of Geosciences,
University of Bremen, 28359 Bremen, Germany
(jlipp@uni-bremen.de, khinrichs@uni-bremen.de)

The deep biosphere contains up to one third of the total carbon in live cells of our planet (Parkes et al., 2000; Whitman et al., 1998). Recent studies have provided information on metabolic activities and quantities of deeply buried prokaryotic cells, while fundamental questions remain regarding the taxonomic composition (e.g. Biddle et al., 2006; Inagaki et al., 2006). For example, various techniques appear to disagree already at the domain level on who actually dominates this vast ecosystem.

We analyzed intact polar lipids (IPLs), a marker for live prokaryotic cells in a set of sediment samples from a depth range of 0.01 to 367 mbsf from sites at Peru margin, Cascadia Margin, Demerara Rise, and Equatorial Pacific (RV Sonne SO147, ODP Legs 201, 204, 207, and IODP Expeditions 301 and 311). The observed IPL concentrations range from 4 to 16,000 ng mL$^{-1}$ sediment and display a similar concentration-depth relationship as observed in a global compilation of direct counts of active cells (cf. Parkes et al., 2000). Surface sediments are clearly dominated by bacterial IPLs with possible admixtures of eukaryotic lipids. Concentrations of bacterial lipids decline rapidly within the first 10 cmbsf to levels significantly lower than those of their archaeal counterparts. The analysis of ODP/IODP samples from deeply-buried horizons shows evidence for bacterial lipids in about 20% of samples analyzed to date. On the basis of these observations in combination with results of degradation experiments of archaeal and bacterial IPLs under typical anaerobic sedimentary conditions (Pamela Rossel et al., unpubl. data), we interpret the predominance of archaeal IPLs as evidence for a far more important role than suggested by other techniques.

Anomalously low δ^{18}O values of oxygen dissolved in groundwaters at a uranium mine

GRZEGORZ P. LIS¹, M. JIM HENDRY¹ AND LEONARD I. WASSENAAR¹,²

¹Department of Geological Sciences, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 5E2; (grzegorz.lis@usask.ca; jim.hendry@usask.ca)
²Environment Canada, Saskatoon, Saskatchewan, Canada S7N 3H5; (len.wassenaar@ec.gc.ca)

Atmospheric oxygen with a constant δ^{18}O value of +23.5‰ is the dominant source for molecular O₂ present in subsurface environments. In the subsurface, O₂ may be consumed by various processes including organic matter decay, respiration, and oxidation of reduced metals. Biogeochemical O₂ consumption reactions preferentially consume the ^{16}O over ^{18}O. As a result, isotopic composition of O₂ in the subsurface becomes ^{18}O enriched and the resulting δ^{18}O values are greater than the initial +23.5‰.

The isotopic composition of dissolved oxygen in groundwater samples collected at a uranium mine in northern Saskatchewan, Canada were characterized by anomalous ^{18}O depletion with associated δ^{18}O values as low as +4.4‰. Subsequent to these observations, air saturated water samples were irradiated at the nuclear reactor facility for 0.5, 1, 2 and 5 h. The isotopic composition of O₂ present in headspace yielded a trend of increasing ^{18}O depletion with increasing irradiation time (Fig. 1). These observations suggest that water radiolysis may be responsible for the anomalous ^{18}O depletion observed in northern Saskatchewan groundwaters in proximity of uranium bodies. Further testing is being conducted; however if the ^{18}O depletion observed in the groundwater is attributed to radiolysis, oxygen isotopic anomalies may prove to be an exploration tool for the uranium mining industry.

Figure 1: Isotopic composition of water dissolved oxygen showing a trend of increasing ^{18}O depletion with irradiation time.

Technology of accounting of water exchange parameters at prospecting and exploration of carbon dioxide-bearing mineral waters

A.B. LISENKOV

Russian State Geological Prospecting University, Moscow, Russia (ryzhenko@geokhi.ru)

The developed technology is assumptive to partial automate evaluative of stage of investigation for carbon dioxide mineral waters to use informational analysis in the combination with the elements of the theory of “discerning forms” (Lisenkov A.B., Goppa V.D.) This is essentially heuristic approach, because it allows combining the apparatus of the theory “discerning forms” and the experience of experts, working in the regime of dialogue with computer technology. The new technology realizing in four stages:

1. The selection of initial exponents for the informational research models. The circle of the exponents is expedient to limit to the list a-priory influential or changing the composition of carbon dioxide mineral waters. In our opinion for these purposes could be allotting next groups of the exponents: landscape, geologic, hydro geologic, tectonic and man-caused load, as well as three groups of the exponents (landscape, tectonic, man-caused load) might be obtaining with consume of the result of encode the SFP. The remained exponents might be received from the results of preliminary and particulars research, experience of exploitation, so as with consume GIS-technology.

2. The formation informative search models are emanating in two stages: on first stage it has to estimate information of the initial exponent’s correlate with function of purpose and selection informative. On second stage, from single indications we composing complex by the method of sorting and calculating the information likewise correlate with function of purpose. From the most informational compound indications is composing train matrix, which presents it the image of learned region and circulation carbonaceous mineral waters (informational search model).

3. Testing informative model accomplishing by the way juxtaposition the test part with form. In case if the model is effective, so on it basis realizing resolution conjectural problem (search sections are suitable for putting-up explorative works), i.e. accomplishing next fourth stage. In the other case is realizing return to the first and second stages. The experience of structure similar models for Kislovodsk territory group of entrails the carbon dioxide mineral water has shown it adequate efficiency and combination the informative indications is stressing the role of thickness water reservoir breed in forming chemical composition of mineral water, the role of tectonic certain configuration and extension in orientation fluid’s streams and also the influence of natural or man-caused border of pressure on mass carrying carbonic acid.

Is mid-ocean ridge basalt chemistry a function of melt-rock reaction in the lower oceanic crust?

C.J. LISSENBERG¹, H.J.B. DICK² AND C. MÉVEL¹

¹Equipe de Géosciences Marines, Institut de Physique du Globe de Paris, 4 Place Jussieu, Tour 14, 5e etage 75252 Paris cedex 05 France (lissenberg@ipgp.jussieu.fr, mevel@ipgp.jussieu.fr)
²Woods Hole Oceanographic Institution, 360 Woods Hole Road MS#8, Woods Hole MA 02543 United States (hdick@whoi.edu)

Gabbroic rocks recovered from the Kane Core Complex (23°N, Mid-Atlantic Ridge), contain evidence for reactions between preexisting cumulates and melts migrating in diffuse, cm-wide channels. Evidence for melt-rock reaction includes disequilibrium compositions (anomalous Ti-Cr relationships in clinopyroxene, anomalous plagioclase-clinopyroxene equilibria) and textures indicative of mineral dissolution. The reaction that formed the reaction channels was: Melt 1 + olivine + high-An plagioclase = Melt 2 + high-Mg clinopyroxene + low-An plagioclase.

Modeling of this reaction as an assimilation-fractional crystallization process revealed that melts undergoing this reaction are enriched in MgO and Al₂O₃, and depleted in CaO. As such, this melt-rock reaction process can account for the global MgO-Al₂O₃-CaO systematics of mid-ocean ridge basalts (MORB). Previously, these systematics, as well as the occurrence of high-Mg clinopyroxene, were attributed to fractionation of mid-ocean ridge basalts in the upper mantle at elevated pressures. However, our modeling shows that the melt involved in the reaction yields increasingly higher pressures as the reaction proceeds, suggesting that such pressures may be artifacts of melt-rock reaction. In addition, our model produces high-Mg clinopyroxene. We suggest that lower crustal melt-rock reaction may significantly influence MORB chemistry, and that calculated pressures are overestimated as a result.

Nickel is proved to be utilized by a variety of bacteria for function and survival, however, high concentration of nickel is toxic to cells. Therefore, regulation of nickel import and export is critical process for bacteria to allow for optimal growth and resist to nickel stress.

In bacteria, control of transcription initiation of RNA polymerase on different promoters is the key step for directing the appropriate cellular response to environmental changes. Generally, bacterial promoters could be divided into two classes: stringent promoter (e.g. rrnB P1, pyrBI) and non-stringent promoter (e.g. lacUV). In this study, two strains RLG1319 and RLG1350 containing lacUV5-lacZ and rrnB P1-lacZ respectively were constructed from wild type MG1655 of E. coli. Compared with RLG1319 and MG1655, which were rarely affected at the given concentrations of nickel, the growth of RLG1350 was inhibited by the nickel (doubling time was 55, 60, 80 and 125 min at the concentrations of 0, 0.2, 0.5 and 0.8mM) but the relative β-galactosidase activity of the growing cells was augmented with the increase of nickel concentrations. Moreover, the transcriptional activity of RNA polymerase on stringent promoter was significantly higher than that on the non-stringent promoters at both log phase (OD600=0.4) and stationary phase (OD600=0.8). The mechanism of bacterial transcription on stringent promoters regulated by nickel is required to disclose in the future.
Highly siderophile element (HSE) compositions of Gakkel abyssal peridotites: Effects of serpentinization and constraints on accretion processes in early Earth

C.Z. LIU1, J.E. SNOW2, E. HELLEBRAND3 AND G. BRÜGMANN4

1State Key Laboratory of Lithospheric Evolution, IGGCAS, Beijing, China AND Max-Planck Institut für Chemie, Abteilung Geochemie, Mainz, Germany (czliu@mpch-mainz.mpg.de)
2Department of Geosciences, University of Houston, USA (jesnow@uh.edu)
3SOEST, University of Hawaii, Honolulu, USA (ericwgh@hawaii.edu)
4Max-Planck Institut für Chemie, Abteilung Geochemie, Mainz, Germany (bruegman@mpch-mainz.mpg.de)

Both fresh and typically serpentinized abyssal peridotites from the ultra-slow spreading Gakkel Ridge, Arctic Ocean, have been selected for HSE analysis (Os, Ir, Ru, Pt, Pd and Re). All but two harzburgites are fertile lherzolites with very low degree of partial melting. Previous Os isotopic studies indicate that the harzburgites have been subjected to low-degree partial melting in the early Proterozoic [1]. Comparison of HSE data between the altered rims and their corresponding fresh cores and between the fresh peridotites and serpentinites suggests that both Pd and Re are potentially affected by seawater alteration, whereas other HSE are not. The fractionation of PPGE (Pt, Pd) and Re from IPGE (Os, Ir, Ru) in Gakkel abyssal peridotites indicates that this is possible even at low degrees of partial melting (5-12%). Both Pd/Ir and Pt/Os show positive correlations with 187Os/188Os ratios, which cannot be explained by percolation of silicate/sulfide melts. We interpret these correlations to reflect the binary mixing of depleted and fertile components. The depleted component with low ratios of Pd/Ir (also Pt/Os) and 187Os/188Os represented by the harzburgites might be recycled ancient oceanic lithosphere or delaminated sub-continental lithospheric mantle (SCLM). The fertile component could have PUM-like HSE pattern and 187Os/188Os ratios in its history. The relationships of HSE/Ir ratios with both 187Os/188Os ratios and bulk Al2O3 contents in the fresh spinel lherzolites are used to estimate the HSE pattern of the PUM. We confirm the previously inferred non-chondritic HSE budget in the PUM [2], i.e., chondritic Os/Ir and Pt/Os ratios but supra-chondritic ratios of both Ru/Ir and Pd/Ir, which can neither be explained by secondary percolation of silicate/sulfide melts nor by addition of outer-core metals. It is also in conflict with the compositions of all known chondritic meteorite classes.

Important roles of sulfur cycling in karstic catchment erosion, Southwest China

C.-Q. LIU1, Y.-K. JIANG1, Y.-C. LANG1, S.-L. LI1, J.-H. PENG1 AND Z.-F. XU2

1State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China (liucongqiang@vip.skleg.cn, jyk@sina.com.cn, langyc822@163.com, lisiliang@vip.skleg.cn, pengjianhua318@126.com)
2Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China (zfxu@mail.igcas.ac.cn)

In southwestern China, there is a large area (about 600,000 km2) of diverse karstic landscape, with well-known eco-environmental problems of land-degradation and rocky kastification. Sulfur isotopic compositions of sulfate from rain, river, ground water and soil leachate in karstic areas were determined to understand the linkage between sulfur cycling and catchment erosion.

The sulfur isotopic compositions of sulfate in the studied area show that a relative large part of sulfate ion comes from oxidation of sulfide mineral and organic sulfur. Combined with carbon isotope studies and water chemical composition, the sulfur isotope study suggests that carbonate rocks in the catchment were weathered by both sulfuric and carbonic acids. Meanwhile, the carbon isotopic compositions of dissolved inorganic carbon in the surface and ground water of the karstic catchment show a large contribution of carbon that was derived from oxidation soil organic matter. In conclusion, the karstic catchment in southwestern China has a high weathering rate and rapid loss of nutrients due to coupled sulfur and carbon biogeochemical cycling.

Zoned zircon from eclogite lenses in marbles from the Dabie-Sulu UHP belt: A clear record of ultra-deep subduction and fast exhumation

FULAI LIU1 AND AXEL GERDES2

1Institute of Geology, Chinese Academy of Geological Science, Beijing 100037 (liufulai@ccsd.cn)
2Institute of Geosciences, Mineralogy, J. W. Goethe University, Frankfurt 60054 (gerdes@em.uni-frankfurt.de)

Eclogite lenses in marbles from the Dabie-Sulu ultrahigh-pressure (UHP) terrane are deeply subducted metasedimentary rocks. Zircons in these rocks have been used to constrain the ages of prograde and UHP metamorphism during subduction, and later retrograde metamorphism during exhumation. Inherited (detrital) and metamorphic zircons were distinguished on the basis of transmitted light microscopy, cathodoluminescence (CL) imaging, trace element contents and mineral inclusions. The distribution of mineral inclusions combined with CL imaging of the metamorphic zircon make it possible to relate zircon zones (domains) to different metamorphic stages. Domain 1 consists of rounded, oblong and spindly cores with dark-luminescent images, and contains quartz eclogite-facies mineral inclusion assemblages, indicating formation under high-pressure (HP) metamorphic conditions of T = 571-668 °C and P = 1.7-2.02 GPa. Domain 2 always surrounds domain 1 or occurs as rounded and spindly cores with white-luminescent images. It contains coesite eclogite-facies mineral inclusion assemblages, indicating formation under UHP metamorphic conditions of T = 782-849 °C and P = 5.5 GPa. Domain 3, with grey-luminescent images, always surrounds domain 2 and occurs as the outmost zircon rim. It is characterized by low-pressure mineral inclusion assemblages, which are related to regional amphibolite-facies retrograde metamorphism of T = 600-710 °C and P = 0.7-1.2 GPa. The three metamorphic zircon domains have distinct ages; sample H1 from the Dabie terrane yielded SHRIMP ages of 245 ± 4 Ma for domain 1, 235 ± 3 Ma for domain 2 and 215 ± 6 Ma for domain 3, whereas sample H2 from the Sulu terrane yielded similar ages of 244 ± 4 Ma, 233 ± 4 Ma and 214 ± 5 Ma for domain 1, 2 and 3, respectively. The mean ages of these zones suggest that subduction to UHP depths took place over 10-11 Ma and exhumation of the rocks occurred over a period of 19-20 Ma. Thus, subduction from about 55 km to more than 160 km deep mantle depth took place at rates of approximately 9.5-10.5 km/Myr and exhumation from depths about 160 km to base of the crust at about 30 km occurred at approximately 6.5 km/Myr. We propose a model for these rocks involving deep subduction of continental margin lithosphere followed by ultrafast exhumation driven by buoyancy forces after break-off of the UHP slab deep within the mantle.

Relationship between Hg and sulfur in coal from Huaibei coalfield, China

GUIJIAN LIU, LIUGEN ZHENG AND CUICUI QI

CAS Key Laboratory of Crust-Mantle Materials and Environment, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

Many authors have reported that Hg in coal can exist in solid solution within pyrite. Correlations between sulfur and Hg are often attributed to this mode of occurrence and are most common in coals that are extremely enriched in Hg.

The result of this study shows that coal samples from the Huaibei coalfield have relatively low sulfur values (average 0.59%). The correlation coefficient between ash and sulfur is -0.08, indicating that sulfur in the Huaibei coals has an intermediate (organic and inorganic) affinity. In a study of 29 coal samples from the Huaibei coalfield, we observed that organic sulfur is the dominant sulfur form when the total sulfur is near 0.5%. Some literatures report that organic sulfur compounds can capture Hg and result in the enrichment of Hg in coals.

The conclusion shows the relationship between Hg and sulfur in all 29 coal samples that we examined; note that the correlation coefficient is only 0.17 (n=29). Interestingly, and it shows a significant positive correlation between Hg and sulfur (n=21, R=0.64, p<0.05) is obtained by excluding the eight samples from the No. 5 and 7 coal seams, which were influenced by a magmatic intrusion. This suggests that the magmatic intrusion not only increased the concentration of Hg in seams 5 and 7, but also changed the mode of Hg occurrence in these seams. The significant, positive correlation between Hg and sulfur in coals from the No. 3, 4, and 10 seams suggests that Hg in these coal seams is bound to both organic sulfur moieties and within sulfide minerals.
Fluorine in Chinese coals and its health impact

GUIJIAN LIU, CUICUI QI, LIUGEN ZHENG AND YINGYING ZHANG

CAS Key Laboratory of Crust-Mantle Materials and the Environment
School of Earth and Space Science, University of Science and Technology of China, Hefei 230026, China (lgj@ustc.edu.cn)

The health problems caused by fluorine released during coal combustion are more extensive than those caused by arsenic. More than 14 provinces and more than 30 million people in China suffer from various forms of fluorosis, and about 15 million people have been diagnosed as having fluorosis. More specifically, around 10 million people in Guizhou Province and surrounding areas suffer from various forms of fluorosis. In Beimen Zheng and Hua Chun in Guizhou, about 78% of the inhabitants are diagnosed as having skeletal fluorosis including osteosclerosis. Almost every family in this district has members suffering from skeletal fluorosis with limited movement of the joints, and outward manifestations such as knock-knees, bow legs, and spinal curvature. In Xiaotang Zheng, Pengshui, Sichuan province, among 5633 residents, there are about 98% of the residents suffering from tooth enamel mottling (dental fluorosis).

The authors carried out a series of fluorosis surveys in Guizhou. In a survey of one elementary school, among 57 students, only one student was found to be free of dental fluorosis, while 99% of the student population was diagnosed as having dental fluorosis. During these surveys, the authors also found that the youngest patient was about 1 year old. Typical signs of fluorosis include mottling of tooth enamel (dental fluorosis) and various forms of skeletal fluorosis.

TEM investigation of the non-oxidative dissolution of galena (PbS) nanoparticles in a hydrochloric acid solution

J. LIU1, D.M. ARUGUETE1, M.F. HOCHELLA JR.1,2 AND J.R. JINSCHEK2

1Department of Geosciences, Virginia Tech, Blacksburg, VA 24061-0420, USA (juanliu@vt.edu)
2Institute for Critical Technology and Applied Science (ICTAS), Virginia Tech, Blacksburg, VA, 24061, USA

Galena (PbS) is one of the most common base metal sulfide minerals in nature. The dissolution of galena in acid solution can be an important reaction controlling the transport and transformation of Pb in natural waters. Moreover, sulfide nanocrystals have been found in the natural environment as a result of bacterial metabolism (Labrenz et al., 2000) or the breakdown of sulfides and silicates (Hochella et al., 2005) which has sparked an intense interest in understanding the dissolution mechanism of sulfide nanocrystals. Chemical properties of crystalline materials are known to be dramatically influenced by crystal size, especially for dimensions of 100 nm or less (Alivisatos, 1996). Nevertheless, much is still unknown about the size-dependence of dissolution. As a result, we are studying the structure and dissolution of galena nanocrystals. This work not only is important for understanding the effects of mineral size on geochemical processes, it also has implications for environmental remediation and the impact of nanotechnology on the environment.

Bright-field TEM and HRTEM have been applied to investigate the morphology and structural characteristics of galena nanoparticles. Galena nanoparticles ~15 nm in diameter were synthesized via variations on a wet chemical method reported by Joo et al. (2003). HRTEM images of the galena nanoparticles exhibit lattice patterns, demonstrating their highly crystalline nature. The nanoparticles aligned along two principal lattice directions, [100] and [110], have been studied most carefully. {100}, {110}, and {111} faces are presented on nanoparticles and {100} faces are more developed than {110} faces, resulting in a truncated cubic shape. By comparing the bright-field TEM and HRTEM images of pre- and post-dissolution nanoparticles, the dissolution rate can be determined by calculating the size change versus time. Shape and structure evolution can also be observed, which will provide important information for understanding the dissolution mechanism.

Melt percolation in Songshugou ultramafic massif

J.F. Liu1, W.D. Sun2 and Y. Sun1

1The State Key Lab of Continental Dynamics, Department of Geology, Northwest University, Xi’an, 710069, China (ljfnwu2002@163.com)
2Guangzhou Institute of Geochemistry, Chinese Academy of Science, 510640, China (weidongsun@gig.ac.cn)

The Songshugou ultramafic massif is located to the north of the Shang-Dan fault, intruding into the Proterozoic Qinling Group in the eastern Qinling Mountains, central China. It is the largest Alpine-type ultramafic body in China, covering an area of ~20 km². Remarkably, this massif consists mainly of dunite (~80%) with minor harzburgite, and olivine diopsidite etc. Harzburgite occurred as lens in the dunite, while olivine diopsidite occurred as vein in the margin of the body.

The formation and tectonic affinity of the Songshugou ultramafic massif is very important for understanding the formation and evolution of the Qinling orogenic belt. Published results however, do not agree with each other [1-3], leading to different models for the early history of the Qinling orogenic belt and the interaction between the North and South China blocks.

Here we show LA-ICP-MS for olivine grains of a transition from dunite to harzburgite in the Songshugou ultramafic massif, show compositional variations. Ni and P are lower, whereas Sc, and incompatible elements, Ti, V, Cr, Rb, Sr, Y, Zr, Nb, Pb and REE, are higher in olivine grains in dunite than those in harzburgite. These observations can be plausibly interpreted by reaction of lherzolite and/or harzburgite with melt through porous percolation flow at high melt/rock ratios, similar to the melt percolation model proposed for dunite in other places [4,5].

The north Qinling orogenic belt is believed to be the result of backarc collision [6]. We propose that the Songshugou massif was part of the depleted mantle wedge peridotite during the early subduction along the Shan-Dan fault, which was intensively recasted through melt percolation. These results provide more constraints on the evolution of the Qinling orogenic belt.

The Paleoclimatic records of stalagmite traced by stable isotopes from Liangfeng cave in Southwest, China

Q.M. Liu1 and S.J. Wang2

1School of Biotechnology Engineering, Jimei University, Xiamen, China (qmliu@xmu.edu.cn)
2Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China. (sjwang@ms.gyig.ac.cn)

Speleothems especially stalagmite are important repositories of Paleoclimatic and Paleoeocological-Paleoenvironmental data. Based on the systematical studies of the sedimentary characteristics and the stable carbon (oxygen) isotopes, the Paleoclimatic Records of stalagmite from Liangfeng cave (E108°02′29″, N25°16′21″) in Southwest, China, have been made, which gives records from 14220 to 1570 aBP as follows: 14220-10500 aBP, Among Last Glaciation to Holocene, theδ13C values of stalagmite varies from –9.314‰ to –7.290‰, average –8.552‰. Theδ18O values of stalagmite varies from –5.651‰ to –6.942‰.

10500-9300 aBP, The temperature increased after the end of Younger Dryas, theδ13C values of stalagmite varies from –10.377‰ to –9.267‰, average –9.910‰, the vegetation above Liangfeng cave be dominated by C3 plants. Theδ18O values of stalagmite decreased obviously, varies from –7.420‰ to –6.077‰, average –6.854‰, rainwater increased and Southwest monsoon was strong.

9300-8300 aBP, The temperature fluctuates obviously along with the changes ofδ13C values (varies from –10.155‰ to –9.096‰, average –9.712‰) of stalagmite, and the proportion of C3 plants of vegetation above Liangfeng cave was unsteady. Theδ18O values of stalagmite varies from –6.796‰ to –6.260‰, average –6.490‰, the affect of East-Asian monsoon increased.

8300-3100 aBP, The temperature increased obviously, theδ13C values of stalagmite is much low (average –9.910‰), the vegetation above Liangfeng cave be dominated by C3 plants. Theδ18O values of stalagmite changes greatly, varies from –7.373‰ to –5.047‰, indicated that the climatic of monsoon is unsteady.

3100-1570 aBP, Theδ13C values andδ18O values of stalagmite increased greatly, theδ13C values varies from –12.097‰ to –6.495‰, average –10.275‰, theδ18O values varies from –8.650‰ to –4.677‰, average –6.854‰, the vegetation above Liangfeng cave be dominated by C3 plants mainly, the climatic of monsoon is unsteady.

3State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

Introduction

The Nanling metallic province is a famous tungsten metallic belt in South China. These tungsten deposits with close relation to the Yanshanian (J3) igneous activities have characteristics of multi-stages of mineralization (Xiao et al., 2006). This paper discusses factors controlled the tungsten formation in Nanling metallic province.

Experiment and Results

The chemical compositions of fluid inclusions are determined with RM-1000 laser Raman spectroscopy produced by Renishaw Company, at Institute of Geology & determined with RM-1000 laser Raman spectroscopy at Institute of Geology &

Mesozoic magmatic activities of western Shandong (Luxi), China

Shen Liu, Rui Zhong Hu, Cai Xia Feng, Liang Qi, Tang Fu Xiao and Hong Zhong

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, PR China (liushen@vip.gyig.ac.cn)

Mesozoic intrusions and volcanic rocks are widely distributed in the western Shandong Province (Luxi). Field relationships and available K-Ar, 40Ar-39Ar and U-Pb zircon ages (Tan and Lin, 1994; Xu et al., 1993; Xu et al., 2004a, b, c; Liu et al., 2004; Zhang and Sun, 2002; Qiu et al., 2001; Guo et al., 2003; Zhang et al., 2004, 2005) suggest that the magmatic activities mainly took place in Luxi during the late Mesozoic, and this area may underwent a quiet period in magmatic activity from 185Ma to ca.130Ma (Zhang et al., 2005). Mesozoic mafic dike swarms are widespread in Luxi. Comparatively few studies, especially precise dating, have been carried out on the voluminous mafic dikes in Luxi. Herein, we present the first precise U-Pb isotopic data on zircons obtained from two mafic dikes. Detailed SHRIMP zircon U-Pb dating yields emplacement ages of 144±2Ma and 143±2Ma for the two mafic dikes from Luxi (Mengyin and Zichuan). This study thus indicates that there did exist magmatic activities between 185 and 130Ma.

Si and O isotopic evidence for the genesis of the secondary quartz in red weathering crusts of carbonate rocks in Guizhou Province

XIUMING LIU, SHIJIE WANG, LIJUN JIANG AND CHUNRU LIU

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (liuxiuming@vip.skleg.cn)

In our previous study, the well-crystallized quartz had been founded in many in situ weathering crusts of carbonate rocks in Guizhou Province, which have been demonstrated the possibility of dating the weathering processed by the method of fission track dating. So, the genesis of the well-crystallized quartz is the key to date the weathering crusts of carbonate.

This paper focuses on the use of the ratio of $\delta^{18}O$ and $\delta^{30}Si$ of well-crystallized quartz, extracted from in soil layer of three weathering crusts. The ratios of $\delta^{18}O$ of well-crystallized quartz have a narrow range from 17.3-22.7‰ (SMOW), which were more positive than igneous rocks (8-10‰), metamorphic rock (10-16‰) and Hydrothermally modified rock (4-10‰), similar to the chert bearing in the low temperature-formed dolomite (14-24‰) and authigenic quartz (20-34‰) in sandstone in Mississippi river, implying the supergene genesis of well-crystallized quartz. Furthermore, the ratios of $\delta^{30}Si$, ranging from 0.8‰ to 1.7‰, were more positive than the crystalline rock, kaoline, diatomite and quartz veins, but overlap the shallow marine radiolarians-bearing siliceous rocks and siliceous dolomite, which implied the quartz were precipitated in low-temperature environment too. Based on the Si and O isotopic evidence, it is deduced that the well-crystallized quartz was secondarily precipitated from Si-rich weathering fluids during weathering processes of carbonate rocks.

According to the argillaceous soil layer lacking of enough space for the precipitation of quartz and well-crystallized quartz was found in small cave or cranny underlying parent rock in field, it can be confirmed that the quartz was precipitated in parent rock. That is to say, the age of secondary well-crystallized quartz in soil layer was the upper limit or oldest age of weathering processes of carbonate rock in Guizhou Province.

Revised petroleum migration history in the Nanbaxian area of the northern Qaidam Basin (NW China): Constraints from oil-bearing fluid inclusion analyses

Y.T. LIU1,2, S.Y. YANG2, K. HU1 AND X.Q. PENG2

1Department of Earth Sciences, Nanjing University, Nanjing 210093, China (kaihu@nju.edu.cn)
2PetroChina Qinghai Oilfield Company, Dunhuang 736202, China

The Nanbaxian area is the presently largest oil-gas producing provinces in the northern Qaidam Basin, NW China. Previous studies have suggested only the northern Middle Jurassic sources mainly feed the reservoir here, with little contribution from the southern Lower Jurassic mudstone. In this study, we obtained new insights on petroleum migration history based on analyses on hydrocarbon fluid inclusions.

Free oil in intergranular pores and petroleum in inclusions hosted by mineral grains of reservoir sandstone samples were analyzed by GC and GC-MS. Analytical results show that there is a distinctive difference of molecular geochemical signatures between the free and inclusion oils, including the peak carbon number present in GC chromatogram, the ratio of pristane relative to phytane, etc. Specifically, the value of tricyclic terpane C19/C20 was suggested as good oil-oil and oil-source correlation proxy by previous authors. Thus, as this value is greater than and lower than 1.0 for free and inclusion oils, respectively, we proposed that there were at least two oil charges ever happened, with the Middle Jurassic mudstone derived hydrocarbons charging firstly and the Lower Jurassic oils arriving later.

Petrography shows that there mainly exist three different fluorescence color hydrocarbons: yellow, yellow-green and brown orange. This indicates a complex petroleum charge history. The histogram of Th data shows three populations with modes at around 60°C, 70-80°C, and 100-110°C. Combined with the burial and paleotemperature history, this reveals that there include mainly two oil charge episodes in Early and Late Paleogene, respectively. In addition, the highest Th range (100-110°C) was indicative of gas charging during Neogene.

In summary, petrographic and geochemical investigations of oil-bearing fluid inclusions tend to suggest a revised petroleum migration history. The complexity here may be attributed to the two hydrocarbon source kitchens and the effect of fault-controlled petroleum migration.
Phases relationships in the actinide waste forms with a garnet structure

T.S. LIVSHITS AND S.V. YUDINTSEV
Institute of Geology of Ore Deposits, Moscow, Russia
(lita_239@yahoo.com)

Complex oxides with a garnet-type structure (sp. gr. Ia3d) are suggested for long-lived actinide waste immobilization (Yudintsev et al., 2007). Three cationic sites in the structure provide for simultaneous incorporation of actinides and other elements into lattice. The highest actinide content (30 wt.%) was found in the ferrate garnet, where the “B” and “X” sites are filled in Fe$^{3+}$. General formulae of the phases corresponds to $\text{VIII}_3\text{VIII}_2\text{VII}_3\text{VII}_2\text{X}_3\text{O}_{12}$, where “A” = Ca$^{2+}$, REE$^{3+/4+}$, An$^{3+/4+}$; “B” = An$^{4+}$, Zr$^{4+}$, Fe$^{3+}$; “X” = Fe$^{3+}$. We have summarized data on the phases relations and compositions in ceramics of the garnet stoichiometry doped with typical impurities of actinide waste (Na, Al, Cr, Mn, Ni, Si, Zr). 50 samples were produced by cold pressing and sintering method at 1300–1500°C and examined with XRD and SEM/EDS. Temperature in this range has a little effect on the phases composition. Addition of Al and especially Si reduced actinides solubility in the garnet structure resulting in appearance of actinide oxide (Fig. 1). Na and Si in precursor leads to decreasing of melting point and formation of glass. High corrosion products (Cr, Ni) content in the initial mixture resulted in appearance of spinel. This work was supported by the Russian Foundation for Basic Research (project 05-05-64005) and the U.S. DOE.

LAM ICP study of cloudy diamonds: Implications for diamond formation

A.M. LOGVINova, I.V. ASHCHEPKOV AND S.V. PALESSKY
IGM SB RAS, Novosibirsk, Russia (logv@uiggm.nsc.ru)

Cloudy centers of octahedral diamonds from the Internationalnaya and Yubileynaya Mines (Yakutia) have been studied by LAM ICP. They are abundant in nanometric melt-inclusions, consist of multi-phase assemblages (silicates, oxides, carbonates, sulfides, brine and fluid bubbles) (Logvinova et al., 2006). The centers (dark zone) of the cloudy area show the increase of TRE content of two orders of magnitude comparing to the clear periphery (Diamond 1). Abundance of TRE and La/Yb$_n$ ratios are close to those of kimberlite melts. Two-folded REE patterns are indicative of multistage melt percolations. The light matter often reveal Y dips common for diamonds. Diamond 2 shows Ta, Nb, Zr, Hf peaks typical of picroilmentines. Inclined REE for centers may suppose crystallization of protokimberlite melts. Multiplied zonation and polymict inclusions in many diamonds suggest a complex model for diamond growth near protokimberlite magmatic systems at which the evolved ultramafic melts splite to form sulfide, silicate and carbonate liquids during the cooling when they interact with surrounding peridotites and eclogites. The TRE patterns show mixed sulfide (Pb, Cu) and silicate melts signatures differing from spongier (Rege et al., 2003) and coated diamonds (Afanasiev et al., 2005). The abundance of Ba, U, Pb, high Cu/Ni ratio and Eu anomalies may suggest admixture of subduction components from the wall rock eclogites.

Figure 1. Trace element pattern for dark and light zones from cloudy diamonds.

The gas-particle partitioning of polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) was examined (i) by re-interpreting results from controlled field experiments and (ii) in diurnal samples taken in the New Jersey - New York City (NJ) region. In the controlled field experiments, aerosol-laden filters were exposed to elevated concentrations of PCDD/Fs. Gas-particle partitioning coefficients, $K_{ps}$, were significantly correlated with octanol-air partitioning coefficients, $\log K_{oa}$. The regression of all individual datapoints resulted in the following best fit ($r^2 = 0.74$, $n= 87$):

$$\log K_{ps, \text{meas}} = 1.00 (\pm 0.13) \log (10^{-12} f_{om} K_{oa} / \rho_{oct}) - 0.15 (\pm 0.48).$$

We interpret this as showing that the ability of organic matter (OM) to absorb PCDD/Fs is generally well described by the octanol-air partitioning model ($f_{om} K_{oa}$).

Results will be compared to previous observations of the gas-particle partitioning of PAHs.

At the NJ land-based sites, samples were taken and analyzed for organic (OC) and elemental carbon (EC), gaseous and particulate PCDD/Fs. $K_{ps}$ were significantly correlated with the $f_{om} K_{oa}$ approach. Adsorption to the GFF and possibly to BC will have contributed to the observed $K_p$ values. Gas-particle predictions based on BC adsorption and OM absorption, with $K_p = f_{om} K_{oa} (10^{12} \rho_{oa}) + f_{BC} K_{BC, air} / (10^{12} \rho_{BC})$ resulted in $K_p$ predictions that were close to measured values.

In favour of adsorption to the GFF being the major reason is that NB displayed highest $K_p$ values, which was also most prone to this sampling artefact based on relatively low sampling volumes and TSP concentrations. In addition, while adsorption to BC would result in better prediction of $K_p$ values, no influence of $f_{BC}$ or $f_{BC}/f_{om}$ ratios was seen, suggesting that it was of lesser importance in our sample set.

Fe$^{3+}/\Sigma$Fe in lower mantle (Mg,Fe)O:
Calibration of the “flank method”

M. LONGO AND C. MCCAMMON

Bayerisches Geoinstitut (micaela.longo@uni-bayreuth.de; catherine.mccammon@uni-bayreuth.de)

The lower mantle, which represents more than half the Earth by volume, is dominated by (Mg,Fe)(Si,Al)O$_3$ perovskite and ferropericlase (Mg,Fe)O. Studying these phases are therefore critical to determining redox conditions and their consequences for mantle properties and dynamics. Studies have shown that the Fe$^{3+}$ concentration in (Mg,Fe)(Si,Al)O$_3$ perovskite is essentially insensitive to oxygen fugacity; hence our attention is turned to (Mg,Fe)O. Our goal is to calibrate the “flank method” [1] on synthetic (Mg,Fe)O using the electron microprobe, and then apply the method to determine Fe$^{3+}/\Sigma$Fe in ferropericlase inclusions from lower mantle diamonds.

Initial experiments focused on synthesis of polycrystalline (Mg,Fe)O with varying Fe/Mg and Fe$^{3+}$ concentrations with run product characterisation using transmission electron microscopy, X-ray diffraction and Mössbauer spectroscopy. However electron microprobe measurements of the X-ray emission $L\beta/L\alpha$ ratios showed up to 10% variation, likely due to the porous nature of the sample surfaces, so further synthesis was performed using a multianvil press to obtain single crystals. The reproducibility of $L\beta/L\alpha$ measurements showed dramatic improvement, and experiments are continuing in order to generate a suite of high quality crystals over a wide composition range. The use of enriched $^{57}$Fe enables Mössbauer measurements to be carried out on the same sample used for the electron microprobe measurements, and an ongoing parallel study on natural garnets shows promising results for this approach.

Neoproterozoic rocks in SW Iberia are largely exposed in the Central Iberian and the Ossa Morena zones. Though different to each other, both areas witness for development within, or adjacent to, an active margin setting during the Late Neoproterozoic (Cadomian orogen). In the Palaeozoic, the following tectonic stages are recognised: 1) rifting event (Cambrian-Early Ordovician), 2) passive margin stage (Ordovician-Silurian-Early Devonian), and 3) Variscan Orogeny. Nd isotopic composition has been determined on fine grained, low-to very low-grade metasedimentary rocks, mainly shales. εNd(T) values range from +2.1 to -13.9. Significant excursions to less negative values between -3 to +2.1 are interpreted to record periods when the corresponding basins were significantly supplied of juvenile components from mantle sources. The εNd(t) values are negative in both areas and do not display any sharp changes during the Palaeozoic; a signature commonly found in recycled crustal-derived sediments. The isotopic data are consistent with the Ossa Morena and Central Iberian Palaeozoic successions being derived from a polycyclic mixture of old crust (≥ 2 Ga) and younger crustal components, coeval with the recorded orogenic and rifting phases. In summary, Nd isotope systematics points to clear differences between the two zones in Neoproterozoic times and significant similarities during the Palaeozoic.

**Do orogenic peridotites preserve platinum-group element systematics of mantle melting processes?**

Jean-Pierre Lorand

Unité “Minéralogie”, CNRS and MNHN, 61 Rue Buffon, 75005, Paris (jplorand@mnhn.fr)

Most recent estimates of the Primitive Upper Mantle (PUM) composition allow significant deviation of Ru/Ir (2.03) and Pd/Ir (2.06) above chondritic values. The rationale behind PUM estimates is that fertile and refractory peridotites are products of a single episod of partial melting and melt extraction. The paradigm has now been questioned for a number of orogenic peridotite massifs such as Lanzo (Italy), Ronda (Spain), Beni Bousera (Morocco), Horoman (Japan) and Lherz (France), the type-locality of lherzolites. Harzburgites of residual origin (Ir N > 1.0; Re/OsN = 0.10-0.15; Pd/IrN = 0.1-0.4; N = PUM-normalized) have been identified in every massif. They contain little or no base-metal sulfide (BMS) : at Lherz, the PGE budget is accounted for by refractory discrete platinum-group minerals (laurite-erlichmanite; malanite-cuprorhodsite; Pt-(Ir)-rich alloys). Orogenic lherzolites display PGE concentrations and PGE patterns close to PUM estimate while showing many features of extensively percolated abyssal peridotites with regard to BMS. The BMS occur as ameboid, angular bodies (up to 500 μm) showing morphologies of blebs of metal-rich sulfide melts. These blebs (pentlandite + chalcopyrite ± bornite ± pyrrhotite) preferentially nucleated onto (or inside) the opx and Al-spinel (or on the cpx in the cpx-rich lherzolites). Extensive reactions between a S-saturated basaltic melt and olivine and Cr-spinel at 1-2 Gpa could produce such associations. Neither harzburgites nor lherzolites show mineralogical evidence of trapped Ms inside olivine, as one would expect from incongruent melting of BMS. Harzburgites, fertile lherzolites and websterites display broadly similar Cu/S ratios (1.5 x PUM estimates) while defining linear correlation trends in S vs. Al plots. Osmium, Ir, Ru and Rh (IPGE) negatively correlate with fertility indices, as predicted by D_mss/sulfide melt. However, harzburgites, lherzolites and websterites are aligned on the same regression lines which are therefore more likely mixing lines. Discrete laurite (less than 500 nm across) discovered in Lherz lherzolites (FEG-SEM data) may have been inherited from harzburgitic protoliths. Platinum concentrations do not correlate with fertility indices, nor with Pd, despite similar D_mss/sulfide melt, reflecting saturation in refractory Pt-rich alloys at mantle temperatures (FEG-SEM data). Palladium positively correlates with Cu, S, Ca and Al, in agreement with its almost exclusive partitioning in sulfide melt. The latter correlations are consistent with refertilisation reactions of refractory peridotites by variable amount of basaltic melts that precipitated Cu-rich sulfide melt, cpx, Al-spinel and opx.
The melting curve of Fe\textsubscript{3}C to 73 GPa

O.T. LORD AND M.J. WALTER
Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queen’s Road, Bristol, BS8 1RJ, UK (Oliver.Lord@Bristol.ac.uk)

Seismic data indicate the Earth’s outer core is about 10% less dense than pure Fe-Ni at the prevailing P-T conditions, whereas the inner core is some 4% less dense. Possible candidates for the light element component required to satisfy this discrepancy include H, C, O, S and Si. Constraints on core composition, phase relations and temperature are derived from knowledge of the melting relations in relevant iron-light element systems. In this study we have determined the melting curve of Fe\textsubscript{3}C up to 73 GPa using the Laser Heated Diamond Anvil Cell (LH-DAC).

Foils made from powdered Fe\textsubscript{3}C (synthesised by R. Dasgupta at LDGO) were loaded into ~100 µm holes in preindented Re gaskets. NaCl, ruby and sapphire were used as pressure media and thermal insulators. Samples were compressed to experimental pressure and then heated using a 60W Nd:YLF laser and a double sided heating geometry. Pressure was measured before and after each melting experiment by ruby fluorescence. Temperatures were determined by spectroradiometry. Congruent melting in a one-component system causes 1\textsuperscript{st} order discontinuities in physical properties. Here, melting is deduced primarily from discontinuities in the temperature and emissivity vs. laser power function, and in some cases by visual observation of melt convection. When these observations occur together they give a consistent melting temperature. The results of our data are shown in figure 1, the solid line being our preferred melting curve from a fit of the data to a Simon equation. An extrapolation of this curve predicts a melting temperature of ~3250±50 K at the core-mantle boundary and ~3800±100 K at the inner core boundary.

Molecular scale study of the synergism between oxalate and desferrioxamine-B on goethite dissolution

JOHN S. LORING, ANNA A. SIMANOVA AND PER PERSSON
Department of Chemistry, Umeå University, Umeå, Sweden (john.loring@chem.umu.se; anna.simanova@chem.umu.se; per.persson@chem.umu.se)

Oxalate significantly increases the rate of dissolution of goethite in the presence of siderophores. This is especially true if the goethite is preequilibrated with oxalate before siderophore exposure. It has been suggested that this phenomenon is due to an oxalate-goethite surface complex that is kinetically labile with respect to iron. In this way, oxalate acts as an efficient shuttle for Fe(III) from the goethite surface to the bulk solution. Once in solution, the strongly complexing siderophore seizes the Fe(III), and oxalate is free to go back to the surface for more iron [1-3].

In this study, we use quantitative \textit{in situ} infrared spectroscopy to further the mechanistic understanding of the role of oxalate in the dissolution of goethite in the presence of the siderophore, desferrioxamine-B (des-B). All experiments were performed at 25 °C in 0.1 M NaCl ionic medium and in the absence of light, and the pH was held at 6 using pH-Stat titration methods. The total concentration of oxalate was 1 µmol/m\textsuperscript{2}, and this concentration causes no significant dissolution of goethite in the absence of des-B. First, infrared spectra at the aqueous-goethite interface were collected as a function of time for one week to follow the adsorption and surface speciation of oxalate and des-B individually. Then, spectroscopic desorption experiments were performed in order to determine the relative stabilities of the ligands in the different types of surface complexes. Next, spectra were collected for several days after the simultaneous addition of 1 µmol/m\textsuperscript{2} concentrations of both oxalate and des-B. Finally, oxalate was reacted with goethite for one week, and then spectra were collected as a function of time after repeated 0.1 µmol/m\textsuperscript{2} additions of des-B every 24 hours. We identify an oxalate-goethite surface complex that increases the mobility of Fe(III) but is otherwise thermodynamically stable in the absence of des-B. These results are discussed with respect to their broader implications toward mechanisms for ligand-promoted mineral dissolution.

Oceanic basalts geochemical heterogeneities distribution in four large scale domains supporting a first order two large cells whole mantle convective structure

MICHEL LOUBET
LMTG, Universite de Toulouse, CNRS, IRD, OMP, 14 Av. E. Belin, F-31400 Toulouse France (loubet@lmtg.obs-mip.fr)

The analysis of compositional heterogeneities displayed at a large scale by the oceanic basalts, using combined isotopic and incompatible trace element ratio diagrams, and in particular the $^{208}$Pb/$^{204}$Pb vs $^{206}$Pb/$^{204}$Pb, and Nb/La vs Th/La representations, leads to identification of four large scale domains. The mentioned representations display interesting properties for evidencing and quantifying intra mantle magmatic differentiation processes, as for estimating the residual characteristics of mantle sources according to the continental-mantle differentiation process. Two domains are identified within the Atlantic-Pacific realm, (specified as the Atlantic-East Pacific (AEP) and the South Central Pacific identified within the Atlantic-Pacific realm, (specified as the continental-mantle differentiation process. Two domains are residual characteristics of mantle sources according to the properties for evidencing and quantifying intra mantle domains. The mentioned representations display interesting representations, leads to identification of four large scale earth mantle flow models which take into account numerous structures issued from numerical modeling results as with domains. Such a structure looks consistent with convective mantle, and located inside the respective AEP and IO (specified as the Indian Ocean (IO), and Kerguelen - South Africa, is proposed for the enriched-type domain in the Pacific area, the enriched-type domain is related to the super-plume rising below the Pacific. A similar super-plume origin, but located below Africa, is proposed for the enriched-type domain in the Indian Ocean - South Atlantic area. A relationship can be drawn, in a more general way, between the geographical repartition of these domains and long wavelength geophysical features as seismic and gravity anomalies. The good advanced structure bears constrains on plumes as on plateau basalts origin.

MC-ICP-MS measurements with d-DIHEN direct injection nebulization

P. LOUVAT¹, J. BOUCHEZ¹, G. PARIS¹ and M. GAERTNER²

¹IPGP, équipe Géochimie & Cosmochimie, 4 Place Jussieu, 75005 Paris, France (louvat@ipgp.jussieu.fr; bouchez@ipgp.jussieu.fr; paris@ipgp.jussieu.fr)
²ANALAB, 10 rue des Métiers, BP 161, 67726 Hoerdt Cedex, France (analab@wanadoo.fr)

Compared to the classical spray chamber nebulization, direct injection nebulization offers to increase the analyte transport efficiency and thus the sensitivity, to reduce the sample amount needed for one analysis and the memory effects, rendering bracketing isotopic measurements much more suitable and precise for elements such as boron.

The recently developed d-DIHEN (demountable Direct Injection High Efficiency Nebuliser, Westphal et al., 2004) has been tested for isotopic measurements on a Neptune (Thermo) MC-ICP-MS.

The spray is optimized by varying the capillary-nebuliser tip distance and observing the water meniscus formed at the end of the nebuliser tip, before the d-DIHEN is positioned into the torch (4mm before the intermediate tube tip) and the plasma lit up (1200W). Best sensitivities are obtained for sample gas flow between 0.15 and 0.20 l/min, and auxiliary gas flow around 1.5 l/min. A peristaltic pump allows uptake rates of 10 to 100 µl/min. Best performances were obtained for 20 to 50 µl/min.

The sensitivities with d-DIHEN are similar to those with APEX for elements such as Mg, Sr, Nd, and Pb (approx. 11, 12, 4.5 and 10 V on larger isotope for 100 ppb solutions at 25 µl/min), and are respectively 7, 2.5, 2 and 2 times higher than double Scott spray chamber ones. Sensitivity gains for B and Li are 4 and 6.

Signal stability is typically 0.07% (RSD for 5 minutes on B). Oxides and doubly charged are more abundant than with the previous introduction systems: typically NdO/Nd = 25%, Ba$^{2+}$/Ba = 2%.

Boron isotope measurements with d-DIHEN led to an external reproducibility of 0.4% (2σ) on purified 100 ppb B seawater samples. Internal reproducibility was 0.1%. 200 seconds of wash were sufficient to reach 1% of the sample signal (2V). Measurement accuracy was successfully tested with enriched standards for $^3^1$B between –50% and +40%.

Neodymium isotope measurements gave internal reproducibility similar to those obtained with a double Scott spray chamber for comparable signal intensity (2 ppm on $^{1^{4}}$Nd/$^{1^{4}}$Nd).

Isotopic and geochemical characteristics of late Neoproterozoic oceans from the Dalradian Supergroup of Scotland: Local basin infilling or global signatures?

D. LOWRY, N. LANG AND N.V. GRASSINEAU

Dept. of Geology, Royal Holloway, University of London, Egham, UK (d.lowry@gl.rhul.ac.uk)

Recent studies have suggested that there are 3 glacial deposits in the Neoproterozoic succession of Scotland and Ireland and that the well-known Port Askaig tillite represents a Sturtian (720 Ma) glaciation. The identification of a boulder bed and overlying cap carbonate above an unconformity in the Easdale subgroup of Ireland suggest that it represents a Marinoan (640 Ma) glacial event (McCay et al., 2006).

New studies have focused on localised black shales and limestones from the middle Easdale subgroup of Western Argyll, Scotland, which are intermittently rich in sulphides. Unlike much of the Dalradian Supergroup, this area has been only subjected to chlorite-grade metamorphism and relatively low levels of deformation. While the organic carbon isotopes have been reset by metamorphism with an enrichment in 13C of around 15‰, the trend still parallels that of 13C carbonate. Geochemical data (K, Ba, Rb) indicate a period of high continental input to the ocean leading to high nutrient levels, elevated organic carbon contents (TOC) and 13C enrichment for the pre-glacial Islay and Tayvallich limestones at lower and higher levels respectively, in the Dalradian sequence (McCay et al., 2006).

Pyrite 34S cycles between +11 and +21‰ in the same sequence of black shales and overlying limestones and this can be correlated with continental inputs and basin infilling, resulting in probable restrictions to sulphate recharge.

The transition from limestone to overlying phyllites with minor limestones is associated with a sudden decrease to very low TOC and a negative carbon isotope excursion for carbonates, paralleled by the curve for organic carbon. δ34S continues to rise in the phyllites before falling to δ34S depleted values, the lowest stratigraphic level in the Dalradian for which δ34S depletion is recorded. Global Neoproterozoic δ34S records for pyrite show that the first depletion post-dates the Marinoan glacial period and is related to a significant increase in the oxygenation of the oceans and hence sulphate content (Hurtgen et al., 2005). This suggests that the Easdale subgroup in Scotland can be correlated with the Marinoan, despite there being no evidence so far for glacial deposits, and confirms the findings of McCay et al. (2006) for similar stratigraphic levels in Ireland.

Isotopic geochemistry of Dexing porphyry Cu-Au deposit of Jiangxi Province, China

JIANJUN LU

State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing, 210093, China, (lujj@icpms.nju.edu.cn)

The Dexing porphyry Cu-Au deposit including Tongchang, Fujiawu and Zhushahong ore district is related to the Early Jurassic granodiorite porphyry stocks. The SHRIMP zircon U-Pb age of both the Fujiawu and the Tongchang porphyries are 171.4±3 Ma (Wang et al., 2004). The 187Re-187Os isochron age of molybdenite from Tongchang ore district is 170.4±1.8 Ma and is remarkably consistent with that of the porphyry stocks, suggesting that the formation of the Cu-Au ores was genetically related to the magmatism (Lu et al., 2005). The Cu isotope also indicates the copper was derived from the magmatic rocks (Lu et al., 2004).

The Si isotopic compositions of 17 quartz samples from the Dexing deposit were analyzed. The δ30Si values of two quartz samples from the Tongchang porphyry are 0.2‰ and 0.3‰ respectively. The δ30Si values of 11 quartz veinlet samples from the Tongchang deposit range from -0.2‰ to 0.5‰, most of which vary from 0.2‰ to 0.4‰. The Si isotopic compositions of the three quartz samples from the Fujiawu porphyry are -0.1‰, 0.0‰ and 0.4‰ respectively. One quartz sample from the Fujiawu ore has the δ30Si values of 0.0‰. The Si isotopic compositions of quartz from the ore-forming quartz veinlets are compatible with those of quartz from the related porphyries.

The characteristics of the isotopic geochemistry of the Dexing deposit show that the ore-forming materials might have been derived from the magmatic rocks.

Evidence and significance of water bridges in smectite of source rocks

LONGFEI LU1, JINGONG CAI1, YUJIN BAO2, CONGXIAN LI1, SHOUYE YANG1 AND DAIDU FAN1

1State Key Laboratory of Marine Geology, Tongji University, Shanghai 200092,China
2Institute of Earth Science, Shengli Oil Componary, Shandong 257015, China

With the aim to examine the role of water in the organo-smectite interaction of source rocks, we study clay minerals from drill cores using situ DRIFT. DRIFT spectra, recorded at room temperature, are characterized by a C=O stretch of COOH at 1720 cm$^{-1}$ and a -OH stretch of H$_2$O at 3130 cm$^{-1}$. With heating further intensities of these bands decrease gradually, and frequencies are shifted towards lower wave numbers. After heating the samples at 400°C they almost disappear. The evolution of the interlayer water is accompanied by significant changes in the location and shape of the C=O. This observation indicates that COOH groups are bonded to water molecules by hydrogen bonds and water molecules are bridges between COOH groups and smectite. In subtracting spectra every 50°C (from 50 to 600°C), the ratio of H$_2$O Peak area to that of COOH tends to be a constant under temperature of 250°C to 400°C, while under 250°C it varies irregularly. It is well known that adsorption water on smectite surface and interlayer free water dehydrate under 250°C, and structure water dehydrate above 600°C, therefore water retained under temperature of 250°C -400°C in complexes is water bridge. The reasonable explain for the constant of $\Delta$H$_2$O/$\Delta$COOH ratio is that when water bridges are broken, water and acids associated with water molecules are expelled from smectite interlayer together. This validate the water bridge exists between acids and smectite further. Besides cationic polarization, water bridge form hydrogen bonds with acids, so it is higher in stability than surface adsorption water and interlayer free water, which leads to water bridge retaining in interlayer up to 400°C. As a result, the expelled temperature of interlayer acids delay, in other words, these acids are preserved well in <400°C temperature range. We suggest water bridges plays an important role in the organic matter preservation in source rocks, and have a great influence on hydrocarbon generation.

Zn isotopes in chondritic components

J.M. LUCK1, D. BEN OTHMAN1, B. ZANDA2 AND F. ALBAREDE3

1GM/cc60/USTL/34095 Montpellier, France
2MNHN Paris 75005, France (zanda@mnhn.fr)
3ENS Lyon 69364, France (albarede@ens-lyon.fr)

Zn isotopic compositions (expressed as $\delta^{66}$Zn in ‰ vs. JMC stdt) measured with high precision with MC-ICPMS have been reported in recent years that show variations of around 0.3‰ for whole rocks (WR) of Carbonaceous Chondrites (CC) and up to 2‰ for Ordinary Chondrites. The three isotopic ratios (66/64, 67/64, 68/64) vary linearly with mass difference, and define a common isotopic fractionation line with terrestrial samples. Zn was derived from an initially homogeneous reservoir. Although not the only answer, the common trend observed for CCs and UOCs in diagrams such as $\delta^{66}$Zn vs. elemental ratios (e.g. Cr/Zn; Luck et al. 2005) could be explained as a mixture between two major reservoirs: one represented by the "matrix" with heavy Zn (around 0.5‰), and another related to chondrules (or alternatively refractory material, in CVs) characterized by light Zn. Results are presented for constituents separated mechanically from Allende and Murchison (matrix, chondrules, aggregates), and sequential acid leachings from CIs. Preliminary data show chondrule (including rim) from Allende to be similar to WR. Sequential acid leachings were performed on IVuna, starting from dilute Acetic Acid to HCl to concentrated HNO3/HF following works on Cr (Rotaru et al. 1992) and Zr (Schönbächler et al. 2005) isotopes. Labile or easily-dissolved fractions seem to carry "normal" Zn (i.e. similar to WR; 0.4-0.5 ‰) while more acid-resistant material point to light Zn. It seems that for Zn – like for Cr and Zr isotopes – at least some isotopic heterogeneities have been retained in CIs.

Genesis of low-mineralised groundwater in a fissured sandstone aquifer, Odenwald, Germany – Where has all the sulfate gone?

FLORIAN LUDWIG1, INGRID STOBER2 AND KURT BUCHER3

1Hessian Agency for the Environment and Geology, Germany (f.ludwig@hlug.de)
2Geological Survey of Baden-Wuerttemberg, Germany (stober@lgrb.uni-freiburg.de)
3University of Freiburg, Germany (bucher@minpet.uni-freiburg.de)

Extensive hydrogeochemical data sampling has been carried out on groundwater in a fissured sandstone aquifer in the Buntsandstein formation of the Odenwald, Germany. The sediment rock sequence comprises quartz arenite and quartzitic sandstone with various content of biotite, K-feldspar, and clay minerals. The poorly-mineralised groundwater show conspicuous variation in ion concentrations and in groundwater composition in a range from Ca-HCO₃ to Ca-Mg-SO₄-HCO₃-type.

Groundwater pumped from wells in the sandstone aquifer shows a significant and marked decrease in sulfate concentration in comparison with spring water from the same area. A significant variation in Ca-Mg-ratio between spring- and well-groundwater samples is also indicated. Springs show low ratios of about 2, whereas wells are distinguished by higher ratios due to progressive calcite solution. The individual groundwater composition appears to be related to distinct mineral (rock) alteration mechanisms. It can be shown that alteration of silicate minerals in the aquifer is tied to the HCO₃-buffer system. Significant differences in water composition result from the presence of detrital feldspars in some sandstone units compared to strata that lack feldspar. Leaching experiments on representative sandstone samples produced leachates that were potassium dominated due to K-feldspar alteration. These findings are in sharp contrast to the very low potassium concentrations in the sampled waters. Fluid inclusions in the original detrital quartz grains contribute to the amount of dissolved chloride and sodium. Measured Cl/Br ratios of the leachates are low (50-100) and are diagnostic for saline fluid in basement complexes. Thus, chloride/bromide ratios reflect fluids from the crystalline basement that formed the pre-deposition source of the sandstone.

Ivory Coast tektites, microtektites, and glassy fallback particles of the Lake Bosumtwi impact crater, Ghana: Geochemical differences

S. LUETKE1, A. DEUTSCH2 AND B.P. GLASS3

1ZLG and Institut für Planetologie, WWU Münster D-48149 Münster, Germany (luetke.s@uni-muenster.de)
2Institut für Planetologie, WWU Münster, D-48149 Muenster, Germany (deutsca@uni-muenster.de)
3Department of Geology, University of Delaware, Newark, Delaware, U.S.A. (bglass@udel.edu)

Lake Bosumtwi, a unique young impact structure

The ~ 10 km-sized 1.07 Ma old Lake Bosumtwi structure, Ghana, is the source crater of tektites (Ivory Coast [IVC] strewn field), microtektites (off-shore drill cores), and fallback particles (ICDP drill core LB-05B). These various glass types may have formed during different stages of cratering by different processes, whose mechanics are not known in detail.

Major element composition

Here we present electron microprobe data for the named glassy materials. Two IVC tektites show low SiO₂ (65.5 and 66.1 wt%) and medium to high CaO contents (4.2 and 3.3 wt%). Ten microtektites (drill hole K9-56) have SiO₂ contents between 63.3 and 67.3 wt%, the other major elements also compare well with published data (Glass, 1969, 2004; Koeberl, 1997), and the microtektites are homogenous in general. One, however, displays irregularly shaped domains of different chemical composition in which Mg, Al, K, and Fe contents increase with decreasing Si and Na contents. This microtektite shows low average concentrations of SiO₂ and Al₂O₃ (63.3 and 14.9 wt%, respectively), and high average FeO and MgO contents (7.6 and 6.7 wt%, respectively). Another microtektite (ODP hole 664) is characterized by remarkable low SiO₂ (55.8 wt%), Na₂O (0.7 wt%), and K₂O (0.5 wt%) and high FeO (8.5 wt%), MgO (13.6 wt%), and CaO (2.1 wt%) concentrations. Results of thirteen fallback particles are concordant to data of Luetke et al. (2007). In general, IVC tektites, microtektites and fallback particles are quite similar in composition, yet significant differences in Ca, and slight differences in Mg and Fe concentrations exist, probably caused by the particular mixture of precursor materials. Current LA-ICP-MS studies may help to understand the formation processes of the various glasses by detection of different trace element characteristics.

Petrochemical characterisation of natural stones from the Etruscan site of Marzabotto (Bologna-Italy): Preliminary results

S. LUGLI2, E. MARROCCHINO1, M. MAZZUCHELLI2, F. SIGHINOLFI1,2 AND C. VACCARO2

1Department of Earth Sciences, University of Ferrara, Ferrara Italy (elena.marrocchino@unife.it)
2Department of Earth Sciences, University of Modena and Reggio Emilia

The tufa rocks used in sacral buildings in the Etruscan site of Marzabotto (Bologna, Italy) were characterised from a petrochemical point of view and compared with lithologies outcropping in the surrounding area in order to recognise the ancient quarries. These tufa, called “travertini” in the Italian literature, are very porous and are rich of macrophyte moulds revealing an origin by freshwater carbonate deposition (Ford-Pedley, 1996) Facies and thin section analyses show that these rocks were formed in cascade and paludal settings. Hypothesising that the possible quarry areas of travertine rocks were not far from the site and using the geological maps of the surrounding of the Etruscan site it was possible to identify few possible supply zones: 1) San Cristoforo di Labante (Castel D’Aiano, Bologna), 2) Rio Sponga (Marzabotto, Bologna) and 3) Rio Bucamante (Serramazzoni, Modena). Petrochemical characterisation were complemented with a statistical elaboration using the SPSS 14.0 (Copyright © 2006 SPSS Inc.) method and have highlighted that the San Cristoforo di Labante deposit could be the most suitable quarry area of the travertine used in Marzabotto.

The geomorphology of the area suggests that blocks were lowered from the San Cristoforo di Labante deposit through a “lizza” way (using rollers along a prepared slope) and then shipped along the Reno River to the Etruscan site of Marzabotto.

Change of iron redox state during terrestrial impact melts (glasses) formation

O. A. LUKANIN

V.I.Vernadsky Institute of Geochemistry and Analytical Chemistry, Moscow (lukanin@geokhi.ru)

Glasses of tektites and impact bombs are characterized by very low Fe$^{3+}$/ΣFe ratios in comparison with their source matter - Earth’s crust rocks. It is supposed that the main reason of reduced state of iron in impact melts (glasses) are redox reactions with the assistance of iron ions that exist during decompression of terrestrial matter exposed to powerful impact effect (Kadik et.al., 2003; Lukhanin and Kadik, 2007).

It is shown that redox reactions inevitably have to occur in oxide melts of Fe-O and SiO$_2$-FeO-Fe$_2$O$_3$ systems, containing various ions of iron, in consequence of incongruent evaporation of melts during pressure decrease under high temperature conditions. Reduction or oxidation of iron takes place during decompression evaporation of melt under both closed and open conditions depending on its initial oxidation degree. Fe$^{3+}$/ΣFe ratio in this process aspire to some extremely low value.

This property of Fe-bearing systems is important for understanding the redox state of melts forming in impact processes as a result of melting and evaporation of crust matter. Adibatical decompression of high temperature impactitic melts should be accompanied by their reduction (Fe$^{3+}$/Fe$^{2+}$ decrease) in comparison with relatively oxidized initial matter of the target. The main condition for reducing reactions to proceed is full melting and partial evaporation of matter, involved in the impact process, and the attainment of very high temperatures (>1800-2000°C) that are characteristic for impact bombs and tektites formation at certain stage of unloading. The higher is the temperature the stronger is the effect of decompression reduction. Extremely low Fe$^{3+}$/ΣFe ratios in tektites (≤ 0.1) are apparently the result of decompression reduction of the most high temperature impact melts.

Magma differentiation in a T gradient: Thermal migration and Soret effects are not dead!

C.C. Lundstrom\textsuperscript{1}, A. Boudreau\textsuperscript{2}, F. Huang\textsuperscript{1} and A.J. Ianno\textsuperscript{3}

\textsuperscript{1}Dept. of Geology, University of Illinois, Urbana-Champaign, Urbana, IL 61801, United State (lundstro@uiuc.edu)
\textsuperscript{2}Nicholas School of Environment, Duke University, Durham, NC 90227, United States (boudreau@duke.edu)

Most magma differentiation probably occurs within a body having significant temperature gradients. Compositional zoning tied to temperature differences in silicic ignimbrites were attributed to thermogravitational diffusion \cite{1}, catalyzing temperature gradient experiments by Walker and co-workers \cite{2}. Experiments showed, however, that compositional zoning in silicic rocks was opposite to Soret effects in a silicate melt \cite{3}. Our experiments/models suggest reassessment of temperature gradient effects.

We report on thermal migration experiments using wet andesite (AGV-1) or wet rhyolite (RGM-1). AGV-1 was run in 2 cm capsule with top at 950°C and bottom at 350°C in a piston cylinder apparatus for 66 days at 0.5 GPa. Bulk major-trace element compositions vary with position reflecting changing mineralogy with form and temperature in a linear “calc-alkaline trend” on an AFM diagram. Surprisingly, static trace element compositions vary with position reflecting in 2 cm capsule with top at 950°C and bottom at 350°C in an andesite (AGV-1) or wet rhyolite (RGM-1). AGV-1 was run temperature gradient effects.

We will also report compositional, isotopic and modelling results for a currently running cold seal experiment using RGM-1 in order to better compare to zoned silicic ignimbrite compositions and conditions.

Changling inorganic carbon dioxide gas field in Songliao Basin, China

X. LUO, J.K. MI AND S.Z. TAO

Research Institute of Petroleum Exploration & Development, Beijing 100083, China. (luoxia69@petrochina.com.cn, jkmli@petrochina.com.cn, tsz@petrochina.com.cn)

Changling gas field is located in Chaganhua town in Qianguo county, Jilin province. Geotectonically, it is located in the uplift of volcanic belt in the central region of Changling fault depression, southwest Songliao Basin. Gas pays lie in the Lower Cretaceous Yingcheng Formation volcanic rocks. It is an important carbon dioxide gas filed with 4 drilled wells, being of controlled reserves of tens of billions cubic metres and controlled gas bearing areas of 8.39 km².

The main geochemistry characteristics of deep gases in the fault depression are listed as follows: (1) The gases are characterized by high CO₂ except Changshen 1 well (CO₂ accounts for 20.05%). Of the main components of gases in Changshen 1 well, CH₄ accounts for 71.99%, the hydrocarbon gases above C₂ account for 1.37%, He and N₂ account for 2.10, respectively. The δ¹³C values of CH₄ from Changling gas field are within the range of -22.26% to 29.71%, and the contents of hydrogen gases above C₂ are within the range of 0.20% - 0.26%. The contents of H₂, He, CO₂ and N₂ are within the ranges of 0.05% ~ 0.84%, 0.0076% ~ 0.012%, 71.64% ~ 67.46% and 4.24% ~ 1.53%, respectively. It was proposed that a gas field with CO₂ more than 60% could be called carbon dioxide gas filed (Dai et al., 2005), so the Changling gas field is a carbon dioxide gas filed. (2) The ranges for the δ¹³C₁, δ¹³C₂, δ¹³C₃ and δ¹³C₄ values of the gases from Changling gas field are -22.2% to -23.4%, -26.3% to -27.0%, -26.5% to -27.3% and -33.3% to -34.0%, respectively. It is a significant characteristic for inorganic hydrocarbon gas that the δ¹³C values are getting lighter with increasing molecular weight (Dai et al., 2005), so the hydrocarbon gases in this field are inorganic. The δ¹³C values of CO₂ from Changling gas field are within the range of -6.8% to -11.9%. It has been pointed out that CO₂ with δ¹³C₄>8‰ is inorganic (Dai et al., 2005). Most of the CO₂ from this field has δ¹³C₄ greater than -8‰, so it is inorganic. (3) In Changling gas field, the ranges of δ¹³C₄ in CO₂ and R/Ra values are 2.61×10⁻⁶ to 3.21×10⁻³ and 1.90 to 2.10, respectively. The He/⁴He values in the upper mantle and radioactive strata are within the range of 1.1×10⁻³ to 1.4×10⁻⁵ and 10⁻⁷ ~ 10⁻⁹, respectively (Wang, 1989). The δ¹³C values of He from this field are around 10⁻⁵, which indicates a large amount of He from the mantle. All these evidences demonstrate that the gases from Changling gas field are mainly inorganic.

Kink sites: A key to surface reactivity and dissolution kinetics

A. LÜTTEGE¹,², C. FISCHER³, L. ZHANG AND R.S. ARVIDSON

¹Department of Earth Science, Rice University, Houston TX 77005, USA (aluttge@rice.edu)
²Department of Chemistry, Rice University, Houston TX 77005, USA

Dissolution and corrosion of crystalline materials have been proven to be as complex as they are important. In recent years significant progress in our understanding of dissolution mechanisms and kinetics was based on experimental studies utilizing atomic force microscopy (AFM), interferometry (e.g., VSI and PSI) and other techniques. Building on the rapidly growing power of computers, these efforts have been complemented by computer models of rapidly increasing sophistication and complexity. Ab initio, DFT, Molecular Dynamics (MD), and lastly Monte Carlo (MC) calculations are contributing to an increasingly detailed picture of reaction kinetics in complex systems [1].

Here, we apply parameterized Monte Carlo simulations to explore dissolution kinetics at critical time and length scales, over which experimental and analytical tools have limited utility or feasibility as sources of precise information [2]. The system size that can be explored with MC simulations is now sufficiently large to permit realistic predictions of surface alteration and dissolution mechanisms that can then be verified experimentally. We use results from ab initio and DFT calculations to parameterize our calculations.

Lasaga [2] demonstrated that the arrival and departure rates (k) of atoms or molecules are equal at surface kink sites only when the crystal surface is at equilibrium, thus:

\[ k_{kink} = k_{kink} \]

The kink site is indeed the most important reactive site at a crystal surface, because a molecule in this position has precisely half the chemical bonds that it would have were it located in a bulk site. At the same time, a kink site is the only self-replicating site at a given crystal surface.

Our MC calculations use the ability to study kink site dynamics from a molecular (versus purely geometric) basis, and are case studies for crystal systems. When combined with a statistical treatment, our MC results demonstrate that the large amount of detailed information involved in the complex problem of surface reactivity, and its role in overall kinetics of dissolution can be significantly reduced by focusing primarily on the number, type, and density of kink sites and their development over time and space.

Geochemical trends in rutile forming reactions
G. L. LUVINZOTTO AND T. ZACK

Mineralogisches Institut, Universität Heidelberg, Germany
gluvizot@min.uni-heidelberg.de; tzack@min.uni-heidelberg.de)

We are investigating the behavior of trace elements in prograde rutile growth reactions. Our aim is to understand how trace elements are behaving during metamorphic reactions, giving special attention to accessory minerals.

One rutile-forming reaction is observed in low- to medium grade (840°C / 0.6-0.9GPa) metapelitic rocks (Ms+Chl+Qtz+Ilm+Rt+Gra+Ap+Zrn+Mz; in order of abundance) from the Garnet-Phylite Unit of the Erzgebirge (Germany), where rutile starts to crystallize from Ilm according to the simplified reaction: Ilm+Silicate+H₂O ↔ Rt+Chl.

The other reaction, observed in the rocks from the Ivrea Zone (northern Italy), takes place in the transition between amphibolite and granulate facies, where rutile-free amphibolite facies (620°C, 0.4GPa) metapelites (Qtz+High-Ti amphibolite and granulite facies, where rutile-free amphibolite facies (620°C, 0.4GPa) metapelites (Qtz+High-Ti amphibolite and granulite facies) are replaced, with increasing metamorphic grade (480°C / 0.6-0.9GPa) metapelitic rocks (Grt+Sil+Qtz+Pl+Kfs+High-Ti Bt). The rutile formation is associated with high-Ti Bt breakdown and is coupled to melting reactions such as Bt+Sil ↔ Grt+Sil+melt.

Remarkably in the two areas, both the rutile-free precursor rock and the rutile-bearing “final product” are present, allowing comparison of the rutile trace element geochemistry in different stages of the reaction. In both cases, during the early stage of rutile formation, its Nb/Ti ratio is strongly controlled by the ratio of the precursor mineral (Ilm and Bt), being evidenced by a large inter-grain spread and Nb/Ti ratios different from those expected for rutiles occurring in equilibrium with the mineral assemblage in question. These features reflect the trace element partitioning between the minerals involved in the reaction and are in good agreement with the published partition coefficient between Ilm[1], Bt[2], Rt[3] and melt. In both examples, as the reactions evolve with increasing metamorphic conditions, the rutile Nb/Ti ratios change toward the value expected for a rutile occurring in equilibrium with the paragenesis in question. Furthermore, in order to equilibrate the rutile Nb/Ti ratio, Nb has to be mobilized, at least on a thin section scale.

Excess 17O – A new tracer in hydrology
BOAZ LUZ AND EUGENI BARKAN

The Institute of Earth Sciences, Hebrew University, Jerusalem 91904, Israel (boaz.luz@huji.ac.il)

For more than four decades, water isotope ratios (18O/16O and 2H/1H) have played a key role in understanding the hydrologic cycle. For lack of analytical precision, it has been assumed that the 17O/16O ratio does not significantly deviate from a constant relation to 18O/16O and its measurement seemed redundant. Here we show that when all oxygen isotope ratios are measured with very high precision, they yield a wealth of valuable information.

We have designed and constructed an automatic fluorination system for producing pure O₂ from water samples. This allows isotope ratio measurements by dual inlet mass spectrometry with overall duplicate difference better than 0.06‰ for δ18O. The analytical errors in δ17O are mass dependent on the δ18O errors and therefore are less than 0.03‰. This allows determination of the relationships between 14O/16O and 17O/16O with extremely high precision.

Using this method together with experimental setups we determined the exponent (0; 17O = 16O a²) relating the fractionation factors in vapor-liquid equilibrium and vapor diffusion in air as 0.529±0.001 and 0.519±0.0006 respectively. The exponents do not depend on temperature. We also determined the global slope ln(17O +1)/ln(18O +1) for meteoric water as 0.528±0.001.

Our measurements show that meteoric water and atmospheric moisture samples fall above a line with a slope 0.528 that originates from VSMOW and thus have an excess of 17O with respect to seawater. This excess is defined as: 17O-excess = ln(δ17O +1) – 0.528·ln(δ18O +1)
The precision in measurements of the 17O-excess is 8 per meg (per meq = 0.001‰).

The magnitude of 17O-excess of meteoric water and atmospheric moisture is in the range of 10 to 70 per meg. It originates, similarly to deuterium excess, from evaporation that is affected by both isotope equilibrium and diffusion transport in air. Yet, in contrast to deuterium excess, 17O-excess is independent of temperature in liquid-vapor equilibrium and, therefore, it is a simpler indicator of hydrologic processes.

In general, 17O-excess in precipitation increases when the source vapor is derived from a region where there is large humidity contrast between the ocean surface and the overlying atmosphere. In contrast, its magnitude decreases in evaporating water bodies as well as in leaf water at low humidity. This behavior will be demonstrated in examples from meteoric waters and polar ice.

Is there a reversible step in $^{45}$Ca sorption onto pure calcite?

J. LY, E. TERTRE, C. BEAUCAIRE AND V. MEVELLEC

CEA, Centre d’Etudes de Saclay, DANS/DPC/SECR/L3MR, 91191 Gif sur Yvette, France.

Metal sorption onto carbonate minerals have been intensively interpreted in literature by two reaction steps: (1) a first one rapid and completed within few hours and (2) a second one slower, eventually irreversible and occurring at a constant rate (Davis et al., 1987; Zachara et al., 1991; Mevellec, 2000). The first step is often attributed to an ion exchange process, but its reversibility is rarely investigated. Consequently, discrimination of the global sorption phenomenon into two different mechanisms is not always justified.

Therefore, we have investigate both sorption and desorption of Ca, radiotraced with isotope $^{45}$Ca, onto synthetic pure calcite in aqueous solutions saturated with respect to calcite and in equilibrium with the atmospheric CO$_2$. Batch experiments were performed as a function of time and at different pH using anionic chemical buffers having no affinity towards calcite. The distribution coefficient of $^{45}$Ca was calculated from radiochemical measurements of the supernatants before and after sorption, and the total Ca aqueous concentration was measured by ion-chromatography.

As mentioned by previously cited authors, our results show that whatever the pH, Kd’s of $^{45}$Ca increase with time without reaching a stationary state within two weeks. Moreover, Kd’s calculated with desorption experimental data are systematically higher than those calculated with the sorption ones. In order to test the occurrence of a first reversible ion exchange step, we applied the approach of Badillo-Almaraz and Ly (2003) put forward for the interpretation of Ca sorption onto hydroxyapatite. More specifically, on the basis of isotopic equilibrium principle and from the knowledge of the isotopic ratios ($^{45}$Ca/Ca$_{total}$), it is possible to calculate “reversible” Kd’s of $^{45}$Ca for both sorption and desorption steps. Doing this, we observe that both calculated Kd’s values are similar, whatever the time and pH. In these conditions, we are able (1) to evidence the reversible step of retention of Ca and more, (2) to quantify the amount of Ca sorbed on the calcite surface, which can be compared to surface cristallochemical data.

P-T conditions and oxygen fugacity estimates suggest suprasubduction setting of Voykar ophiolites, Polar Urals

Z. E. LYASKOVSKAYA$^{1,2}$, V.G.BATANOVA$^1$ AND I.A. BELOUSOV$^1$

$^1$Vernadsky Institute of Geochemistry, Moscow, Russia (sobolev@geokhi.ru)

$^2$Moscow State University, Moscow, Russia

Mantle section of Voykar ophiolites, Polar Urals, Russia contains exceptionally fresh harzburgites, dunites and pyroxenites. Dunites and pyroxenites indicate melt percolation event dated by Re-Os isotopes as 0.6 Ma old (Batanova et al., 2007). Host harzburgites yields much older ages (up to 2.5 Ga). Here we report estimations of P-T conditions and oxygen fugacity for harzburgites, dunites and pyroxenites based on mineral compositions.

P-T conditions of harzburgites correspond to T=950 C and P=1.2-1.4 GPa (Wells, 1977; Mercier, 1980). Oxygen fugacities -1.5-2.5 log units higher than QFM (Ballhaus, 1991). Pyroxenites yield T=950-1050 C and P around 1.4 GPa. The oxygen fugacity of pyroxenite and dunites still has to be evaluated.

The obtained high oxygen fugacities and low temperatures suggest suprasubduction settings for Voykar ophiolites.

Carbonate concretions as a window to the evolving chemistry of the early ocean and atmosphere

T. Lyons1, R. Raiswell2, A. Robinson1, C. Scott1, X. Chu2, C. Li1, G. Love1, A. Sessions3 and B. Gill1

1Department of Earth Sciences, University of California, Riverside, CA, USA (timothy.lyons@ucr.edu)
2School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK (raiswell@earth.leeds.ac.uk)
3Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China (xlchu@mail.igcas.ac.cn)

Ellipsoidal calcium carbonate concretions with diameters ranging up to meter-scale are common in organic-rich shales throughout the Phanerozoic. These features arise through early (pre-compactional), highly localized cementation. This precipitation is catalyzed by enhanced alkalinity production (pre-compactional), highly localized cementation. Each of these conditions was likely well established by the late Neoproterozoic, when sulfate as an electron acceptor for BSR with concomitant anaerobic oxidation of organic matter (OM) and/or methane. Identical features are well expressed in the upper portions of the late Neoproterozoic Doushantuo Formation in south China, which shows trace metal enrichments consistent with increasing sulfate reduction (BSR) with concomitant anaerobic oxidation of organic matter (OM) and/or methane. Identical features are well expressed in the upper portions of the late Neoproterozoic Doushantuo Formation in south China, which shows trace metal enrichments consistent with increasing oxygenation of the ocean and atmosphere.

Several factors are important in the formation of large, distinct, shale-hosted concretions, including (1) availability of sulfate as an electron acceptor for BSR, (2) pore-water saturation states that are strongly elevated relative to ambient bottom water, and (3) sites of decaying OM that act to initiate localized cementation. Each of these conditions was likely well established by the late Neoproterozoic, when sulfate delivery to the ocean increased through greater oxidative continental weathering while pyrite burial decreased, and carbonate saturation decreased in the global ocean well below the hypersaturated conditions of the earlier Proterozoic. With decreasing ambient saturation, localized cementation became more likely and easier to sustain in response to sharp concentration gradients. Also, the Neoproterozoic advent of fecal pellet production enhanced the delivery of labile OM to the seafloor. This study seeks to explore the relationship of these late Neoproterozoic examples to carbonate concretions described from earlier Precambrian units. The paleoceanographic implications of older “concretions” can be obscured by the frequently generic use of the term to describe masses that differ in mineralogy, morphology, and likely mode of formation compared to those of the late Neoproterozoic/Phanerozoic. The suggestion is that the upper Doushantuo and equivalent strata may mark the beginning of Phanerozoic-style ocean chemistry as expressed in concretion formation, implied carbonate saturation, metal enrichments, and perhaps other tracers of the evolving biosphere.

Hydrochemistry of four tropical watersheds in central Panama

W. B. Lyons1, R. S. Harmon2, H. Mitasova3, I. Förizs4 and A. Demény4

1Ohio State University, Columbus, OH, USA
2Army Research Office, Research Triangle Park, NC, USA
3North Carolina State University, Raleigh, NC, USA
4Hungarian Academy of Sciences, Budapest, Hungary

Surface waters from 4 watersheds in central Panama that have similar pristine source regions in steep mountainous tropical rain forest, but are affected by different downstream land-use practices were sampled for major element chemistry during the dry season in 2005 and 2006. The bedrock geology of the region consists of Upper Cretaceous to Tertiary age basalts, basaltic andesites, gabbrons, and diorites plus less-abundant granodiorites, tonalites, and plagiogranites. The Rio Pacora (374 km2) watershed is developed on gabbro-diabase lithologies, whereas the Upper Rio Chagres (580 km2), Rio Pequini (281 km2), and Rio Cuango (175 km2) are formed on mixed terrains consisting of hydrothermally altered andesite, mafic-intermediate volcanic rocks, and minor felsic intrusive lithologies.

Overall, δD and δ18O values for the Chagres region waters fall on the Global Meteoric Water Line without systematic δ-excess change, suggesting that the H and O isotope variations are governed by air mass trajectories rather than altitude or topographic effects. There is a geospatial trend in Cl that mirrors the NE-SW precipitation gradient across the region. Low-order streams in the Pacora watershed have distinctly higher TDS values plus H4SiO4 and Ca2+ concentrations than those forming in the mixed lithology terrain. The gabbro terrane streams and rivers are also slightly more enriched in cations (TZ+) and HCO3-, relative to H4SiO4, than streams and rivers in the mixed lithology terrane, whereas K+ concentrations are uniformly low and, like Mg2+ and Na+, are similar in both terranes. Major rivers in both areas are similar in chemical character to their respective headwater streams, indicating that the most intense chemical weathering within the watersheds occurs in the headwater regions, and dilution of these solute-rich waters occurs at lower elevations downstream. Ca/Mg ratios for all watersheds are lower than the world river average, indicating the importance of the weathering of Mg-rich minerals. The Ca/Na, HCO3/Na and Mg/Na ratios for the Rio Pacora streams and rivers fall within the mid-range of what has been observed globally for other streams/rivers draining mafic rocks. Estimated TZ’ yields are very large, suggesting significant weathering rates in headwater watersheds of the Chagres region in central Panama.
Carbon isotopes of black shales in NW Hunan, China and the Early Cambrian atmospheric CO₂ level

D.-S. MA¹, S.-L. CAO¹², J.-Y. PAN² and S.-H. CHEN¹

¹The State Key Laboratory for Mineral Deposits Research, Nanjing University, Nanjing 210093, China (dongsma@public1.ptt.js.cn)
²Resource and Environment Engineering Center, Technology Institute of East China, Fuzhou, JX 344000, China

Total 82 Lower Cambrian black shale samples from the three sections in NW Hunan, China are analyzed for C isotopes of organic carbon (δ¹³Corg = −34.9 to −28.8 ‰ with average −31.9 ‰) and carbonate. Because of very low carbonate contents in the black shales, only 11 samples analyzed yielded credible δ¹³C_carb values from −4.0 to +1.7 ‰ with average −2.1 ‰. By which δA defined as the isotopic difference between the burial fluxes of sedimentary organic matter and carbonate is −30.5 ‰. Kump and Arthur (1999) developed a model, according to Henry’s Law at 25°C and assuming phosphorus as an ultimate bio-limiting nutrient, to obtain an expression relating δA to pCO₂:

\[ \Delta A = ((159.5 \times [PO₄] + 38.39)/0.034\text{pcO₂}) - 33 \]  

where [PO₄] (μmol/kg) proxies nutrient concentration in surface-ocean. Substituting the average carbon isotopic difference (−30.5 ‰) between the δ¹³C_carb and δ¹³Corg for δA in equation (1), rearrangement of the equation yield a linear expression for relationship between pCO₂ and [PO₄]:

\[ pCO₂ = 1881.2\text{[PO₄]} + 451.6 \]  

and thus would provide a means of estimating CO₂ concentration during sedimentation. Using our calculated average value for δA −30.5 ‰ and assuming that [PO₄] concentrations of the Early Cambrian ocean were similar to present (Holland, 1984) ranging roughly from 0.20 in oligotrophic surface-water to 3.5 μmol/kg in the nutrition-enriched deep water mass in modern ocean, the Early Cambrian atmospheric CO₂ concentration could range from 828 to 7036 ppmv. It should be 3 to 25 times pre-industrial revolution levels (ca. 280 ppmv). This is broadly consistent with predictions that the Early Cambrian atmospheric CO₂ level was as much as 20 times present day values (Kasting, 1993; Berner et al., 2001; Kaufman et al., 2003). If so, it would imply a high level of nutrient availability represented by phosphorus in the Early Cambrian. We relate the unusually low δ¹³Corg values of the black shales to an anoxic oceanic environment, high atmospheric CO₂ content and warm greenhouse climate. It should be propitious to trigger the “Cambrian explosion”.

The Paleozoic SSZ-type ophiolite and subduction rollback in the eastern Junggar, northwestern China

ZHONGPING MA, LINQI XIA, XUEYI XU AND XIANGMIN LI

Xi’an Institute of Geology and Mineral Resource, Xi’an 710054, China (xamzhongping@cgs.gov.cn)

There are two Paleozoic ophiolite belts, Karamaili and Aermantai, in the eastern Junggar orogene, northwestern China. The northerly Aermantai ophiolite, aged by 503 to 481Ma (Xiao et al., 2006; Jian et al., 2003), has been testified to forming in interarc basin setting (Jin et al., 2001) of supra-subduction zone (SSZ). Our data show that the southerly Karamaili ophiolite, generated in Silurian to early Devonian, contains some basaltic rocks with intermediate N-MORB/IAT composition (fig.1), in addition to E (N)-MORB and OIB reported by former investigators. We infer that the Karamaili ophiolite should have formed in a backarc basin of SSZ. The basalts with intermediate N-MORB/IAT composition formed in the early stage of the backarc basin, while the MORB-like and even OIB-type rocks formed in the “more expanding” stage of the backarc basin resulted from influx and upwelling of relatively enriched mantle driven by convective drag and succeedent rollback of the subducted oceanic slab. Thus the two ophiolite belts constituted the Paleozoic intraoceanic “dual arc-basin systems” in Eastern Junggar by subduction rollback of oceanic slab, similar to the multiple arc-basin systems of northwestern Pacific region. This dual arc-basin systems collapsed and closed at the early period of Later Paleozoic, and assembled in order to the southern margin of Siberian continent, on which the middle Cambrian (505Ma) active continental magmatic arc has been revealed by Windley et al. (2002).

Fig.1: N-MORB-normalized trace element patterns for basaltic rocks from the Karamaili ophiolite

Recycled oceanic crust as a possible source of kimberlites - Isotopic evidence from perovskite, Udachnaya-East pipe, Siberia

ROLAND MAAS¹, VADIM S. KAMENETSKY² AND VICTOR V. SHARYGIN³

¹School of Earth Sciences, Univ. of Melbourne, Australia, (maasr@unimelb.edu.au)
²School of Earth Sciences, Univ. of Tasmania, Hobart, Australia
³Inst. of Geology & Mineralogy, Novosibirsk, Russia

In an effort to better understand the sources and petrogenesis of kimberlitic melts, we report new results from the ultrafresh Udachnaya-East kimberlite, Siberia. Earlier results [1,2] indicate that initial kimberlite magmas are H₂O-poor and rich in mantle-derived Cl and CO₂. Additional insights come from a recently identified inclusion from this pipe, which may represent a high-purity sample of the kimberlite melt component, uncontaminated by disaggregated xenoliths. Mineral compositions (fresh olivine, phlogopite, perovskite) in this inclusion are identical to those in the host kimberlite groundmass, but phlogopite and perovskite are unusually abundant (10 wt% perovskite). The bulk composition of the inclusion is ultramafic (32% MgO) and trace element concentrations are controlled by perovskite, with strong LREE enrichment and depletions at Sr and Zr; the latter are absent in the host kimberlite groundmass. Phlogopite Rb-Sr and Ar-Ar dating indicate a ≈370 Ma age, consistent with published pipe emplacement ages. The inclusion is thus best described as a late-stage cognate inclusion, or autolith. Initial Sr-Nd isotope ratios in inclusion perovskite (0.7030, εNd +5.5) differ from those of the (acid-leached) host kimberlite groundmass (0.7048, +4.0), possibly reflecting xenocrystic contamination in the latter. Alternatively, age corrections may be compromised, even in acid-leached groundmass, by the complex, polyphase nature of the kimberlite [2]. By contrast, the inclusion perovskite, with Rb/Sr =0, is a much simpler matrix and thus preserves a more straightforward isotopic record of the kimberlite melt component. The isotopic data, in particular the low ⁸⁶Sr/⁸⁸Sr, provides support for earlier suggestions [3], partly based on Hf-Nd isotope data [4], that recycled subducted MORB may form part of the kimberlite melt mantle source. Further isotopic data (Pb, Hf) will be reported.

Harnessing biomineralization: From cell factories to functional bionanomaterials

L.E. MACASKIE
Unit of Functional Bionomaterials, School of Biosciences, The University of Birmingham, Edgbaston, Birmingham, B15 2TT, United Kingdom (L.E.Macaskie@bham.ac.uk)

Bacteria from the environment carry out many diverse processes which result in the production or transformation of minerals. This biomineralisation leads to the formation of mineral deposits which are retained on the bacterial cell surface or are scaffolded outside the cell or upon, or within, extracellular polymeric matrices. The cell therefore has a dual function in supporting the solid material, while providing the metabolic activity and localised chemical environment to promote biomineral growth.

Many of the biomaterials formed by bacterial action have potentially useful properties in various technological applications. Bio-growth is particularly useful because the scaffolding helps to prevent the agglomeration processes that beset the commercial production of nanoparticles, while the controlled growth can be steered towards the production of particular particle sizes. Both of these objectives are difficult to achieve by chemical production processes.

Nanoparticles are highly prized because they are very reactive and have properties which can be different from bulk materials. The ‘cell factory’ is a scalable approach to the bulk production of stable nanoparticles in a reproducible way.

Case histories will be presented to illustrate the production of bionanoparticles for applications in biomedicine, chemical industry, environmental remediation and clean energy, and the scope for using wastes as resources for nanomaterial production will also be discussed.
The rutile (110)-electrolyte solution interface to 250°C: A surface complexation synthesis of titration, ab initio, MD, and X-ray spectroscopic results

We have been conducting potentiometric titrations of rutile powders dominated by the 110 crystal face to 250°C in several so-called “inert” electrolyte solutions (NaCl, NaTr (Tr=trifluromethanesulfonate), RbCl) over the past dozen years. More recently (since about 2000) these bulk, macroscopic measurements have been augmented by ab initio and molecular dynamics (MD) simulations, as well as synchrotron-based x-ray spectroscopic measurements, in order to obtain an unambiguous understanding of the rutile 110-electrolyte interface from the micro- to macroscopic scales.

The focus of this contribution will be our most recent attempts at incorporating the molecular information afforded by our ab initio, MD, and x-ray results into Surface Complexation Models (SCM’s) that accurately reflect both this microscopic reality and our bulk surface titration data. A MUSIC model description of surface protonation that utilizes this microscopic reality and our bulk surface titration data. A Complexation Models (SCM’s) that accurately reflect both complexation synthesis of titration, ab initio, MD, and X-ray spectroscopic results.

Planetary formation from icy planetesimals around 1 AU

R. Machida and Y. Abe

Department of Earth and Planetary Science, The University of Tokyo, Tokyo, Japan (mach@eps.s.u-tokyo.ac.jp, ayutaka@eps.s.u-tokyo.ac.jp)

Formation and Evolution of Icy Planetesimals

Standard scenario of planet formation have been developed on the assumption that the primordial solar nebula was optically thin, so that H₂O ice condenses only outside 2.7 AU from the Sun. The solid material is composed of only rocks at the terrestrial planet formation region (Hayashi 1981).

However, it is widely accepted in the astronomical community that the protoplanetary disks are initially opaque owing to the floating small dust particles and become transparent at the late stage of planetary formation. In optically thick disks, the interior of the nebula is shadowed from direct exposure to sunlight, so that H₂O ice is prevented from sublimation outside about 0.7 AU (Chiang and Goldreich 1997).

As planetesimals are likely formed in such opaque protoplanetary disks, they should contain a large amount of H₂O ice. We call such planetesimals “icy planetesimals” hereafter. We perform numerical simulations of formation of protoplanets from icy planetesimals focusing on the competition between accretion and sublimation of H₂O.

![Figure 1: Water content in protoplanets.](image)

Results and Discussion

Fig. 1 shows the water content in the system when Mars-sized objects are formed after runaway accretion. It indicates that planets with diverse water contents (i.e., from dry planet to water-ball planet) can be formed. Water content is strongly dependent on the initial surface density of solid material and the time interval, t₀, between the icy planetesimal formation and the onset of icy planetesimal sublimation. We also find that final water content is dependent on object size. Most of water in the system is contained in largest protoplanets, while most of small planetesimals have lost their initial water.

Mineralogy of Zaroo ilvaite bearing skarns, Central Iran

M.A. MACKIZADEH¹, M. RAHGOSHAY¹, I. NOORBEHESHT², F. DALIRAN³ AND B. TAGHIPOUR³

1Faculty of Science, University of Shahid Beheshti (ma_mackizadeh@yahoo.com)
2Faculty of Science, University of Isfahan (goharriri@yahoo.com)
3Institute of Mineralogy and Geochemistry, Technical University of Karlsruhe, Germany (farahnaz.daliran@img.uni-karlsruhe.de)

Zaroo Cu-skarns are located north-west of Yazd province and this region is included in Cenozoic magmatic belt of Central Iran. The widespread rocks in this region are Eocene age volcanic with granitoid intrusives. The Cretaceous limestones in western parts of Zarro are hosted by skarn-marble mineralization in parts. The skarns are distal type and characterized by following assemblages: clinopyroxene + magnetite + quartz + calcite. The paragenetic relationships of these minerals have revealed a polygenetic nature of skarn. Black crystals and masses of ilvaite have a close association with hedenbergite clinopyroxene and andradite garnet zone, likely as replacement bodies.

The formation of ilvaite is related to the following reactions:

andradite + Fe(OH)₂ + CO₂ = ilvaite + magnetite + quartz + calcite + H₂
hedenbergite + magnetite + Fe(OH)₂ = ilvaite

The early skarn minerals are formed at 550°C and the decomposition of early minerals to formation of final hydrous assemblages started below 470°C in high fO₂. The peak metamorphisms for marbels are about 540°C with mineral assemblage as follows:

Garnet + vesuvianite + termolite + epidote + calcite + quartz

Magmatic architecture and geochemical variability at the 9°N segment of the East Pacific Rise

J. MACLENNAN¹, M.R. PERFIT², D. FORNARI³, W.I. RIDLEY⁴ AND S.A. SOULE³

1Department of Earth Sciences, University of Cambridge, UK, (jmac05@esc.cam.ac.uk)
2Department of Geological Sciences, University of Florida, (perfit@geology.ufl.edu)
3Department of Geology and Geophysics, Woods Hole Oceanographic Institution, (dfornari@whoi.edu, ssoule@whoi.edu)
4US Geological Survey, Denver, (iridley@usgs.gov)

The 9°N region of the East Pacific Rise (EPR) has been densely sampled by submersible and wax-coring techniques, with over 1200 samples available from less than 100 km of ridge axis. Major and trace element and isotope data is available for many of the samples and can be used to quantify the role of source heterogeneity, mantle melting, fractional crystallisation and melt mixing in petrogenesis at a segment of fast-spreading mid-ocean ridge. The spatial control on the sampling locations and the growing catalogue of geophysical observations from the segment allow the geochemical variations to be understood in the context of the imaged distribution of melt at the ridge axis. The shallow axial melt lens plays an important role in the mixing of melts and destruction of mantle-derived compositional heterogeneity. Samples collected from the sea-floor lying above this melt lens show a narrow range of incompatible trace element ratios. In contrast, samples collected away from the ridges axis, or close to suspected ridge-parallel discontinuities in the melt lens, show much greater variation in their trace element composition. These samples appear to have bypassed mixing within the axial region. In addition, evolved compositions, with <7.3 wt% MgO, are rarely sampled above the imaged melt lens and may have been sourced from cooler regions containing low melt fractions. Along-axis major element compositional variations in samples collected <0.5 km from the axis show a strong correlation with variation in ridge bathymetry and depth to the axial magma chamber. However, trace element ratios show poor correlations with geophysical variation on the scale of the segment. It is therefore likely that variations in along-axis bathymetry reflect spatial focussing of melt in the crustal plumbing system rather than changes in mantle properties.

These results have important implications for the interpretation of downhole compositional variation in IODP core such as that from Hole 1256D. Systematic vertical variations in the composition of upper crustal rocks may result from steady-state crustal accretion at a typical fast-spreading ridge, rather than from large-scale variation in the temperature or composition of the mantle source regions.
Fast-spreading mid-ocean ridge magma chamber processes: Insights from the Oman ophiolite

C.J. MacLeod¹, R.M. Thomas² and L.A. Coogan²
¹School of Earth, Ocean & Planetary Sciences, Cardiff University, Cardiff CF10 3YE, UK (macleod@cf.ac.uk)
²School of Earth & Ocean Sciences, University of Victoria, Victoria, BC, V8W 3P6, Canada (lacoogan@uvic.ca)

We investigate the physical and chemical processes in axial magma chambers and constrain the mechanisms of accretion of the lower crust at fast-spreading mid-ocean ridges by means of a combined structural, petrological and geochemical investigation of gabbroic lower crustal sections in the Oman ophiolite. Magmatically-deformed layered gabbros with fabrics parallel to the petrological Moho form the lower half of the plutonic sections. These normally pass upward via a transitional horizon a few hundred metres thick into massive, non-layered gabbros with vertical magmatic foliations and lineations, and thence into a thin (~200m) horizon of heterogeneous varitextured gabbros. We have previously suggested that the varitextured gabbros represent a fossil melt lens that was filled with variably fractionated, essentially basaltic liquids [1], overlying cumulates formed in the underlying crystal mush from which liquids were efficiently extracted. The vertical foliated gabbros we have interpreted as relict channelways of ascending melts that fed the melt lens. In this study we present major- and trace-element whole-rock and mineral chemical data together with quantitative textural and petrofabric information from complete lower crustal sections in Oman, with the aim of constraining the processes operating in the lower crustal crystal mush. Systematic changes in mineral trace element characteristics are observed. For example, La/Nd ratios in cpx in the layered gabbros increase progressively up section and show little intra-crystalline variability; however, at the transition into the foliated gabbros the extent of intra-crystal variability increases significantly. Whereas the variation in La/Nd between layered gabbro samples could, in isolation, be interpreted as being due to variations in parental melt composition, the same trends within individual crystals and the progressive change in ratio up-section are difficult to interpret in this way. Instead, they may be successfully reproduced using an assimilation–fractional crystallisation model of magmatic metasomatism: probably compaction-driven reactive porous flow of melt migrating upward through the crystal mush. Possible implications for magma chamber models will be discussed.

Differentiation of basaltic melt in the shallow mantle wedge: Implications for mass fluxes into the arc crust

Colin G Macpherson
Department of Earth Sciences, University of Durham, Durham, UK. (colin.macpherson@durham.ac.uk)

In general, magmatic differentiation is regarded as a process that affects primary basaltic melts after they have encountered a significant density interface. For this reason, many studies of differentiation in arc lithosphere focus on processes occurring at, or above, the Moho. However, there is ample evidence that subduction zone magmas can interact with the mantle wedge. Recent work in Surigao, eastern Mindanao, indicates that hydrous basaltic melt can also differentiate beneath the Moho [1].

The Surigao suite comprises a continuous spectrum of compositions from high-Mg andesite to adakitic rhyolite. Isotopic ratios and most incompatible trace element ratios are indistinguishable from contemporaneous calc-alkaline magmatism. These similarities point to derivation from similar sources i.e. metasomatised mantle wedge. Rare earth elements, notably Dy/Yb ratios, demonstrate that high-Mg andesitic and adakitic compositions developed through differentiation of hydrous basaltic magma at >30km depth, where garnet is stable. In the Philippines, where arc crust is thin, this represents sub-Moho depths.

The Philippine example suggests that both adakitic and high-Mg andesitic magmatism should be regarded as part of the natural range of magmatic compositions that might arise in any subduction zone. Their presence, or absence, reflects the suitability of a particular subduction zone to generate and then preserve these distinctive compositions. Crust-hosted differentiation could overprint or obscure the distinctive magma chemistry produced at deeper levels, which may be more widespread than is currently perceived.

Adakitic rocks, in particular, are often emplaced where subduction has unusual characteristics e.g. above young slabs or slab edges, and the majority of previous effort has been directed at linking the chemistry of magmatic products to features of the down-going plate. Specifically, both high-Mg andesitic and adakitic magmatism has been linked to melting of subducted oceanic crust. Data from the Philippines and several other locations challenge this finding and suggest that differentiation at more than 30km depth could generate adakitic magma from hydrous basaltic precursors. Differentiation at such levels will have important implications for mass fluxes from the mantle to the arc crust and, potentially, for the evolution of mantle wedge compositions.

Redox and solution behavior of c-type cytochromes from iron mineral-respiring bacteria

T.S. MAGNUSON AND M.W. SWENSON
Idaho State University. (magntimo@isu.edu)

Mono- and polyheme c-type cytochromes have been linked to ferruginous mineral respiration in a variety of bacteria, such as Acidithiobacillus, Geobacter, Shewanella, and Acidiphilium. While excellent genetic and genomic studies have been conducted, there is a paucity of information regarding the purification, manipulation, and redox behavior of these proteins in vitro. Many of these proteins are membrane or cell-surface associated, and preliminary evidence suggests that they can act as multiprotein electron transfer complexes. Our research goal was to identify methods for the effective purification and manipulation of these proteins, in order to facilitate subsequent study. Many redox active proteins are extractable by salt (NaCl, KCl) or mild detergent washing of cells, suggesting a cell surface location. Two examples are the polyheme cytochrome c OmcS from Geobacter sulfurreducens, and a 42 kDa cytochrome c from Acidiphilium cryptum. Sequential extraction of membrane fractions with incrementally stronger detergents yielded additional redox proteins, and this strategy is useful for targeted purification of particular proteins of interest. Since it is suspected that some of these redox proteins are embedded in a biofilm matrix, experiments were conducted to determine whether this material could be digested away to enable purification. Viscozyme, a mixture of polysaccharidases, was effective at depolymerizing the EPS and reducing problems associated with high levels of polysaccharide contamination. Once extracted out of the cellular and extracellular milieu, some of these proteins are extremely difficult to work with, due to hydrophobicity and subsequent aggregation. Some of these issues can be circumvented by use of non-denaturing detergents at low (sub-critical micellar concentrations) concentrations. Finally, our extraction and stabilization methods were applied to the directed proteomic detection of large-mass heme c-containing proteins directly from complex microbial communities, with the hypothesis that these proteins are similar in function to those found in pure cultures of iron reducing or iron oxidizing organisms. In all, our research efforts in protein purification of this interesting class of enzymes has revealed useful information regarding their behavior, which is critical for successful studies using voltammetry, Optical Waveguide Lightmode Spectroscopy, and other techniques used to characterize these proteins.

Variations in stable sulfur isotopes in acid sulfate soil materials

CRYSTAL A. MAHER, LEIGH A. SULLIVAN AND RICHARD T. BUSH
Centre for Acid Sulfate Soil Research, Southern Cross University, P.O. Box 157 Lismore, NSW, Australia, 2480. (cmaher@scu.edu.au)

This study represents the first comprehensive investigation into the use of stable sulfur isotopes in acid sulfate soil materials (ASS). The aim of this study was to: 1) examine the isotopic composition of a range of acid sulfate soils, 2) compare stable sulfur isotope ratios in terms of the ASS environmental setting and landuse history, and 3) examine the likely utility of using stable sulfur isotopes to identify the source(s) of sulfate (SO$_4^{2-}$) contributing to the formation of contemporary ASS materials. The sulfur isotopic composition of the acid volatile sulfur (AVS), chromium reducible sulfur (CRS) and soluble SO$_4^{2-}$ fractions were determined on sulfidic materials from coastal and inland floodplain landscapes.

In mangrove sediments the stable sulfur isotopic ratios of iron sulfides were strongly negative, indicating SO$_4^{2-}$ reduction from an open seawater SO$_4^{2-}$ source. In contrast, positive stable sulfur isotope ratios in other acid sulfate soil materials were indicative of a closed freshwater SO$_4^{2-}$ source. At one location, the Tuckean Swamp, both marine and freshwater sources of SO$_4^{2-}$ exert an influence, which may be related to changes in management practices such as opening flood gates to allow the ingress of tidal water. Stable sulfur isotope data for the inland sites suggest SO$_4^{2-}$ has been incorporated into sulfide precipitates from a range of potential sources. Similarities between the $\delta^{34}$S of the sulfide and soluble SO$_4^{2-}$ ratios at severely acidified sites indicate the oxidation of sulfides is contributing to the sulfur isotope signature of the SO$_4^{2-}$. This process may be responsible for supplying a source of SO$_4^{2-}$ which contributes to the seasonal formation of monosulfidic black ooze (MBO). The production of SO$_4^{2-}$ from sulfides also resulted in the freshwater overlying one study site having a sulfur isotope signature well outside the range previously given for freshwater SO$_4^{2-}$.

The results indicate the ‘open/closed’ concept as often used in stable sulfur isotope studies of sulfidic sediments is problematic in ASS landscapes in eastern Australia. The data also indicates that stable sulfur isotope ratios are a valuable tool to help understand environmental processes occurring in ASS landscapes. The application of stable sulfur isotopes in sediments and ground waters to help discriminate and quantify the contribution the oxidation of ASS is making to the SO$_4^{2-}$ concentration of surface and ground waters during different flow regimes is being examined.
Control of chemical weathering rates by secondary mineral precipitation: a reactive transport approach for understanding soil genesis

KATE MAHER¹, CARL I. STEEFEL², DAVID A. STONESTROM³ AND ART F. WHITE¹

¹U.S. Geological Survey, Menlo Park, CA (kmaher@usgs.gov)
²Lawrence Berkeley National Laboratory, Berkeley, CA

The geochemical evolution of a soil chronosequence developed on progressively older marine terraces (65-226 ka) near Santa Cruz, CA is considered using a reactive transport approach. The model includes the aqueous concentrations, quantitative mineral abundances, and mineral-specific cation exchange. Using the reactive transport approach, we are able to quantify the rate of clay precipitation and directly assess the importance of clay precipitation in moderating chemical weathering rates. In the absence of clay precipitation, the model predicts that weathering fronts for plagioclase and K-feldspar would be restricted to the upper 0.5 meters of the profile, while in reality the weathering fronts extend to a depth of 3 meters for a 226 ka soil. This suggests that clay formation is required to generate the observed weathering profiles. Kaolinite precipitation facilitates primary mineral dissolution by removing aqueous Al and Si and therefore controlling the saturation state of the primary minerals, providing the driving force for dissolution. This effect is particularly important in natural systems where fluid residence times range from months to decades and the fluids would be saturated with respect to the primary minerals in the absence of secondary mineral precipitation.

Our analysis suggests that the "bulge" in clay abundance associated with an argillic horizon at about 1 meter depth can be explained by in situ clay precipitation and does not require or support significant translocation of clays. The incorporation of mineral-specific cation exchange did not affect the profile evolution. However, the addition of dust to the simulated profile effectively decreased the dissolution rate because of the increase in total mineral abundances. The weathering gradients and location of the reaction fronts were affected by differences in solubility of the primary minerals, the rate of kaolinite precipitation and fluid flow. The best fit to the data suggests kaolinite precipitation rates of $10^{12.4}$ mol/m²/sec, K-feldspar and plagioclase dissolution rates are $10^{14.6}$ and $10^{14.3}$ mol/m²/sec, respectively.

Successes and failures of garnet Lu-Hf and Sm-Nd geochronology: Examples in eclogites from the Western Alps

N.J. MAHLEN¹, Ç.M. JOHNSON¹, L.P. BAUMGARTNER², S. SKORA³, T.J. LAPEN³ AND B.L. BEARD¹

¹Univ. Wisconsin - Madison; (mahlen@geology.wisc.edu, clarkj@geology.wisc.edu, beardb@geology.wisc.edu)
²Univ. Lausanne; (Lukas.Baumgartner@unil.ch, Susanne.Skora@unil.ch)
³Univ. Houston; tjlapen@uh.edu

The potentially high Lu/Hf and Sm/Nd ratios in garnet make these isotope systems attractive to geochronological applications in garnet-bearing rocks such as eclogites. Rayleigh fractionation modeling predicts that, due to the variation of Lu, Hf, Sm, and Nd distribution coefficients, Lu-Hf ages will tend to date early garnet growth due to high Lu/Hf ratios in the core, whereas Sm-Nd ages should reflect the average garnet growth age (Lapen et al., 2003, EPSL), assuming the blocking temperatures of these isotope systems were not exceeded. When Lu-Hf or Sm-Nd data fail to provide statistically meaningful garnet-whole rock and garnet isochrons, this is often ascribed to contamination of garnet by inclusions, and partial dissolution, annealing, and leaching strategies have been developed to address this.

The Zermatt-Saas ophiolite in the Western Alps is an example of a relatively cool (500-600 °C), dry eclogite terrane that was metamorphosed to HP and UHP conditions. Core-torim zoning of Lu, Hf, Sm, and Nd in garnet may be controlled by diffusion-limited uptake, deviating significantly from that predicted by Rayleigh fractionation. If their uptake is limited by diffusion, overall Lu/Hf ratios in garnet will sharply decrease from the garnet core resulting in a low bulk Lu/Hf ratio. Although low Lu/Hf ratios have been commonly ascribed to mineral inclusions such as zircon and rutile, this may not always be the case. For Sm-Nd geochronology, diffusion-limited uptake will produce low Sm/Nd ratios in garnet, reducing isochron precision. Such very low Sm/Nd ratios in garnet have been observed in a number of studies, and our element zoning studies indicate that low-Sm/Nd inclusions are not the sole explanation.

Partial dissolution tests demonstrate that "hot plate" dissolution, often thought to avoid dissolution of low-Lu/Hf phases, cannot always be relied upon to produce meaningful isochrons because the measured $^{176}$Hf/$^{177}$Hf ratios may be decoupled from the measured Lu/Hf ratio due to elemental fractionation associated with incomplete sample digestion. Distinction between Rayleigh fractionation and diffusion-limited uptake is critical for successful geochronology, and this requires detailed elemental traverses across central cuts of garnet, guided by 3D x-ray tomography. The likelihood of successful geochronology can be increased through consideration of 3D garnet distribution of specific samples, water contents, and peak metamorphic temperatures.
Calibration of the cosmogenic nuclide production rate of $^{36}$Cl on Fuerteventura, Canary Islands, Spain

KATRIN MAI AND KLAAS VAN DER BORG

University of Utrecht, Dep. Physics and Astronomy, AMS / R. van de Graaff Laboratorium, Utrecht, The Netherlands (K.Mai@phys.uu.nl)

Cosmogenic nuclides are a promising tool of investigating the time span rocks have been exposed to cosmic radiation. Exposure dating has been applied in many geoscientific fields such as volcanology, (glacial) tectonics, structural geology and geomorphology. However, there is still major disagreement in determination of scaling factors and production rates for the cosmoneutrons.

Due to geographic position and presence of basaltic lava flows the island of Fuerteventura was chosen by CRONUS-EU to serve as a $^{36}$Cl calibration site. Young basalts from this island are analysed to better constrain scaling factors and production rate. Due to its relative short half-life $^{36}$Cl is well suited for age determination of rocks of relatively little exposure age.

The quality of the scaling factors that describe the influence of a number of parameters such as height, topographic shielding, and coverage is tested in terms of sensitivity to changes due to geologic/geophysical reasons and in terms of sensitivity for uncertainty in actual measurement and calculation of paleo-values. Special attention is focused on the effect of intensity and orientation variations of the Earth magnetic field throughout geologic time based on paleomagnetic data. The testing procedure is performed with different approaches of calculating scaling factors. Samples of varying ages provide essential information of changes of time-integrated production rates.

Results of AMS measurements in Utrecht as well as laboratory cross calibrations using other AMS facilities throughout CRONUS shed insight into site specific production rates of $^{36}$Cl at the island of Fuerteventura. This will help in future to better constrain scaling factors and production rates for other sampling sites.

Platinum-group elements in mantle xenoliths from the Kaapvaal craton

W.D. MAIER¹, I. MCDONALD², P PELTONEN, S-J BARNES³, J. GURNEY⁵ AND C. HATTON⁶

¹Centre for Exploration Targeting, UWA, Australia (wdmaier@cyllene.uwa.edu.au)
²University of Cardiff, UK (iain@earth.cf.ac.uk)
³Geological Survey of Finland, Espoo, Finland (Petri.Peltonen@gtk.fi)
⁴Université du Québec à Chicoutimi, Canada (sjbarnes@uqac.ca)
⁵University of Cape Town, South Africa (John.Gurney@minserv.co.za)
⁶MSA Geoservices, Parkhurst 2120, South Africa (chris.hatton@mweb.co.za)

We analysed 103 peridotite mantle xenoliths from 15 kimberlite pipes located on the Kaapvaal craton (Kimberley cluster, Jaagersfontein, Roberts Victor, Newlands, Frank Smith, Monastery, Lethlakane, Finsch, Venetia, Premier, Letseng la Terae, Liqhobong, Matsoku) and adjacent off-craton areas (Melon Wold, Markt, Gibeon) for their concentrations of platinum-group elements (PGE). The following results are highlighted: (i) We can model most of the observed PGE patterns by progressive partial melting of a primitive mantle source assuming PGE partitioning into mss, iss, and PGM/alloys. Refertilization by asthenospheric melts/fluids may locally cause elevated Pt and Pd contents, particularly in some LILE enriched MARIDs and PICs and in some high P-T samples derived from the base of the lithosphere. However, in most samples there is no correlation between the concentrations of incompatible trace elements and Pt or Pd, both at on-craton and off-craton localities. This suggests limited addition of Pt and Pd. (ii) Xenoliths from Group I kimberlite pipes tend to have higher IPGE/Pt+Pd and Pt/Pd ratios than those from Group II kimberlite pipes. This indicates that the mantle source represented by xenoliths in Group I kimberlites experienced more partial melting than the source represented by xenoliths in Group II kimberlites. (iii) Kaapvaal mantle xenoliths tend to have higher Pt/Pd ratios than primitive mantle, and relative to deep and shallow mantle samples from other areas. This suggests that Pt has been preferentially retained during evolution of the Kaapvaal mantle. The reason why Pt has been less effectively retained in other cratons is unclear. It could be a sampling problem, or the Kaapvaal craton could contain more refractory Pt alloys, or Pd could have been more effectively removed by metasomizing agents (melts and fluids).
Heat capacity and entropy of MgSiO$_3$ and Mg$_2$SiO$_4$ glasses

J. MAJZLAN$^1$, J.A. TANGEMAN$^2$ and E. DACHS$^3$

$^1$Institute of Mineralogy and Geochemistry, University of Freiburg, D-79104 Freiburg, Germany; (Juraj.Majzlan@minpet.uni-freiburg.de)
$^2$Containerless Research, Inc., 825 Chicago Avenue, Suite E, Evanston, Illinois 60202-2376, USA
$^3$Fachbereich Materialforschung & Physik, University of Salzburg, Hellbrunnerstraße 34, A-5020 Salzburg, Austria

Melting of the material in the crust and mantle of the Earth is one of the principal processes of this geologically living planet. The two most common rock types of the crust – granite and basalt – both originate from molten silicate liquids generated in depth.

In this work, we have measured the thermophysical (heat capacity, $C_p$, and entropy, $S^o$) properties of two glasses with composition relevant to basic and ultrabasic rocks. The glasses correspond in their composition to the minerals enstatite (MgSiO$_3$) and forsterite (Mg$_2$SiO$_4$). The thermophysical properties were measured with a commercial PPMS system in the temperature range 5 - 300 K on ~25 mg samples prepared by levitation and containerless quenching techniques. In combination with high-temperature DSC $C_p$ measurements, our data have the potential for constructing a complete thermodynamic dataset for glasses and liquids of enstatite- and forsterite-composition.

The entropy of the MgSiO$_3$ glass at 298.15 K was calculated as 73.0 J/(mol·K) and the heat capacity at this temperature is 80.2 J/(mol·K). The entropy of the Mg$_2$SiO$_4$ glass at 298.15 K is 105.6 J/(mol·K) and the heat capacity is 118.8 J/(mol·K). None of these entropy values includes the configurational contribution which cannot be estimated from our low-temperature calorimetry data alone.

The $C_p$ curves for both glasses display a pronounced “boson” peak at low temperatures (< 150 K), i.e., a pronounced positive difference of the $C_p$(glass) – $C_p$(crystal) value. Although this peak has been assigned simply to a variable coordination number of cations in glasses, it seems more likely that it is due to the presence of low-frequency modes in the relatively open framework of the glasses. The origin and cause of this difference will be discussed in further detail in a separate contribution.

Unusually high trace element abundances in residual peridotites: Implications for mantle-melt interactions at a Mid Oceanic Ridge

SANJEEWA P.K. MALAVIARACHCHI, AKIO MAKISHIMA AND EIZO NAKAMURA

Pheasant Memorial Laboratory (PML), Okayama University at Misasa, Yamada 827, Misasa, Tottori 682-0193, Japan (sanjeewa@misasa.okayama-u.ac.jp; max@misasa.okayama-u.ac.jp; eizonnak@misasa.okayama-u.ac.jp)

We report unusually high trace element concentrations in clinopyroxene (CPX) and extremely high whole rock trace element abundances of a set of unmetasomatized peridotites from a ~2m high peridotite-gabbro section from the Horoman Peridotite Complex, Japan. Trace elements exceeding Primitive Mantle values suggest a fertilization event by addition of a melt producing a highly fertile peridotite suit. Gabbros represent added melts having higher Cr$_2$O$_3$ than both Type I [TiO$_2$ and rare earth elements (REE) rich] & II (Cr$_2$O$_3$ rich with distinct positive Sr & Eu anomalies) gabbros (Takazawa et al., 1999), whereas TiO$_2$ and REE contents are lower than Type I but greater than Type II. Mineral textures preserved in the peridotites support melt interaction and bulk rock trace elements can be successfully modelled by a gabbro-peridotite binary mixing process. Absence of metasomatic evidence and are signature in these samples clearly rules out the occurrence of melt interaction at a subduction zone. Highly depleted light REE patterns of both CPX and bulk peridotites and occurrence of two pyroxene spinel symplectites imply the peridotites are residues of polybaric melt extraction started from the garnet field. Thus, we propose these peridotites were intruded by magma and consequently melt-rock interaction occurred under mid ocean ridge tectonic setting. Intruded melts were then frozen as gabbros within the residual peridotites during decompression to the spinel facies conditions, eliminating any chance for melt-driven metasomatism. Subsequently, rocks were incorporated into a subduction zone setting and undergone deformation with extreme stretching and folding in H$_2$O bearing wedge-mantle forming millimetre to meter scale layering (Yoshikawa and Nakamura, 2000).

Zircons from ultramafic-mafic intrusions at Noril’sk area (Russia): A compositional and U-Pb study

K.N. MALICH, O.V. PETROV, I.YU. BADANINA AND S.L. PRESNYAKOV
All-Russia Geological Research Institute, St. Petersburg, 199106, Russia (Kreshimir_Malich@vsegei.ru)

World-class platinum-group-element (PGE)-Cu-Ni deposits closely linked to intracontinental paleorift-related ultramafic-mafic intrusions are located in the northwestern corner of the Siberian craton, Russia. In spite of its significant metallogenic potential, age constraints for the ore-bearing intrusions are poorly defined. Similarly, timing and duration of the ore concentration responsible to form an economic deposit has been rarely evaluated quantitatively.

This study presents the results of trace element data and uranium-lead ages for about 550 grains of zircons, which were extracted using ppm-mineralogy technique (NATI Research JSC, St, Petersburg, http://www.natires.com) from drill core samples from the various types of igneous bodies. The latter include economic PGE-Cu-Ni deposits associated with the Noril’sk-1 (drill core MN-2), Talnakh (OUG-2) and Kharacelakh (KZ-844) intrusions, subeconomic deposits related to the Chernogorsk (MP-2), Zub-Marksheider (MP-27) and Vologochan (OV-29) intrusions and none economic the Chernogorsk (TG-31) intrusion. Isotope geochemical data (102 REE analyses and 616 U-Pb measurements) were determined with secondary ion mass spectrometer SHRIMP-II at All-Russia Geological Research Institute.

Zircons are characterized by a fuzzy (smoky) cathode luminescence, with a virtual total absence of zoning. Petrographic inspection, however, revealed at least two generations of zircon that show distinct solid inclusion discrimination diagrams (Sm/La) – La and Ce/Ce* - (Sm/La)zircons mainly plot in the field of “magmatic” zircon (after Hoskin, 2005), with a tale approaching the “hydrothermal” field.

Four age groups of zircon were determined, with concordant U-Pb ages that vary in the range 220-260 Ma. Polyphase grains also preserve domains with U-Pb ages that cluster around 300 and 340 Ma. Rare detrital grains (around 1900 Ma) have been observed. Our new findings are in a good agreement with assumption about the interaction of distinct magmas and a prolonged duration of component fractionation in the magmatic system. Consequently, these processes could lead to high degrees of separation and concentration of ore elements and formation of specific ore magma of unique scales and concentrations.

Linking between Mid Ocean Ridge basalts and Abyssal peridotites from Nd isotopes

S. MALICK1 AND V.J.M. SALTERS2
NHMFL and Dept. of Geological Sci, FSU
(mallick@magnet.fsu.edu, salters@magnet.fsu.edu)

We have analyzed the trace element concentrations and Sr, Nd isotopic compositions of clinopyroxene (cpx) separates from abyssal peridotites (AP) from three different locations – South West Indian Ridge (SWIR), Mid Cayman Rise (MCR) and Mid Atlantic Ridge (MAR).

AP from all locations have trace element characteristics indicative of variable degrees of melt depletion. The SWIR peridotites from three different dredges show similar moderate to strong LREE (Light Rare Earth Elements) depletion, however the three dredges have distinct Nd isotopic composition. Nd-isotopic compositions of the cpx from the SWIR are on average higher than the ridge basalts. Cpxs from dredge VAN85 have some of the most depleted in REE abundances with CeN < 0.1 and YbN < 10. Cpxs from this dredge have high Nd-isotopes ratios (0.513086-0.513320) all higher than the Nd-isotopes ratios of the associated basalts. Dredge VAN78 is more homogeneous in Nd-isotope ratios (0.513003-0.513046) that fall within the range of Nd-isotope ratios of the associated basalts and display a less depleted REE pattern (CeN = 2-5) than dredge VAN85. In contrast cpxs from dredge VAN96 have elevated LREE abundances (CeN >0.4) and have most enriched Nd-isotope ratios (0.512885-0.512933) and are similar to the associated basalts. The cpxs from dredge VAN85 and VAN78 are not in equilibrium with the ridge basalts whereas the REE patterns from dredge VAN96 indicate that these cpxs could be in equilibrium with the associated MORB.

Cpxs from MCR peridotites all show extreme depletion in LREE abundances (CeN <0.4) and have variable HREE (YbN >4-17). The cpxs are too depleted in LREE to be in direct equilibrium with MORB. Nd-isotope ratios (0.513115-0.513425) of the cpxs overlap with the Nd-isotopes ratios of the associated basalts (0.512961-0.513190) and extend to higher ratios.

Cpxs from MAR show two orders of magnitude variation in Ce concentration (CeN =0.7-0.007) with YbN ~3. Nd-isotope ratios (0.513011-0.513190) of the cpxs are indistinguishable from the associated basalts.

The large variation in REE patterns at all locations indicates that there is significant heterogeneity in the sub-ridge mantle. The discrepancy in Nd-isotope ratios between basalts and AP at SWIR and MCR requires a low Nd-isotopic composition component not shown in the peridotites to contribute to the basalts. However, the fact that at some places basalts and peridotites overlap indicates that this low-Nd-isotopic composition component is not a ubiquitous component in the sub-ridge mantle.
**Geochemical hazard by coal-ash from a coal-based thermal power plant in Kolaghat, West Bengal, India**

A. Mandal\textsuperscript{1} and D. Sengupta\textsuperscript{2}

\textsuperscript{1}Department of Geography and Geology, University of West Indies, Mona, Kingston-7, Jamaica
(arpitamandal2000@yahoo.com)

\textsuperscript{2}Department of Geology and Geophysics, IIT Kharagpur, Kharagpur-721302, West Bengal, India
(dsgg@gg.iitkgp.ernet.in)

**Introduction**

Coal combustion of thermal power plants in India is a major source of environmental pollution due to the generation of huge amounts of ash rich in toxic and radioactive elements, which are disposed off in large ponds and on open grounds surrounding the power plant. Absence of an underground lining permits easy mixing of the ash with the top soil of the area. Geochemical and radionuclide study of coal, ash, water and soil was carried out around a major thermal power plant in India to assess the potential contamination of the soil and the groundwater system.

**Experimental methods**

Major, minor and trace elements in the ash, coal and soil samples around the ash ponds of the power plant by x-ray fluorescent spectrophotometer. ICP-MS was used to determine the concentration of the trace elements in the water samples collected from the wells located near the vicinity of the ash ponds and in the surrounding villages of the study area. NaI (Tl) induced gamma-ray spectrometer.

**Results and Discussions**

Major and minor oxide analyses of the coal and ash document predominance of silica and alumina. The coal-ash is significantly enriched in the trace elements Pb, Cu, Ni, As, Cd, Cr, V, Mo etc. Radiometric analysis of the ash shows that the radionuclides (\(^{238}\)U, \(^{232}\)Th) are enriched 3-5 times in the coal ash as compared to their crustal average. The average absorbed gamma dose rates at 1m above the ground from the ash as compared to their crustal average. The average which is ~4 times higher than the world average (43nGy h\(^{-1}\)).

Combustion of coal thus causes serious environmental concern due to the release of the toxic trace elements and the radionuclides in the ash, thus contaminating the top soil and the subsurface aquifer. People living near the ash ponds are subjected to a high radiation dose from the ash ponds and the soil cover, which is ~ 2.6 times higher than the world average.

**Temperature-dependent molecular cell membrane adaptation of microbial populations in Siberian permafrost**

K. Mangelsdorf\textsuperscript{1}, E. Finsel\textsuperscript{1}, S. Liebner\textsuperscript{2} and D. Wagner\textsuperscript{2}

\textsuperscript{1}GFZ Potsdam, Telegrafenberg B423, 14473 Potsdam; (K.Mangelsdorf@gfz-potsdam.de)

\textsuperscript{2}AWI Potsdam, Telegrafenberg A43, 14473 Potsdam

Permafrost is a common feature in polar regions. The uppermost permafrost layer, thawed in summer, is characterized by an extreme temperature regime from about +15°C to −35°C. Even so a diverse range of microorganisms have been discovered in this so-called active layer.

The aim of the current study was to examine as to how the microbial populations within the different horizons of the active layer were adapted to the extreme variable temperature regime of the permafrost area. Thus, two soil samples were taken from the active layer on Samoylov Island in the central Lena Delta, Siberia: one surface-near sample (11-18 cm) and one permafrost-near sample (25-32 cm). Aliquots of each sample were incubated under 4 °C and 28 °C for about 4 weeks. Subsequently, the molecular cell membrane composition (phospholipids) was qualitatively and quantitatively evaluated using HPLC-ESI-MS/MS.

To maintain the membrane fluidity at low temperatures, microbial cells can decrease their solid-liquid phase transition temperatures below the ambient temperature. They change their phospholipid fatty acid composition to more bulky-shaped cis-unsaturated fatty acids and/or to more shorter-chain fatty acid, because of the lower melting temperatures of unsaturated and shorter-chain fatty acids.

The comparison of the phospholipid fatty acid (PLFA) distribution of the different horizons at 4 and 28 °C shows that the microbial population of both horizons does not incorporate significantly more unsaturated fatty acids under cooler conditions. In contrast to this the surface near as well as the permafrost near microbial communities reveal for both a distinct relative increase of short chain fatty acids of 7.3 and 10.3% in the 4 °C incubation experiment.

In addition to this distinct chain length adaptation, the PLFA proportions of the microbial population of the active layer differ with the different depth horizons. The permafrost near microbial community shows, in general, a higher relative proportion of unsaturated and shorter chain fatty acids. This indicates a stronger adaptation to cooler environmental conditions, whereas the surface near population reveals a higher flexibility towards warmer temperature conditions.
Mass-independant fractionation during TIMS measurements: Evidence of nuclear shift effect?

G. MANHES AND C. GÖPEL

Equipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris et Université Paris-Diderot, CNRS; 2 place Jussieu, 75005 Paris, France (manhes@ipgp.jussieu.fr; gopel@ipgp.jussieu.fr)

“Abnormal fractionation” of the $^{207}\text{Pb}$ isotope relatively to the mass dependent fractionation between $^{206}\text{Pb}$, $^{206}\text{Pb}$ and $^{208}\text{Pb}$ has been detected during long high precision Pb isotope measurements by thermal ionization mass spectrometry (TIMS) of the standard SRM-981 (Thirwall, 2000; Doucelance and Manhès, 2001).

Zn, Cd and Pb isotope measurements with TIMS (Manhès and Göpel, 2003) revealed that the odd isotopes ($^{65}\text{Zn}$, $^{207}\text{Pb}$, $^{111}\text{Cd}$-$^{113}\text{Cd}$) were affected during extended runs by a mass-independent fractionation in addition to the purely mass-dependent fractionation shown by the even isotopes, leading to an accumulated depletion of the odd isotopes. TIMS Pb isotopic measurements of the standard SRM-981 spiked with $^{202}\text{Pb}$ and $^{207}\text{Pb}$ (Amelin, Davis and Davis, 2005) confirmed this effect. Both studies suggested the nuclear spin carried by the odd nuclides as responsible for these mass independent fractions.

Recently, Amelin, Davis and Davis (2006) suggested that these observed accumulated depletion of odd isotopes relatively to the even isotopes result from a larger volatility of odd isotopes due to the differences in the shape of the nuclei. This idea results from a new interpretation of mass independent isotope fractionationation observed in FUN inclusions of Allende meteorite (Fujii, Moinier and Albarède, 2006) implying the nuclear field shift (Bigeleisen, 1996). The nuclear field shift effect is evocated for the origin of mass-independent fractionation in chemical exchange reactions (Bigeleisen, 1996).

The aim of our study is to identify the process that induces the mass independant fractionation during the thermal ionization processes. Our experiments of the thermal ionization of Pb and Cd suggest that the evocated difference in volatility between odd and even isotopes is not the key process but the change in oxidation states of the elements inside the glass beads.

Geochemical characteristics of adakites from different greenstone belts of Eastern Dharwar Craton, India – Implications on subducted slab-mantle wedge interaction

C. MANIKYAMBA AND TARUN C. KHANNA

National Geophysical Research Institute, Upal Road, Hyderabad-500 007 (cmaningri@yahoo.com, khanngri@yahoo.com)

The continental crust in the Dharwar Craton of Peninsular India has evolved through terrain accretion and amalgamation of oceanic plateaus and island arcs. The adakites identified from Sandur, Gadwal and Kushtagi greenstone belts exhibit geochemical variation reflecting on their petrogenesis. Adakites of Gadwal belt have SiO$_2$ = 56 – 72 wt.%, Al$_2$O$_3$ = 11 – 17 wt.%, high MgO (0.67 – 3.9 wt.%), Na$_2$O (2.2 – 4.9 wt.%), K$_2$O (0.57 – 1.9 wt.%), low Mg# (35 – 55), Ni (0.7 – 11 ppm), Cr (1.8 – 27 ppm), Sr (142 – 420 ppm), Y (10.3 – 19 ppm), Yb (0.79 – 1.5 ppm) whilst Sandur adakites have comparatively high SiO$_2$ (75 – 78 wt.%), low Al$_2$O$_3$ (12 – 13 wt.%), MgO (0.15 – 0.24 wt.%), high Mg# (58 – 85), Na$_2$O (4.7 – 7.2 wt.%), K$_2$O (1.01 – 2.05 wt.%), Ni (1.3 – 41 ppm), Cr (9.6 – 292 ppm), low Sr (175 – 237 ppm), Y (4.5 – 6.9 ppm), Yb (9.3 – 0.5 ppm). The Rare Earth Element (REE) patterns of Sandur adakites are highly fractionated compared to Gadwal (La/Yb = 43 – 71 and 9 – 29, respectively). Sr/Y ratio in Gadwal adakites is depleted (12 – 27) compared to Sandur adakites (26 – 46) whereas the Zr/Sm ratio of Gadwal adakites is 32 – 58, slightly higher than Sandur adakites. Phanerozoic adakites studied from different parts of the world along with Archaean adakites (from Abitibi) have been interpreted as melts derived from the subducted slab. The geochemical characteristics of slab melts is modified by their interaction with mantle wedge during its ascent and thereof the magmas derived from the partial melting of metasomatized wedge will reflect the composition of slab derived fluids/melts. The overall geochemical characteristics of these adakites and their occurrence with arc basalts, boninites, NEB and high Mg-andesites signify a transition from slab dehydration-wedge melting to slab melting-wedge hybridization and these new observations of adakite geochemistry in different greenstone belts endorse the emergence of complex are magmatism in Neoarchaean terranes.
Unequivocal evidence for a deep magma ocean from metal/silicate partitioning of Ta, V and Si during core formation  

U. MANN, D.J. FROST AND D.C. RUBIE  
Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (ute.mann@uni-bayreuth.de)

Heterogeneous core formation models propose a stepwise accretion process generally starting with metal-silicate equilibration in small bodies at relatively reducing conditions (Wänke, 1981; O'Neill, 1991). Initially reducing conditions are required in these models to explain why moderately siderophile elements such as Si, V, and Cr have been depleted from the Earth’s mantle. Studying the metal-silicate partitioning behaviour of refractory, undepleted elements such as Ta allows constraints to be placed on the lowest redox state under which significant terrestrial core formation could have taken place.

High-pressure experiments in the range of 2 - 24 GPa, temperatures of 1750 – 2600°C and low oxygen fugacities (ΔIW -1 to –5) have been performed using piston cylinder and multi-anvil devices. In two separate series of experiments, the metal-silicate partition coefficient for Ta was determined together with (a) Ga, In, Zn and (b) V, Cr, Mn, Ti, Nb. These elements were added as oxides in concentrations of 4-10 wt% to powdered starting mixtures of ~55 wt% synthetic peridotite and 35-40 wt% Fe-alloy (with 2 wt% Ni, 1 wt% Co, 9-17 wt% S).

Our data show that at pressures up to 6 GPa, Ta, Ga, In and Zn would have been strongly depleted from the mantle at the redox conditions required to extract V and Cr to the core. Moreover, the depletion of Ta would have been much greater than the depletion of Si required to explain the low Si/Mg ratio of the mantle compared to CI chondrite, if significant core/mantle equilibration occurred at low pressures. At higher pressures (≥18GPa) and very high temperatures, Si and V can be extracted into the core without depletion of Ta and without requiring strongly reducing conditions. This means that metal-silicate partitioning must have occurred in a relatively deep magma ocean during core formation and that the redox state of accreting material may, on average, have remained constant with time.

Hf-Nd isotopic decoupling in enriched Icelandic lavas  

CHRISTINA J MANNING AND MATTHEW F THIRLWALL  
Royal Holloway University of London, Egham Hill, Egham, Surrey. TW20 OEX; (c.manning@gl.rhul.ac.uk)

The range in isotopic and chemical compositions of Icelandic lavas is commonly interpreted as resulting from mixing between isotopically depleted and enriched components, thought to originate by melting an entire section of recycled oceanic crust [1,2]. In these models the gabbroic section forms the depleted endmember and the crustal layer forms the enriched component. Lead isotopic data has shown the mixing relationships to be more complicated than simple binary mixing, indicating that at least 5 separate components are needed to account for the compositional range [3].

The lavas most enriched in incompatible elements in Iceland, representing the closest approach to an enriched endmember, are found in the Snaefellsnes peninsula (SNP) and in the central volcanoes of southern Iceland (SI). We present new Nd-Hf-Pb isotopic data from these areas. The SNP and SI show $^{176}\text{Hf}/^{177}\text{Hf}$ ratios between 0.283077–0.283192 and 0.283076–0.283149 respectively. Nd-Hf ratios correlate with incompatible element enrichment, as elsewhere in Iceland, and thus also with Sm/Nd and Lu/Hf ratios. These correlations give minimum ages for the isotopic variation in SNP and SI of 200-350Ma. However, more recent partial melting events probably have reduced these ages.

Sources originating from recycled slabs are expected to have flat HREE patterns. Samples from the SNP and SI exhibit elevated Dy/Yb$_N$ compared to other Icelandic regions. SNP shows lower Dy/Yb$_N$ than SI indicating smaller garnet facies contributions, consistent with higher Lu/Hf ratios, whilst the high Dy/Yb$_N$ and low Lu/Hf of SI are consistent with a larger contribution from the garnet field.

Samples from the SNP exhibit higher $^{176}\text{Hf}/^{177}\text{Hf}$ and $^{176}\text{Lu}/^{177}\text{Hf}$ for given $^{144}\text{Nd}/^{144}\text{Nd}$ and $^{143}\text{Sm}/^{144}\text{Nd}$ than those from SI forming 2 sub-parallel trends on Hf-Nd isotope and the equivalent parent/daughter diagrams. This implies that the Hf-Nd isotope decoupling is a product of ancient source differences in Lu/Hf and Sm/Nd, which have not been eliminated by garnet-facies melting. Calculations using the differences between the 2 correlations give ages which are partially corrected for melting and so may provide insight into earlier differentiation processes. Lu/Hf ages calculated for Eastern SNP and SI gave ages of ~550Ma. These ages are consistent with the lower Palaeozoic age proposed for the recycled slab based on lead isotopes [3]. This could indicate that the Hf-Nd decoupling between SNP and SI reflects heterogeneity within the recycled component.

Rutile solubility in albite-H$_2$O fluids at high P and T: Implications for HFSE mobility in subduction zones

C.E. MANNING$^1$, A. ANTIGNANO$^1$, M. WILKE$^2$, C. SCHMIDT$^3$, S. SUTTON$^{4,5}$ AND M. NEWVILLE$^6$

$^1$Earth & Space Sci. Dept, U. of Calif. Los Angeles, CA 90095 USA

$^4$Dept. of Geophysical Sciences, U. Chicago, Chicago, IL USA
$^5$CARS, U. Chicago, Chicago, IL USA

Ti and other HFSE are considered immobile in high-P fluids, but rutile is common in eclogite-facies veins. Rutile occurring with vein Na-Al-silicates motivates experiments on the role of NaAlSi$_2$O$_6$ (Ab) dissolved in H$_2$O on rutile solubility at 800-900°C and 0.5-1.5 GPa. At 800°C, 1 GPa, hydrothermal piston-cylinder (HPC) methods[1] indicate that rutile solubility rises linearly from 19±7 ppm (1σ) in pure H$_2$O to 275±10 ppm at 8.8 wt% Ab. Results give higher solubility than reported by [2] using hydrothermal diamond-anvil cells (HDAC). The discrepancy was examined by measuring rutile solubility in Ab-H$_2$O in HDAC by synchrotron XRF at ESRF, ID22. Ti solubility rose from 159±11 to 210±5 ppm with Ab increasing from ~2.5 to 8 wt % (P=0.7-1.1 GPa), in agreement with our HPC results but not [2]. The role of Ab is important. Rutile solubility in supercritical Ab-H$_2$O (HPC, 900°C, 1.5 GPa) increases from 85 ppm in pure H$_2$O to ~1500 ppm at the critical composition (X_{Ab}~0.09); solubility rose further to ~5000 ppm at albite saturation (X_{Ab}=0.52). Independent evidence points to polymerization of Na-Al-Si species in solution at these conditions[3], which implies that the solubility increase with X_{Ab} is controlled by access to more energetically favorable sites in the polymers. As a preliminary test, we carried out Ti K-edge XANES at APS (GSECARS) on quenched hydrous rutile-saturated Ab glasses (X_{Ab}=0.29-0.50). Ti pre-edge at 4970.5±0.1 eV and 0.23±0.01 normalized intensity indicates coordination by oxygen that is ~95% octahedral and 5% tetrahedral[4], in contrast to IV-coordinated Ti(OH)$_4$ in H$_2$O. Evidently, the higher Ti solubility arises from the change in coordination afforded by dissolved Ab components. Ti, and by extension HFSE, are surprisingly soluble in realistic subduction-zone fluids.

Changes in ion pairing across the H$_2$O liquid-liquid transition: Implications for planetary fluids

C.E. MANNING$^1$ AND C. SCHMIDT$^2$

$^1$Department of Earth and Space Sciences, University of California, Los Angeles, CA 90095 USA (manning@ess.ucla.edu)
$^2$GeoForschungsZentrum, Telegrafenberg, 14473 Potsdam Germany (hokie@gfz-potsdam.de)

Compression of H$_2$O at ambient temperature leads to a transition at 0.2–0.4 GPa from low-density water (LDW) to high-density water (HDW) [1,2] due to second coordination-shell collapse [3] or interstitial H$_2$O [4]. This transition may play an important role in fluid-rock interactions in cold, deep planetary settings, such as the interiors of the icy moons of Jupiter and Saturn. To explore potential effects, we studied pressure-dependent variation in contact ion-pairing in MgSO$_4$ solutions at 23°C by Raman spectroscopy using hydrothermal diamond-anvil cells. Solutions were 0.5, 1.75 and 2.0 m, as determined by freezing-point depression. Pressure (P) was determined from the frequency shifts of the 206 cm$^{-1}$ line of quartz [5].

Raman spectra in the region of the OH stretching mode of H$_2$O were collected for 2.0 m MgSO$_4$ and deconvoluted into 3 components. Frequencies of all peaks (1 atm positions: ~3280, ~3450, ~3580 cm$^{-1}$) decrease linearly with $P$. A well-resolved decrease in linear slope at 0.4 GPa is interpreted to record the liquid-liquid transition. A negative correlation between frequency and $P$ is consistent with strengthening of hydrogen bonding with compression; the lower slope at >0.4 GPa implies less strengthening with $P$ in HDW. Spectra in the v$_1$-SO$_4^{2-}$ region were deconvoluted into 2 components, v$_1^{CIP}$=993 cm$^{-1}$ (contact ion pairs, CIP), and v$_1^{*}$=980 cm$^{-1}$, which includes Raman-indistinguishable contributions from free SO$_4^{2-}$ ions and single and doubly solvent-separated ion pairs [6]. Values of v$_1^{*}$ increase linearly with $P$, and also display a well-resolved slope break at ~0.4 GPa. The fraction of CIPs decreased with $P$ to 0.4 GPa, but the trend reversed at >0.4 GPa, signifying increasing CIPs with $P$ in HDW. Salt reassociation with $P$ in deep, cool environments – e.g., beneath the ocean floors of icy satellites – will enhance the progress of dissolution reactions relative to expected values based on LDW, and result in higher mineral solubility in HDW.

Micro-scale oxygen isotopic variation in 1.9 Ga Gunflint cherts: New constraints on their paleo-environmental significance

J. MARIN1, M. CHAUSSIDON1, F. ROBERT2

1CRPG-CNRS, Nancy France (jmarin@crpg-cnrs.nancy.fr, chocho@crpg-cnrs.nancy.fr)
2LEME Museum national d’histoire naturelle, Paris, France, (robert@mnhn.fr)

Precambrian sedimentary cherts have the potential to preserve a record of O and Si isotopic composition (δ18O and δ30Si) of seawater and may give access to oceanic paleothermatures (Knauth and Lowe, 1973 ; Robert & Chaussidon, 2006). However, bulk δ18O of individual cherts at a given age show a typical 3-4‰ range (Knauth, 2005) which complicates paleo-temperatures reconstruction. In addition, some cherts may be of hydrothermal origin and δ18O-values may be altered by metamorphic fluids. We looked for μm-scale δ18O variations in the 1.9 Ga old Gunflint iron-formation (Canada), which contains among the least metamorphosed precambrian cherts, in order to (1) constrain their origin and (2) to assess their preservation.

Four cherts samples, containing different types of silica (microcrystalline quartz, druzy quartz, megaquartz, and quartz veins) and minor carbonates (siderite and ankerite), hematite and pyrite, were analysed (> 100 spots per sample) by multicollector Cameca ims 1270 ion microprobe, with an external reproducibility on quartz standards of 0.31‰ (1 σ, n=22).

The four Gunflint cherts show (i) large megaquartz with δ18O 10-12‰ lower than microcrystalline quartz, (ii) a typical 3-5 ‰ δ18O range for microcrystalline quartz and (iii) quartz veins with δ18O 5-7‰ lower than microcrystalline quartz. The variation in the proportion of the differences types of silica appears to explain bulk variations (i.e. sample 4 of 06/30/84 ; bulk = 22.75‰, δ18O calculated from modal proportions of silica = 23.18%). Considering microcrystalline quartz only, a δ18O range from 0‰ to 3‰ higher than previous bulk δ18O (Winter and Knauth, 1991) is found, which would correspond to a difference of temperature of 0-15°C. This approach may allow to better constrain oceanic paleo-temperatures in the Precambrian.

Iron isotope fractionation during hydrothermal ore deposition and alteration

GREGOR MARKL1, FRIEDHELM VON BLANCKENBURG2, THOMAS WAGNER3 AND INGO HORN2

1Inst. f. Geowissenschaften, D-72074 Tuebingen, Germany; markl or th.wagner@uni-tuebingen.de
2Inst. f. Mineralogie, D-30167 Hannover, Germany; fvb or i.horn@mineralogie.uni-hannover.de

Iron isotopes fractionate during hydrothermal processes. Therefore, the Fe isotope composition of ore-forming minerals characterizes either iron sources or fluid histories. 51 samples of iron ores and iron mineral separates from the Schwarzwald region, southwest Germany, were analyzed for their iron isotope composition using multicollector ICP-MS. Further, the ore-forming and ore-altering processes were quantitatively modeled using reaction path calculations.

The Schwarzwald mining district hosts mineralizations that formed discontinuously over almost 300 Ma of hydrothermal activity. Primary hematite, siderite and sulfides formed from mixing of meteoric fluids with deeper crustal brines. Later, these minerals were partly dissolved and oxidized, and secondary hematite, goethite and iron arsenates were precipitated.

Two types of alteration products formed: (1) primary and high-temperature secondary Fe minerals formed between 120 and 300 °C, and (2) low-temperature secondary Fe minerals formed under supergene conditions (<100 °C). Measured iron isotope compositions are variable and cover a range in δ56Fe between -2.3‰ and +1.3‰. Primary hematite (δ56Fe: -0.5 to +0.5‰) precipitated by mixing oxidizing surface waters with a hydrothermal fluid that contained moderately light Fe (δ56Fe: -0.5‰) leached from the crystalline basement. Occasional input of CO2-rich waters resulted in precipitation of isotopically light siderite (δ56Fe: 1.4 to 0.7‰). The difference between hematite and siderite is compatible with published Fe isotope fractionation factors. The observed range in isotopic compositions can be accounted for by variable fractions of Fe precipitating from the fluid. Therefore, both fluid processes and mass balance can be inferred from Fe isotopes.

Supergene weathering of siderite by oxidizing surface waters led to replacement of isotopically light primary siderite by similarly light secondary hematite and goethite, respectively. Because this replacement entails quantitative transfer of iron from precursor mineral to product, no significant isotope fractionation is produced. Hence, Fe isotopes potentially serve to identify precursors in ore alteration products.

This iron isotope study illustrates the potential of the new technique in deciphering ore formation and alteration processes. Isotope ratios are dependent on and characteristic of fluid and precipitation histories. Therefore, they are less suitable to provide information on Fe sources. However, it will be possible to unravel the physico-chemical processes leading to the formation, dissolution and redeposition of ores in great detail.
Sodic pyroxene and sodic amphibole as potential micro-analytical reference material for Li isotopes

MICHAEL A.W. MARKS1, ROBERTA L. RUDNICK2, THOMAS LUDWIG3, HORST MARSCHALL4, THOMAS ZACK4, RALF HALAMA2, WILLIAM F. MCDONOUGH2, DETLEF ROST5, THOMAS WENZEL, EDWARD P. VICENZI1, IVAN P. SAVOV6, RAINER ALTHERR3 and GREGOR MARKL3

Two large pegmatitic crystals of sodic pyroxene (aegirine) and sodic amphibole (arfvedsonite) from the agpaitic igneous Ilímaussaq Complex, South Greenland are suitable reference materials for in-situ Li isotope analyses.

Li concentrations [Li] and isotope compositions (δ7Li) determined by SIMS and micro-drilled material analyzed by MC-ICP-MS generally agree within analytical uncertainty. The arfvedsonite crystal is homogeneous with [Li] = 639 ± 51 µg/g (2σ, n = 69, MC-ICP-MS and SIMS results) and a mean δ7Li of +0.7 ± 1.2 ‰ (2σ, n = 10, via MC-ICP-MS) or −0.5 ± 1.1 ‰ (2σ, n = 23, via SIMS). Accordingly, we propose adopting of δ7Li = 0 ‰ for this crystal.

The aegirine crystal shows strongly developed sector zoning, which is a common feature of aegirines. Using qualitative element mapping techniques (EPMA), the homogeneous core of the crystal is easily distinguished from the outermost sectors of the crystals. The core has mean [Li] of 50.5 ± 3.6 µg/g (2σ, n = 33) as determined by SIMS, whereas the seven micro-drilled regions measured by solution MC-ICP-MS returned slightly lower concentrations, between 41 and 46 µg/g. The δ7Li of the core determined by SIMS (−3.4 ± 1.6‰, 2σ, n = 5) is in excellent agreement with the MC-ICP-MS data (−3.7 ± 1.2‰, 2σ, n = 7).

A limited quantity of these two crystals will be available upon request.

Kinetic Li isotopic fractionation in the alkaline plutonic Ilímaussaq complex, South Greenland

MICHAEL A.W. MARKS1, ROBERTA L. RUDNICK2, CATHERINE MCCAMMON1, TORSTEN VENNEMANN3 AND GREGOR MARKL3

1Institut für Geowissenschaften, Universität Tübingen, Germany (michael.marks@uni-tuebingen.de)
2Department of Geology, University of Maryland, USA
3Bayerisches Geoinstitut, Universität Bayreuth, Germany
4Institut de Minéralogie et Géochimie, Université Lausanne, Switzerland

Li concentrations [Li] and isotopic compositions (δ7Li) of mafic minerals (mainly amphibole and clinopyroxene) from the alkaline to agpaitic Ilímaussaq complex, South Greenland, track the behavior of Li and its isotopes during magmatic differentiation and final cooling of an alkaline plutonic system.

[Li] in amphiboles increase with magmatic differentiation from about 10 ppm in Ca-amphiboles of the least differentiated unit to >3000 ppm in Na-amphiboles of the highly evolved units. In contrast, clinopyroxenes are generally low in Li (15 – 84 ppm) and show no systematic variation with differentiation. The most important factors influencing the distribution of Li between these two phases appear to be changes in the major element composition of the minerals and changes in oxygen fugacity during differentiation. δ7Li of all minerals span an extremely wide range from +17 to −8 ‰, with the different intrusive units having distinct Li isotope systematics.

Amphiboles from the inner part of the complex have constant δ7Li of +1.8 ± 1.1 ‰ (n=15) indicating a homogeneous melt reservoir, consistent with their mantle derivation and in agreement with published O and Nd isotopic data. Clinopyroxenes of these samples are consistently lighter, with δ7Liamph-cpx as large as 8 ‰ and are thus not in Li isotopic equilibrium. These light values might reflect late-stage diffusion of Li into clinopyroxene during final cooling of the rocks, thus enriching the clinopyroxene in 6Li.

At the margin of the complex δ7Li increases systematically, from +2 to exceptionally heavy values of +17‰. This, coupled with the observed Li isotope systematics of the granitic country rocks, whose δ7Li dips to −9 ‰ 5 m from the contact and rebounds to +4 ‰ over 100 m away, supports post-magmatic open-system processes occurring during final cooling of the Ilímaussaq rocks. The country-rock profile reflects fluid infiltration from, and Li diffusion out of, the complex. In contrast, the fractionation within the pluton is too large and not of the right shape to represent diffusional loss of Li. Instead, the extremely heavy values reflect the ingress and circulation of an external fluid phase with a high δ7Li value (possibly seawater) along the chilled contact. This study demonstrates the power of Li isotopes in deciphering fluid- and diffusion-governed processes.
Sulfur speciation and metal transport in surface geothermal waters

S.H. MARKÚSSON, A. STEFÁNSSON AND I. GUNNARSSON
Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland (shm@hi.is, as@hi.is, ingvig@hi.is)

Geothermal waters are generally reduced with elevated hydrogen sulfide concentrations. When these waters assent to the surface sulfide mineralization occurs upon cooling, mixing and boiling (phase separation) as well as oxidation. The oxidation of hydrogen sulfide proceeds through a series of complex reactions with the formation of metastable sulfur species including sulfur (S\(^2\)), polysulfides (S\(_n\)), thiosulfate (S\(_2\)O\(_3\)), polythionates (S\(_i\)O\(_{i+}\)), and eventually to sulfate, often resulting in acid waters. The associated metal speciation and transport is largely influenced by the redox chemistry of sulfur.

We have developed methods for on-site determination and/or sample preservation and lab determination of the concentrations of redox sensitive sulfur and selected metal species in geothermal waters using both ion chromatographic and spectrophotometric techniques. In geothermal surface waters associated with basaltic and rhyolitic rocks in Iceland, H\(_2\)S, S\(_2\)O\(_3\) and SO\(_4\) are found to be the dominant forms of sulfur with concentrations up to 73, 22 and 5060 mg/L, respectively, and H\(_2\)S:S\(_2\)O\(_3\):SO\(_4\) molar ratios between 0.0:1 to 1.2:0.7:1. These waters are often enriched in trace elements like Al, Fe, Mn, Cr, V, Zn, Ni and As with concentrations in the range <1-390 mg/L, <1-756 mg/L, 0.04-4.64 mg/L, <0.01-754 µg/L, 7-890 µg/L, 1-698 µg/L, 0.06-1004 µg/L and 0.2-258 µg/L, respectively. The dissolved metals are predominantly transported in the reduced form as simple ions and hydroxide complexes as sulfur containing species.

Combined field and modeling study indicates that the main processes governing the chemistry of sulfur species are H\(_2\)S discharge (flux), H\(_2\)S oxidation via S\(_2\)O\(_3\), SO\(_4\) reduction, and native sulfur hydrolysis. These reactions are sometimes catalyzed by metals and metal surfaces as well as bacteria. Further, the sulfur redox chemistry and metal transport and precipitation are closely linked together.

Trace element composition of metasomatic reaction zones: Insights into the evolution of the slab-mantle interface

M. MAROCCHI\(^1\), J. HERMANN\(^2\), G.M. BARGOSSI\(^3\) AND V. MAIR\(^3\)

1Dipartimento di Scienze della Terra e Geologioco- Ambientali, University of Bologna, Italy (marta.marocchi@unibo.it)
2Research School of Earth Sciences, Australian National University, Australia (joerg.hermann@anu.edu.au)
3Amt für Geologie und Baustoffprüfung, Aut. Prov. Bozen, Kardaun, Italy (volkmar.mair@provinz.bz.it)

The peridotite-gneiss reaction zone may be regarded as a natural window on the processes affecting crust-mantle interaction. A spectacular outcrop of the contact between garnet-peridotite and gneisses is located in the northern side of Mt. Hochwart (Ulten Zone, Italy). The ultramafic body consists of strongly serpentinitized metaperidotites associated to monomineralic zones that developed at the contact between the peridotite body and the garnet gneiss country rocks. The composition of monomineralic zones records an order of metasomatic zoning formed by phlogopite-rich to tremolite- anthophyllite-rich rocks from the host gneiss towards the peridotite. Phlogopite aggregates (phlogopitite) with accessory zircon, tourmaline and Cl-apatite also occur.

Whole-rock geochemistry and trace element (LA ICP-MS) composition of hydrous phases (phlogopite and amphibole) in different metasomatic zones indicate mobility of many elements, including elements such as Ta which are considered to have scarce mobility in fluids. Trace element composition of accessory minerals in the phlogopite-rich zone suggests that the trace element signature of subduction zone fluids may be fractionated in this zone. The progressive depletion in some trace elements (LREE) and enrichment in LILE and Li from the peridotite towards the gneiss suggests a strong influence of bulk composition on the trace element budget of hydrous minerals.

The reaction between mantle and gneissic rocks was enhanced by considerable influx of H\(_2\)O-B-Cl-rich fluids, causing crystallization of hydrous phases and release of a trondjhemitic residual melt. We interpret fluid flow responsible for metasomatism at the peridotite-gneiss contact to have occurred at \(≈700-800^\circ\)C, after the migmatization of crustal rocks and incorporation of the peridotite inside the slab. In this contribution we highlight that the chemical composition of fluids in collisional settings can be substantially modified by metasomatic reactions occurring in the mantle wedge.
Helium and argon solubility in silicate melts: Relationship between solubility and liquid structure

Y. MARROCCCHI¹, M.J. TOPLIS² AND P. BURNARD¹

¹Centre de recherches pétrographiques et géochimiques, BP 20, 54501 Vandoeuvre-lès-Nancy cedex, France (yvesm@crpg.cnrs-nancy.fr; peteb@crpg.cnrs-nancy.fr)
²DTP, UMR 5562, Observatoire Midi-Pyrénées, 14, Avenue Belin, 31400 Toulouse, France (toplis@dtp.obs-mip.fr)

The interpretation of elemental noble gas ratio in magmatic rocks requires the knowledge of the solubility of these elements in silicate liquids and crystals. Argon solubility in silicate melts appears to be controlled by tetrahedral units rather than oxides as previously reported (Marrocchi and Toplis, 2005). This model successfully accounts for reported argon solubility in Al-free systems, in simple Al-bearing systems and in natural liquids. It strongly suggests the link between melt structure and noble gas solubility.

In order to test this predictive model, we computed helium data available from the literature (Jambon et al., 1980; Shibata et al., 1998). As for argon, helium solubility is controlled by the molar silica content, whatever the nature of the network modifying cations. However, we did not observe the two linear segments with a break in slope at ≈ 67 mol% SiO₂ reported for argon (Marrocchi and Toplis, 2005). Such an observation suggests that helium solubility is less sensitive than argon to the polymerization state of the liquid but might be predicted using this parameter. We define partial molar helium solubility of Q₂ (-11.16), Q₃ (-13.87) and Q₂ (-15.11) MMR species as used in the argon model. Such species corresponds to fully polymerized units (Q₄), sheet like units (Q₅) and chain like units (Q₆).

In Al-bearing systems, the nature of the low-field strength cation plays an important role. Determination of helium solubility in such systems is underway in order to define the partial molar helium solubility of the NaAlO₂, Ca₁₋₃AlO₂ and Mg₆₋₄AlO₂ components. Comparison of the He and Ar solubility parameters will allow us to assess differences (if any) between the solubility mechanisms for both gases and thus, develop a predictive model for He/Ar fractionation during magmatic degassing.

Heavy lithium in subducted slabs

HORST MARSCHALL¹, PHILIP POGGE VON STRANDMANN¹, HANS-MICHAEL SEITZ² AND TIM ELLIOTT¹

¹Dep. Earth Sciences, University of Bristol, UK (horst.marschall@bristol.ac.uk)
²Institut für Mineralogie, Universität Frankfurt, Germany

Modelling of the Li budget of subducting oceanic crust during dehydration completed previously [1], suffered from a poor constriction on essential input data, such as the Li isotopic fractionation as a function of temperature, the partition coefficient between metamorphic rocks and fluids and the representative range of Li abundances and Li isotopic compositions of altered oceanic crust (AOC) and sediments. These values have been quantified since [2,3,4,5] and were used in this study to revisit the impact of dehydration on the Li isotopic composition of AOC. The results show that dehydration can account for a decrease in δ⁷Li of only ≤3‰, including the entire prograde metamorphic process up to the unhydrous eclogite stage. Dehydration can, therefore, not account for light Li in high-pressure metamorphic (HPM) rocks. Eclogites in subducting slabs are predicted to contain Li at MORB-like concentrations and to be moderately enriched in the heavy isotope. The fore-arc mantle will be strongly enriched in Li with a heavy Li isotopic composition.

We analysed Li abundances and Li isotopic compositions of 56 orogenic HPM rocks from 8 different localities. The investigated samples (together with eclogite samples from [1]) show a wide range in Li abundances from 1 to ~50 µg/g (one sample 77 µg/g). Li isotopic compositions of the rocks display both very heavy (δ⁷Li > 6‰) and very light (δ⁷Li < 0‰) compositions, as low as -21.9‰. However, the δ⁷Li histogram displays a strong peak between 0 and +4‰.

Li abundances in excess of 20 µg/g in orogenic HPM rocks of basaltic composition (eclogites) can only be explained by addition of Li after the onset of subduction, most probably during eclogitisation or exhumation. Light-δ⁷Li values are probably generated by kinetic fractionation of the Li isotopes during diffusive influx of Li from the country rocks into the exhuming eclogite bodies. The consequence of this hypothesis is that Li found in orogenic eclogites is not representative of rocks within subducting slabs. The investigation of subduction-related HPM rocks has always suffered from retrogression of the natural rock samples during exhumation. In the case of Li, this problem seems to be particularly vicious, due to the high diffusivity of Li, its fluid mobility and its liability to kinetic isotope fractionation. On the other hand, Li and its isotopes may be highly sensitive tools to detect HP and retrograde metasomatism in eclogites and peridotites.

Dust chemistry and accumulation rate in a long-term full-scale heater test at Yucca Mountain, Nevada, USA

BRIAN D. MARSHALL AND ZELL E. PETERMAN
U.S. Geological Survey, MS 963, Denver CO 80225-0046, USA (bdmarsha@usgs.gov)

Yucca Mountain, an eastward-tilted fault block of Miocene-age volcanic rock in southwestern Nevada, is the proposed site for storage of high-level radioactive waste in the USA. The repository would be built within a ~300-meter (m)-thick welded tuff about 200 m above the water table. A full-scale heater test was conducted in a sealed 47.5-m-long, 5-m-diameter drift with concrete invert and partial concrete liner. Steel canister heaters within the drift and borehole heaters on the sides of the drift maintained an in-drift temperature of approximately 200°C for more than 2 years. After 4.2 years of cooling, samples of dust were collected from the upper surfaces of the canister heaters. The amount and composition of the dust, especially the water-soluble fraction, are important factors in understanding the chemistry of the near-field environment in the proposed repository.

Fine dust (~63 micrometers) accumulated on the canister heaters at rates from 0.8 to 4.3 milligrams/square centimeter/year. The major dust components were derived from the host rock (rhyolite), concrete, and oxidized steel. Calcite from limestone aggregate in the concrete constitutes as much as 18 percent. Iron oxides (6 to 9 percent) are derived from the host rock (average 1.0 to 1.8 weight percent of the accumulations beneath partially oxidized steel rock bolts. Water-soluble salts constitute 1.0 to 1.8 weight percent of the dust samples and are enriched in Na+, K+, Ca++, CI-, SO42-, F-, and Br-, and strongly depleted in Mg++, and NO3- relative to dust from ventilated tunnels at Yucca Mountain. The low NO3- in the soluble salts may indicate lack of dust supply to the heated drift via ventilation or may indicate consumption of NO3- through redox reactions that occurred on the canisters or within the wall rock or liner prior to dust fall.

Six of the dust leachates also were analyzed for strontium isotope composition. The samples from canister heaters beneath the concrete liner have 87Sr/86Sr ratios of 0.70930 and 0.70963, indicating derivation of Sr from the liner materials, rather than from the host rock (average 87Sr/86Sr = 0.71715). The four samples under areas with no liner have larger 87Sr/86Sr than the other two, but still lower than the host rock, indicating limited mixing of dust within the heated drift over the 8.3-year isolation period.

This study indicates that dust in the underground environment isolated from ventilation is derived locally from both the host rock and introduced materials. Chemical differences between dust samples and dust from ventilated areas may be due to isolation of the drift and (or) chemical reactions during the heater test.

REE and HFSE mobility from eclogite to amphibolite metamorphism (Vårdalsneset, Norwegian Caledonides)

CELINE MARTIN, STEPHANIE DUCHENE, BEATRICE LUAIS AND ETIENNE DELOULE
1CRPG – CNRS, UPR 2300, 15 rue Notre Dame des Pauvres, BP 20, 54501 Vandoeuvre les Nancy, France (cmar@crpg.cnrs-nancy.fr)

Hf and REE mobility during chemical diffusion and recrystallization controls the resetting of Sm-Nd and Lu-Hf geochronometers during metamorphism. It is therefore interesting to characterize HFSE and REE mobility at different scales - intergranular to outcrop scale - according to pressure, temperature and fluid circulation.

Hf and REE mobility is here exemplified by the retrogression of an eclogitic sample (16 kbars, 670 ± 40°C) into an amphibolitic sample (7.5 kbars, 640 ± 20°C) of identical protolith during Caledonian metamorphism, in the Vårdalsneset area (Western Gneiss Region, Norway). The initial eclogitic paragenesis (garnet, omphacite and rutile) is transformed in the amphibolite into a second paragenesis (amphibole, oligoclase, titanite and ilmenite), where garnets are partially resorbed and rutiles are present as relics.

Elemental data allow to discuss chemical mass balances in each sample and during amphibolitization. In eclogite, more than 40% of Hf but only 10 to 15% of LREE are is within paragenetic minerals. The remainder lies within accessory minerals (zircons). In the amphibolite, accessory minerals (zircons and epidotes) concentrate not only LREE but also Hf (85%). Thus, mass balance indicates mobility of Hf from cardinal minerals in the eclogite to accessory minerals in the amphibolite. Moreover, the increase in LREE contents (+ 20%) from eclogite to amphibolite indicates the contribution of fluids during retrogenesis, and reopening of the Sm-Nd system. By contrast, the HFSE content decreases only slightly (ca. 5%). However, isotopic data show significant difference for Hf between eclogitic isotopic ratio (176Hf/177Hf = 0.282804 ± 6) and amphibolitic ratio (176Hf/177Hf = 0.282620 ± 4). At the outcrop scale, whole rock isotopic ratios scatter from 0.2824 to 0.2828. This may be due either to limited reopening of the system during amphibolitization or to the isotopic heterogeneity of the protolith.

Four garnets fractions (three from the eclogite and one from the amphibolite) show a large variability in both 176Lu/177Hf and 176Hf/177Hf ratios and plot along a straight line. This line can be interpreted either as a mixing line between pure garnet and inclusions (e.g. zircons), or as a record of the reopening of Lu–Hf system. In this case, this alignment describes the reequilibration of Hf in garnet after eclogitic metamorphism, probably due to fluid circulation.
Magmatic timescales using diffusion profiles in olivine from Nea Kameni, Santorini, Greece

V.M. MARTIN¹, D.J. MORGAN² AND J.P. DAVIDSON¹

¹Department of Earth Sciences, Durham University, Durham, DH1 3LE, UK (victoria.martin@durham.ac.uk)
²School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK

Mafic enclaves, interpreted as fragments of replenishing magma batches, are abundant in all the dacitic lava flows of Nea Kameni, Santorini. Periodic replenishment of shallow crustal magma chambers with batches of mafic magma has been widely accepted as a potential eruption trigger. Thus, developing an understanding of the evolution of shallow magma chambers after replenishment, and the duration of any delay between the triggering mechanism and subsequent eruption, represents a significant advance in our ability to predict volcanic activity.

Glomerocrysts and xenocrysts of gabbroic cumulate material are present in a number of the mafic enclaves. Isotopic and chemical disequilibrium between the cumulate crystals and the andesitic host enclaves indicate that these fragments are derived from pre-existing gabbroic crystal mush piles that were pervaded by the replenishing andesitic melts as they migrated to shallow levels, creating disequilibrium between the cumulate mineral cores and the replenishing melts.

High-resolution back-scattered electron (BSE) images reveal that when in contact with enclave magma groundmass, the xenocrystic olivine crystals display narrow (10-30 µm) Fe-Mg diffusion profiles. This diffusion must have occurred after entrainment of the crystals in the replenishing magma, and thus can be used to estimate the interval between entrainment, replenishment and eruption.

Initial modelling of diffusion profiles from more than 60 crystals suggests short timescales, ranging from 6 to 46 days, for the combined migration-replenishment-eruption cycle at Nea Kameni. Such information may prove useful in terms of volcanic hazard prediction and mitigation.

Biogeochemistry of metalliferous peat cores: Distribution of Zn, S, Mn, Fe and dsrAB genes and sulfur and zinc speciation

CARMEN ENID MARTÍNEZ, SOH-JOUNG YOON, CAROLINA YÁÑEZ, NADIA MARTÍNEZ-VILLEGAZ AND MARY ANN BRUNS

The Pennsylvania State University, University Park, PA 16802 U.S.A.

Biogeochemical processes have resulted in the accumulation of elevated concentrations of Zn and S in soils of the Manning peatland region in western New York. Peat cores were collected during dry and wet seasons across a transect of variable Zn concentrations. Element distributions, Zn and S speciation and detection of dsrAB genes were independent of season but related to peat depth. The pH increased with depth. The highest levels of S and Zn occurred at intermediate depths, whereas Mn concentrations were highest in topmost soils. Iron showed relatively uniform vertical distribution profiles. These data indicated vertical redox stratification in peat cores where topsoils were typically acidic and oxidizing and deeper soils were typically circumneutral and reducing. Surface peats contained >50% of the total S in reduced forms while deep peats contained <5% of the total S in oxidized forms. dsrAB gene detection followed redox stratification chemistry in peat cores closely.

Zn-EXAFS analyses of surface peats indicated Zn binds to O/N functional groups of soil organic matter. Zn-EXAFS analyses of deep peats identified ZnS minerals as the primary Zn specie while SEM, S isotopic analyses and synchrotron-based XRD showed that ZnS species occur as framboidal aggregates of biogenic nanocrystallites. We can therefore conclude that exposure to prolonged dry-wet cycles resulted in the formation of two redox stratified zones with distinct chemical and microbiological signatures.
Characterization of carbonate mineral formation by cyanobacteria and the implications in CO₂ sequestration

R.E. Martinez, O.S. Pokrovsky, J. Schott and E.H. Oelkers
LMTG-OMP, Université Paul Sabatier, 14 av. Edouard Belin, 31400 Toulouse, France (raul.martinez@lmtg.obs-mip.fr)

Biomineral-fluid reactions, including dissolution, adsorption, nucleation, and precipitation minerals are key to solving pressing issues such as minimizing the risk of groundwater extraction, optimizing CO₂ sequestration, safe storage of radioactive waste products, and minimization of pollutant transport. Current understanding of the biomineral-fluid interface is only fragmentary. Although we have a good understanding of the reactivity of minerals in abiotic systems little is known about the kinetics and thermodynamics of biomineral fluid reactions. The major limitation of past biomineralization kinetic studies performed in batch reactors to quantify reaction rates is that it is not possible to control many rate influencing parameters, such as pH, solution saturation state, and bacterial activity and biomass. As such it is impossible 1) to determine the effect of each of these rate influencing parameters individually and thus 2) develop robust equations that can be applied to describe these rates in natural systems. These limitations were overcome in the present study by the modification and application of mixed-flow reactor systems to biomineralization.

Results from Synechococcus sp. photosynthetic cyanobacteria in supersaturated calcium carbonate systems presented are used to determine steady-state thermodynamic and kinetic parameters for the development of macroscopic models capable of predicting carbonate bio-mineralization rates as a function of bacterial cell activity/metabolism, biomass, temperature, pH, and pCO₂.

Different plutons, the same feeding zone

H.C.B. Martins, H. Sant’Ovaia and F. Noronha
GIMEF, Geology Dep./Geology Center, Porto University, Portugal; (hbrites@fc.up.pt; hsantov@fc.up.pt)

Multidisciplinary studies integrating petrography, geochemistry, anisotropy of magnetic susceptibility (AMS) studies and gravimetry were carried out on Vila Pouca de Aguiar (VPA) and Águas Frias-Chaves (AF) porphyritic biotite granite plutons which distance ca 20 km one from the other. These plutons are spatially related to Penacova-Régua-Verín fault (PRVF), a late Variscan fault, which belongs to the NNE-trending brittle system that crosscuts the whole of Northern Portugal. VPA pluton is zoned and composed by two main facies: a peripheral biotite-rich medium-grained monzogranite (VPA granite) and a central medium- to fine-grained leucogranite. The AF granite pluton is composed by a marginal coarse-medium grained cordierite-bearing monzogranite (AF granite) and by a central two-mica medium-grained granite.

The modelling of the residual gravity indicates that the shapes from the two granite plutons are quite different: (i) VPA pluton is laccolithic in overall shape, less than 1 km in thickness on 60% of its thickness area; (ii) AF pluton has a greater thickness (~10 km) and is a thicker and deeply rooted body. However gravity data shows a connection of the two gravimetric anomalies. Assuming this connection, a possibility of a relationship between the two plutons was investigated. AMS studies yield magnetic susceptibility averages of 101.0 x 10⁻⁶ SI to VPA pluton and 80.7 x 10⁻⁶ SI to AF pluton. The magnetic anisotropy are quite low and similar, 1.4% to VPA pluton and 1.6 % to AF pluton, confirming their classification as late orogenic (post-tectonic) plutons wich agrees with field data.

The studied granites are slightly peraluminous monzogranites, 1.02<ASI<1.07, and have similar geochemical features (major, trace and REE). However biotite compositions are quite different, namely in content of octahedral Al and XMg wich are higher in AF granites. The tipology features of biotite from VPA granite indicates a sub-alkaline affinity while the biotites from AF granite suggest a aluminopotassic signature, wich are in agreement with the presence of cordierite. These features, the mantle-like isotopic data (Sr₀= 0.704-0.707 and εNd=-1.98 to -2.5) and the available δ¹⁸O (+10 to +11) led us to propose a model of mantle input followed by mantle crust interactions for the origin of these granites, although implying a major crustal contribution for AF granite.

We propose the PRVF as the same feeding zone for the two plutons This fault is also a preferential location for several CO₂ rich thermal water springs, that reach temperatures of 74°C near AF pluton, at Chaves, while in VPA pluton temperature is much lower, 15°C at Pedras Salgadas. A deeper circulation explain the hotter water from Chaves spring, wich is consistent with a deeper root and a thicker shape for AF pluton than for VPA pluton.
Geochemical evidence for extensive carbonate assimilation by CAMP tholeiites from Algarve (S Portugal)

L. MARTINS, J. MUNHA, J. MADEIRA, N. YOUBI, J. MATA and R. KERRICH

1CeGUL, Faculdade de Ciências da Universidade de Lisboa; (lmartins@fc.ul.pt; jmunha@fc.ul.pt; jmata@fc.ul.pt)
2LATTEX, Faculdade de Ciências da Universidade de Lisboa; Portugal; (jmadeira@fc.ul.pt)
3Departement de Géologie; Univ. Cadi Ayyad, Marrakech, Maroc; (youbi@ucam.ac.ma)
4Dept. of Geological Sciences, Univ. of Saskatchewan; Canada; (robert.kerrich@usask.ca)

In the Algarve Basin (S Portugal), Lower Jurassic volcanic successions from CAMP include tholeitic flows, pyroclasts, rare dikes, peperites and volcanic derived sediments. Fine-grained porphyritic carbonate-contaminated lavas coexist in the same sequences with opthic uncontaminated flows. Carbonate contamination is expressed by low SiO$_2$(45.67 to 50.00 wt%), high CaO, Sr contents (12.5 to 20.4 wt% and 235 to 1337 ppm, respectively), and ($^{87}$Sr/$^{86}$Sr)$_{0}$ isotope ratios (0.70665 to 0.70746) relative to those parameters in the uncontaminated rocks (SiO$_2$ = 50 - 53 wt%; CaO = 9 - 12 wt%; Sr = 149 – 233 ppm; ($^{87}$Sr/$^{86}$Sr)$_{0}$ = 0.70539 – 0.70634).

High-CaO rocks also display distinct mineral assemblages, including An-rich plagioclase (An$_{nat}$), olivine (Fo$_{nat}$) and high-Al clinopyroxene (Al$_2$O$_3$ up to 9.1 wt%). Enrichment of Al$_2$O$_3$ in clinopyroxenes (reflecting extensive incorporation of Ca-Tschermak component) correlates with increasing CaO contents of the host rocks, consistent with the mineralogical/geochemical data which indicate a significant decrease of melt silica activity in the high-CaO domains relatively to the typical SiO$_2$ saturated character of the dominant tholeitic magmas.

Binary mixing models (SiO$_2$/CaO vs. 1/CaO; $^{87}$Sr/$^{86}$Sr vs. $^{18}$O/$^{16}$O; $^{87}$Sr/$^{86}$Sr vs. SiO$_2$/CaO; $^{87}$Sr/$^{86}$Sr vs. Sr ppm) indicate that contamination resulted from variable degrees of assimilation of 2-10% of an almost pure Ca-carbonate component. The contaminant component should have had high Sr contents (Sr ~ 6200 ppm) and relatively high $^{18}$O (3% to +25%) and ($^{87}$Sr/$^{86}$Sr) ($>$ 0.70771) isotope ratios, consistent with the chemical characteristics of Visean platform marine carbonates such as those present in the underlying Palaeozoic basement. Significant undercooling by CO$_2$ loss may have increased crystal nucleation rates, producing the fine-grained texture that characterizes the carbonate-contaminated rocks.

Clinopyroxene-liquid geobarometry indicates that the main fractionation occurred at an average depth of 26 ± 4 km, reflecting extensive magma underplating at the Lower Jurassic SW Iberia crust/mantle boundary (promoting assimilation of Visean carbonate basement) during the initial stages of the Atlantic opening.

Monazite preservation and formation during anatexis: An example from garnet-bearing migmatite, Brazil

L. MARTINS, V.A. JANASI and S.R.F. VLACH

Geosciences Institute, Universidade de São Paulo, São Paulo, Brazil (lucemart@usp.br, vajanasi@usp.br and srfvlach@usp.br)

Backscattered images, Y and Th mapping and U-Th-Pb$_{(total)}$ electron microprobe dating reveal complex compositional and age zonings of monazite crystals from a garnet-bearing migmatite (Fig. 1).

Monazite chemistry reflects in part its textural position: late interstitial crystals are Y+HREE-poor and Th+LREE-rich, while crystals included in garnet and biotite are Y+HREE-rich. Cores of leucosome monazite have high Y and HREE, and are similar to mesosome monazite, suggesting that they are inherited, and were not dissolved during the melting reactions because of their textural position. Associated to compositional zones, at least two main age domains (~827 Ma and 645 Ma) could be recognized through in situ U-Th-Pb$_{(total)}$ electron microprobe dating (147 analyses). Monazite cores or Y-rich zones correspond to the oldest ages (827 Ma). Some monazite rims or Y-poor and Th-rich zones can be interpreted as products of anatectic melt precipitation at 600-610 Ma, the age of a well-recognized regional metamorphic event (750°C and 5 kbar). The meaning of some portions with intermediate dates (~670 Ma) and chemical contents is unclear (Fig. 1), and could record partly resolided monazite or reprecipitated domains that incorporated some Pb from the anatectic melt.
**Plume-lithosphere interaction at Santiago Island (Cape Verde)**

S. MARTINS¹, J. MATA¹, J. MUNHA¹ AND N. MATTIELLI²

¹Centro de Geologia, Departamento de Geologia da Fac. Ciências da Universidade de Lisboa, Portugal
(smmartins@fc.ul.pt; jmata@fc.ul.pt, jmunha@fc.ul.pt)
²Department of Earth and Environmental Sciences, Université Libre de Bruxelles, Belgium (nmattiel@ulb.ac.be)

Santiago Island belongs to the southern group of the Cape Verde archipelago which is implanted in old and thick oceanic lithosphere (140-120 Ma). This paper will address elemental and isotopic data for ≤6 Ma Santiago lavas, i.e. those that were formed after the erosive phase which exposed the basal (mainly) intrusive complex.

Santiago samples are ultrabasic alkaline lavas, with Nb and Ta enrichment and significant REE fractionation. Elemental characteristics of primitive lavas indicate complex and variable residual paragenesis including garnet, amphibole and phlogopite. The inferred hydrous residual parageneses are more obvious from geochemical characteristics of recent lavas (<3 Ma), reflecting lithospheric metasomatism by a carbonatic agent, consistent with their lower Ti/Eu, Sc/Ca, Sm/Sr and Pb/Ce ratios and aSIO2 values, as well as included carbonate bearing lherzolitic xenoliths. Santiago lavas exhibit a significant isotopic variation ([87Sr/86Sr = 0.703177 to 0.703907, εNd = -0.4 to 4.5 and εHf = 2.5 to 7.2), implying the involvement of HIMU and EM1 like mantle components, in accordance with the overall isotopic characteristics of southern Cape Verde islands.

Given that the evidence for both hydrous residual mantle parageneses and carbonatic metasomatism are best preserved in the more recent formations, metasomatism should have been developed during previous (>3 Ma) magmatic phases of Santiago building; thus, it is suggested that these features were related to interaction of plume derived magmas with the overlying lithosphere, induced by the intense carbonatite melt reaction/diffusibility through regional lithospheric mantle peridotites. Besides the carbonatic metasomatic component, the relatively low [143Nd/144Nd of Santiago lavas implies an enriched mantle component that must be distinct from typical EM1. This feature strongly suggest the influence of low [143Nd/144Nd, subcontinental lithospheric derived melts (lamproite – kimberlite) in Santiago magma sources. The data demonstrate the variable role of lithosphere to Santiago magma genesis; thus, endorsing the influence of plume-lithosphere interaction on oceanic island magmatism.

This is a contribution of the FEDER/FCT project PLINT (POCTI/CTA/45802/2002) and a PhD scholarship from FCT (SFRH/BD/17453/2004).

**Impact of the late heavy bombardment on Earth**

BERNARD MARTY¹ AND ANDERS MEIBOM²

¹CRPG-CNRS and ENSG, BP 20, 54501 Vandoeuvre Cedex France. (bmarty@crpg.cnrs-nancy.fr)
²Museum National d'Histoire Naturelle, Case Postale 52, 61, rue Buffon, 75005 Paris. (meibom@mnhn.fr)

The Lunar cratering record is consistent with the occurrence of a late heavy bombardment (LHB), which marked the end of terrestrial planet accretion 3.8 billion years ago. At that moment, migration of the giant planets triggered a cascade of icy planetesimals from the outskirts of the solar system (i.e. ≥15 AU from the Sun) to the terrestrial planet formation region [1]. However, clear evidence of a LHB on Earth has not yet been identified. Here we show that the LHB did indeed occur on Earth and that we are breezing its aftermaths. The terrestrial atmosphere and hydrosphere is enriched in noble gases relative to the abundances of volatiles in the mantle. This noble gas composition is a signature of the LHB on Earth and requires a contribution of cold, noble gas-rich bodies formed in the outer solar system. The present day atmospheric composition is consistent with the estimated mass delivered to Earth during the LHB only if it consisted of ~0.5% Kuiper-belt objects mixed in with a population of largely chondritic (i.e. asteroidal) impactors. It seems likely that during the terrestrial LHB, considerable amounts of complex hydrocarbons were also delivered, conceivably providing essential building blocks for the near simultaneous rise of the biosphere

Genesis and the isotopic composition of nitrogen in the solar wind

BERNARD MARTY, LAURENT ZIMMERMANN AND PETER BURNARD

CRPG-CNRS, B.P. 20, 54501 Vandoeuvre lès Nancy Cedex, France; (bmarty@crpg.cnrs-nancy.fr)

The isotopic composition of protosolar nitrogen is a long standing problem in planetary sciences. The goal of the Genesis mission (NASA Discovery class) was to determine the solar isotopic composition of some key elements in order to document the protosolar nebula and, by comparison, to investigate planetary formation processes that have led to the observed isotopic structures in planets and meteorites. Despite the hard landing of the sample return capsule, fragments of targets irradiated by the Sun during 27 months have been recovered and are currently analysed by several teams around the world. We have developed a new NB isotope analytical system in CRPG Nancy. The new line, partly automated, is made exclusively of stainless steel, Pyrex and quartz, and is pumped by fluid-free pumps. Targets were ablated with a UV laser having a wavelength of 193 nm over surfaces up to 1 cm². N₂ was concentrated on Pt at low temperature, then purified over CuO. Noble gases were purified classically in another section of the line. AuS spare targets implanted with ¹⁵N at energies mimicking those of SW N were ablated over surfaces of typically 1 mm² and we obtained a well reproducible recovery yield close to 100 %. The amount of implanted SW N (2 . 10¹² atoms N/cm²) is so low that contamination not only due to the crash but also resulting from target manufacturing is always dominant; Nevertheless, using the measured Ne amount and isotopic composition and the solar wind Ne/N ratio (from spacecraft measurement), we are able to put constraints on the N isotopic composition of the Sun. Results obtained so far suggest a terrestrial-like composition rather than a ¹⁵N-depleted one, which, if confirmed, will lead to a significant change in our view of the distribution of nitrogen isotopes in the solar system.

This study is funded by the Centre National d’Etudes Spatiales (CNES), the Centre National de la Recherche Scientifique, and the Region Lorraine. We are indebted to the members of the Genesis Team, in particular D.L. Burnett, A. Jurewicz, J.J.H. Allton and S. Sestak.

Sulfur isotope geochemistry of sulfdic springwaters at Marche region, central Italy

T. MARUOKA¹, S. GALDENZI² AND J. MATSUDA³

¹Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan (maruoka@ies.life.tsukuba.ac.jp)
²Istituto Italiano di Speleologia, Italy
³Osaka University, Japan

The genesis and development of caves are usually controlled by seepage of meteoric waters supplied from the surface. In contrast, some caves, known as hypogenic caves, are formed by fluids coming from the depth. Hydrogen sulfide is one of the most common gases in the springwaters related to cavern environments and has a great impact on the formation of hypogenic caves. The oxidation of H₂S to H₂SO₄ induces the corrosion of the host rock and the deposition of many secondary cave minerals, like gypsum. Gypsum is observed where the emission of H₂S occurs in limestone caves and at least some portion of the gypsum deposits survives long after its emission ceases (e.g., Galdenzi and Maruoka, 2003). The gypsum deposits are often observed as a crust covered on limestone walls above the watertable. Such vadose gypsum crusts have δ³⁴S values similar to those of H₂S in the springwater (e.g., Galdenzi and Maruoka, 2003), implying the oxidation of H₂S to H₂SO₄ and the reaction between calcite and sulfuric acid occurs above the watertable.

The δ³⁴S values of H₂S in the aquifer reflect the activity of sulfate-reducing bacteria. Therefore, those are not constant through the time. The δ³⁴S_S₂H₂S values in the past can be estimated from the δ³⁴S values of the gypsum in the cave where the emission of H₂S ceases. Therefore, the δ³⁴S_gypsum values of the hypogenic caves can be used as a paleoindicator for environmental factors that influence the activity of the sulfate-reducing bacteria. However, so far it is uncertain what is the primary factor that controls δ³⁴S values of H₂S in the aquifer. To clarify this problem, we determined δ³⁴S values of sulfide and sulfate collected from the springwaters related to hypogenic caves in Marche region, central Italy, and compared them with other parameters. In such parameters, sulfate concentration seems to be the most important factor that influences isotopic fractionation between sulfate and sulfide. Pure culture experiments demonstrated that the extent of isotope fractionation is not affected generally by sulfate concentration at concentrations above 1 mM; however sulfate concentrations in the springwaters studied here ranges from 1 to 18 mM. Therefore, the correlation between isotopic fractionation and sulfate concentration might reflect the difference of bacteria community compositions rather than the response of single bacteria community.

40Ar/39Ar ages of CAMP in North America (Hartford, Deerfield and Fundy basins)

6Laurentian University, Canada
7ESER, USA

The Central Atlantic magmatic province (CAMP) is one of the largest igneous provinces on Earth (>1x106 km3) and spans four continents. Recent high-precision 40Ar/39Ar dating of mineral separates have provided important constraints on the age, duration, and geodynamic history of CAMP (e.g. [1]). Yet, the North American CAMP is strikingly under-represented in this dating effort.

Here we present 13 new statistically robust, mostly plagioclase separates, plateau and mini-plateau ages obtained on lava flows from the Hartford and Deerfield (n=3; USA) and Fundy (n=10; Nova Scotia, Canada) basins. Ages mostly range from 198.6 ± 1.1 to 201.5 ± 1.1 Ma (2σ), with 1 date substantially younger at 190.6 ± 1.0 Ma. Careful statistical regression show that ages from the upper (200.0 ± 2.0 Ma) and bottom (200.1 ± 0.9 Ma) units of the lava pile in the Fundy basin are statistically indistinguishable, confirming a short duration emplacement (<< 2 Ma). These results are in agreement with the minimum duration estimates (> 0.6 Ma) obtained by cyclostratigraphy for the Newark basin CAMP [2]. Three ages obtained on the Hartford (198.6 ± 2.0 Ma and 199.8 ± 1.1 Ma) and Deerfield (199.3 ± 1.2 Ma) basin were measured on sericite from the higher lava flow units. We interpret these dates as reflecting syn-emplacement hydrothermal activity within these units. Altogether, CAMP ages gathered so far (cf. compilation in [1] and this study) suggest a short duration of the main magmatic activity (2-3 Ma), but also address the possibility of a temporal migration of the active magmatic centers (e.g. Nova Scotia at 200.3 ± 0.7 Ma and Brazil at 198.0 ± 0.3 Ma). Such a migration challenges a plume model that postulates a radial outward migration of the magmatism and is more compatible with different models such as the supercontinent global warming hypothesis [3]

A possibly significant age at 191 Ma confirms a minor CAMP late tailing activity (190-194 Ma) already observed for dykes and sills in Africa [4] and Brazil [5]. We speculate that this late activity may be due to a major extensional event, possibly heralding the oceanisation process at ~190 Ma [6].

The model of the four-sub-grate ferrimagnetic

A.V. MASHUKOV, V.V. ONUFRIENOK AND A.E. MASHUKOVA

Siberian Federal University, Krasnoyarsk, Russia
(phys@color.krasline.ru)

There were investigated the magnetic properties of Ferrous sulphides in a metastable phase condition and the change of magnetization of non-stehiometric pyrrotites depending on the concentration of vacancies in their structure. Ferrous sulphides with composition Fe1+xS decrease of magnetization practically to a zero when hardening with the temperature of synthesis. It is shown that the observed effect is explained not only by the redistribution of the vacancies of iron in a base plane of the crystalline structure of the type NiAs, but by the process of the spin flip on the node. For the first time in the frame of the model of the four-sub-grate ferrimagnetic it is given a theoretical description of magnetic transformations in non-stoechiometric ferrimagnetics. For explaining the effect of the ordering of vacancies it is used the method of the secondary quantization. It should be noted that the operators correspond to the quantum statistics of Pauli. The calculations are made considering the interactions between the cation vacancies. It is noted that the appearance of the vacancy interaction is explained by breaking the connections of d-electronic tracks and forming of non-compensated electrical charge on the vacant unit consequently.

Based on the proposed model of the vacancies theoretically possible magnetization depending on the temperature are presented.

**Figure 1:** Theoretical dependence relative magnetization of non-stehiometric ferrimagnetic from temperature.
**Organic Carbon Oxidation State (C_{ox}): A new proxy for the Earth's C and O cycles**

C.A. MASIELLO, W.C. HOCKADAY AND M.E. GALLAGHER

Department of Earth Science, Rice University, 6100 Main St, MS 126, Houston, TX 77005; (masiello@rice.edu)

Carbon oxidation state (C_{ox}) is a basic property of the Earth's carbon pools, and has the potential to be used as a tracer in a broad range of ecological and Earth system questions. It is relevant to questions such as the controls on tracer in a broad range of ecological and Earth system questions. It is relevant to questions such as the controls on tracer in a broad range of ecological and Earth system questions. It is relevant to questions such as the controls on tracer in a broad range of ecological and Earth system questions. It is relevant to questions such as the controls on tracer in a broad range of ecological and Earth system questions. It is relevant to questions such as the controls on tracer in a broad range of ecological and Earth system questions.

**Fig. 1:** Natural variation in C_{ox} values (lower axis) and oxidation state values (OR, upper axis, assuming N from NH_{3}).

C_{ox} varies with 1) initial form of organic matter (e.g. marine vs terrestrial organisms) and 2) degree of diagenesis. On short timescales (decades) precursor organism controls organic pool C_{ox} values. Organism C_{ox} values are themselves likely controlled at a fine scale by ecosystem N status and CO_{2} concentration at the time of C fixation, as well as the history of ecosystem disturbance (Randerson et al., 2006). On longer timescales, degree of diagenesis is at least as important as precursor organism in controlling C_{ox} values.

The utility of C_{ox} is enhanced by its linear relationship with another C cycle parameter, oxidative ratio (OR), defined as ratio of mols O_{2} released/mols CO_{2} fixed by photosynthesis. Currently, the global terrestrial OR value is both unconstrained and required in calculations of the fate of fossil fuel CO_{2} in the environment (Manning and Keeling, 2006). On both long and short timescales, organic matter OR values record the efficiency of the biosphere's production of O_{2}.

³Dept Earth Sciences, University of Bergen, Allegaten 41, N-5007 Bergen, Norway (jan.kosler@geo.uib.no)
⁴Swedish Museum of Natural History, SE-104 05 Stockholm, Sweden (martin.whitehouse@nrm.se)

Convincing stable isotopic evidence for microbial sulfate reduction is limited to only one locality in the early Archaean rock record at the 3.48 Ga North Pole dome in the Pilbara Block (Shen et al. 2001), even though molecular phylogeny suggests it to be one of the most ancient metabolic processes on Earth. Here we studied some of the oldest barite-rich deposits of both hydrothermal and sedimentary origin in the Barberton Greenstone Belt, South Africa, where excess sulfate could have led to significant δ^{34}S fractionation. We focus on samples from the Theespruit formation of the lower Onverwacht group (3.54-3.50 Ga, Kroner et al. 1996). The rocks, from localities at Londozi and Stentor, contain massive barite, chert- and re-worked barite-rich layers of sedimentary origin with abundant pyrite that in places shows petrographic evidence for detrital deposition. Trace elements within the sedimentary pyrites support a low temperature origin with Co/Ni of 0.1 to 1 and low Se/S of <5 x 10^{-5}.

δ^{34}S in bedded and fine grained barite varies between +4 and +6‰, that could represent the isotopic composition to sulfide derived from seawater or an enclosed basin. Pyrite included within and closely associated with the barite, measured by both bulk and in situ techniques, shows δ^{34}S that varies between -4 and -13‰. Individual pyrite grains reveal mass independent fractionation (δ^{33}S) of up to -2‰ consistent with an atmospheric-derived sulfate component. If both barite and pyrite were in isotopic equilibrium then the shift recorded here would match enrichment factors for microbial sulfate reduction in modern sediments (Canfield, 2001). The variations we show here represent the largest amount of fractionation yet found in early Archaean sedimentary sulfides outside the North Pole locality.

Copper addition by organic matter degradation in the freshwater reaches of a turbid estuary (Gironde Estuary, France)

M. Masson¹, G. Blanc¹, J. Schäfer¹, E. Parlanti², P. Le Coustumer³ and A. Dabrin¹

¹University Bordeaux1, UMR 5805 EPOC, Géochimie et Ecotoxicologie des Métaux dans les Systèmes Aquatiques (GEMA), France (m.masson@epoc.u-bordeaux1.fr; g.blanc@epoc.u-bordeaux1.fr)
²University Bordeaux1, UMR 5472, Physico et Toxico Chimie des Systèmes Naturels (LPTC), France
³University Bordeaux1, Géosciences HYdrosciences MAtériaux et Construction (GYHMAC), France

The Gironde Estuary is a macrotidal estuary with a permanent maximum turbidity zone (MTZ) that moves upstream and downstream depending on hydrologic conditions. In 2004, monthly samples have been conducted in the freshwater reaches of the estuary (from the limit of the tidal zone to the beginning of the salinity gradient). In May and September 2005, longitudinal profiles of surface water have been sampled in the freshwater reaches. Additionally, sampling was carried out in the salinity gradient of the estuary in May 2005. Dissolved Cu (<0.2 µm and <0.02 µm) concentrations and C18-Sep-Pak extracted metal-organic complex fractions were analysed. The organic matter (OM) was quantified by measuring dissolved and particulate organic carbon, the dissolved OM was then characterized using 3D-fluorescence and transmission electronic microscopy.

The presence of the MTZ in the freshwater reaches of the estuary induces significant Cu addition, mainly in the “truly” dissolved phase (<0.02 µm). In addition, major transformations of OM (e.g. humification index) were observed in the MTZ which suggests that degradation of fluvial OM plays a strong role in Cu addition. In 2004, dissolved Cu addition (~5 t a⁻¹) represented ~25% of the annual dissolved Cu fluxes entering into the estuary (~21 t a⁻¹). Copper addition occurred mainly in the “truly” dissolved (<0.02 µm) phase, increasing fluxes of hydrophobic (C18-extracted) metal-organic Cu complexes.

Experimental simulations of freshwater inputs into the MTZ were performed by mixing river water with different concentrations of MTZ particles. Important and rapid (inferior to tidal period) Cu desorption followed pseudo-second order kinetics and depended on particle concentration. The amount of Cu desorbed (qₐ) represented ~40% and ~2% for particle concentrations of 20 mg l⁻¹ and 2000 mg l⁻¹, respectively. The relationship between Cu desorption and particle concentration can be described as follows: log (Cu) = a*log(MES) + b. The coefficients a and b obtained for both, the experimentation and in-situ observations were found to be similar. This supports the hypothesis that Cu addition is closely related to particulate OM degradation in highly turbid estuaries.

Origin, migration, fate and impact of hydrocarbon gases from mud structures in the Nile deep sea fan (eastern Mediterranean)

V. Mastalerz¹, G. J. de Lange¹, A Dahlmann¹, T. Feseker² and the NAUTINIL, THE MIMES, AND THE BIONIL SCIENTIFIC PARTIES

¹Faculty of Geosciences, Department of Earth Sciences, Utrecht University, P.O. Box 80021, 3538 TA Utrecht, The Netherlands (v.mastalerz@geo.uu.nl)
²Ifremer, Géosciences Marines, B.P. 70, 29280 Plouzané, France (Tomas.Feseker@ifremer.fr)

At all investigated mud volcanoes in the Nile deep sea fan, not only methane but also heavier hydrocarbons have been measured in the sediment column. At Isis and Amon MV’s the origin of CH₄ is mainly thermogenic with variable microbial contribution. However, in regards to the stable carbon isotopic composition of the heavier hydrocarbons, two distinct thermal source are found for Isis and Amon MV’s.

Gas advection occurs mainly at the centre of the mud structures, while at off centre sites. Moreover, another important process occurring at those mud volcanoes is a downward flow of seawater following each gas expulsion, as indicated by the compositional and isotopic signature of the pore water indicating a pure seawater signature within the upper sediment column.

In the upper sediment section, anaerobic oxidation of methane occurs within the Sulfate-Methane Transition Zone (SMTZ). In addition, major shifts in the δ¹³C and δD of propane and n-butane have been observed in the upper 20 cm of the sediment column. This indicates that these hydrocarbons are also efficient terminal electron donors for sulfate reducing bacteria.

Finally, and despite that microbial filter, enhanced fluxes of hydrocarbons are encountered in the water column, with up to several tens of µmol/L. These gas plumes can extend to several hundreds of meter up in the water column and, for the shallowest mud structures, can even reach the sea surface.
Earth’s mantle Th/U and U/Pb evolution in the Archean

J. Mata¹, R. Kerrich² and M. A. Gonçalves¹

¹CeGUL; Creminer; Dept. Geologia, Faculdade Ciências, Universidade Lisboa, Portugal (jmata@fc.ul.pt; mgoncalves@fc.ul.pt)
²Dept. Geological Sciences, University of Saskatchewan, Canada (robert.kerrich@usask.ca)

The present Th/U ratio of depleted mantle at $\kappa \approx 2.5$ is clearly lower than the time-integrated value as calculated from Pb isotope ratios ($\kappa_{Pb} \approx 3.75$) or the estimates for the $\kappa$ value of the primitive mantle. This Th/U decrease has been ascribed to post-Archean deep-mantle U recycling. However, such models are not compatible with: 1) increasing geochemical evidence severely limiting the amount of recycled U; 2) the Collerson and Kamber (1999) compilation showing that Th/U decrease in the upper mantle started in the Archean, an eon whose anoxic atmospheric conditions were not suitable for U mobilization and subsequent recycling. Archean continental crust formed dominantly from TTG liquids generated by slab melting under higher geothermal gradients. For slab melting, $D_U > D_{Pb}$, such that Archean arc crust has high Th/U and a complementary residual slab was recycled, decreasing mantle Th/U and $\kappa_{Pb}$ down to circa 3.82 and 4.09, respectively. The feasibility of this hypothesis was numerically tested by box-modelling. The obtained results (lines) compare favourably with the observed (black dots) Th/U variation in the upper mantle.

Archean crustal extraction being dominated by slab melting also caused a significant U-Pb fractionation ($D_U < D_{Pb}$) which was responsible by the U enrichment of Archean crust as testified by the relatively high $^{207}Pb/^{204}Pb$ signatures of sediments. The recycling of the complementary low U/Pb residue can explain the Archean $\mu$ decrease from $\approx 9.2$ to $< 8$ inferred from the two-stages model for recent oceanic basalts. In conclusion, the Archean mantle evolution was characterized by Th/U and U/Pb decrease caused by the extraction of continental crust through slab melting.

This is a contribution of the FEDER/FCT project PLINT (POCTI/CTA/45802/2002)

Mineralogy and genesis of Lashak plain clay deposit in the North of Alborz Mountain, Iran

E. Mataji and R. Ansari
Islamic Azad University, Chalus Branch, Iran

The studied area is situated in North of Alborz Mountains. Expound of drainage basin is 75 Km2 and its cirque is 15 km2. The purpose of this study is investigation of mineralogy and genesis of Lashak plain clay deposit. Fifty profiles pedology are provided and three boreholes (360m) are excavated. Pedology profiles are shown three groups of inceptisol, mollisol and alfisol. XRF and ICP analysis show that TiO$_2$ and K$_2$O oxide and Ag, V, Ni, Mo, Cr, Co elements are dominant. Illite, Mica and kaolin are main mineral percentage in the upper top soil. Minerals size is less than 2 micron that originate from bed rock and alluvium deposit. Boreholes sedimentology studies indicate that pasadenian orogeny phase effect on this area and filling cirque since 500,000 years. Usually, boreholes lithofacies is high thickness mud, gravelly mud and muddy gravel. Illite, mica and kaolin are major minerals in the boreholes samples and X-Ray analysis show that their crystalline shape. Chlorite, Smectite, Palygorskite and Nontronite are existed in the samples, occasionally. Abundance of these minerals and lack of sedimentary are shown that basal bed rock changing to clay minerals in a burial stages. Palygorskite subhedral crystalline and Illite as a result upper soil PH and lower aluminum oxide in this area.
Potential utility of Cu isotopes to recognize secondary Cu mineralization and the degree of enrichment

1Department of Geology, Juniata College, Huntingdon, Pennsylvania, 16652 (mathur@juniata.edu)
2Center for Environmental Kinetics Analysis, Department of Geosciences, Pennsylvania State University, University Park, Pennsylvania, 16802 (brantley@essc.psu.edu, awall@geosc.psu.edu, bkimball@geosc.psu.edu)
3Department of Geosciences, University of Arizona, AZ, 85712 (sitley@geo.arizona.edu, fbarra@geo.arizona.edu)
4Departamento de Geologia y Geofisica, Universidad de Chile, Santiago (fmunizaga@cec.uchile.cl, vmaksaev@cec.uchile.cl)

In this contribution we examined the copper isotope ratio of both Cu-oxides and Cu-sulfides from hypogene and supergene mineralization in porphyry copper deposits (PCD). Copper isotope ratios are reported as $\delta^{65}\text{Cu}_{\%} = \left(\frac{^{65}\text{Cu}_{\text{sample}}}{^{65}\text{Cu}_{\text{NIST 976 standard}}} - 1\right) \times 10^3$. Errors for the all analyses are $\pm 0.14\%$ (determined by multiple analyses of the samples) and mass bias was corrected through standard-sample-standard bracketing. Primary high temperature chalcopyrite and bornite (hypogene mineralization) from 15 PCD varied between -0.72 to 0.92‰. In comparison, Cu-chalcocite from 8 enrichment blankets (supergene mineralization) varied between 0.45 to 5.4‰. Although the collected dataset is relatively small (n=54 total minerals analyzed), a distinct pattern shift to heavier copper in supergene samples exists. The heavier copper isotope signature present in the supergene samples is consistent with experimental batch leach experiments. The causes of fractionation could relate to kinetic, biologic, crystallographic and/or equilibrium isotope effects. Regardless of the cause, the magnitude of isotopic fractionation can be modeled using Rayleigh fractionation trends to indicate the degree of leaching that occurred.

The diurnal variation of carbon isotopic ratios of carbon dioxide in human breath

J. Matsuda, T. Maruoka, and S. Maruta

1Department of Earth and Space Science, Graduate School of Science, Osaka University, Japan (matsuda@ess.sci.osaka-u.ac.jp)
2Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba (maruoka@ies.life.tsukuba.ac.jp)

The carbon dioxide of our human breath reflects the digestion and assimilation of our human body and could be a good indicator of our health condition. Dodds (1920) first measured the partial pressure of CO$_2$ in the breath to examine the digestive function. Nowadays, $^{13}$CO$_2$ breath tests are widely carried out using $^{13}$C-labelled compounds. Among them, the most famous one is the $^{13}$C-urea breath test (UBT). This test is very sensitive and safe to check Helicobacter pylori infection. In these tests, infrared spectroscopy is generally used to measure the carbon isotopic ratios.

It is also known that the carbon isotopic ratios reflect those of the diet in our daily life. For example, the carbon isotopic ratios of the hair correlated with the calculated values of the dietary protein on the country where the individual lives (Nakamura et al., 1982). The changes in the carbon isotopic composition of beard samples were 2-3 per mil when German residents traveled to Japan and United States.

In this study, we have examined the diurnal variation of the concentration and the carbon isotopic ratios of carbon dioxide in our human breath using the mass spectrometer ANCA-SL installed in Osaka University. We found that there is about 2.5 per mil variation of carbon isotopic ratios during a day. This variation is rather large, comparing to the beard variation of 2-3 per mil reported by Nakamura et al. (1982). We also carried out the measurement of blood pressure, body temperature, and blood sugar level at the same time. There was no correlation between carbon isotopic ratios and these fundamental data values. Thus it was supposed that the variation of carbon isotopic ratios of the human breath depend on the diet itself rather than the digestion and assimilation inside the human body. To confirm this, we carried out the experiment in case that examinee did not take diet. The variation of carbon isotopic ratios of the breath was only 1 per mil in this experiment. Thus we can conclude that the diurnal variation of 2.5 per mil is mainly attributed to the variation of carbon isotopic ratios of the diet that the examinee took in his human bodies.

Water content variation in low temperature eclogite inferred from the Sesia Zone, Western Alps

KEISAKU MATSUMOTO and TAKAO HIRAJIMA

(keisaku@kuep.s.kyoto-u.ac.jp; hirajima@kueps.kyoto-u.ac.jp)

H₂O derived from dehydration in a subducting slab has important roles in causing various geological/geophysical processes in the subduction zone, such as the island arc magmatism, the enhancement of serpentinization of mantle wedge and the induction of intraslab earthquake. However, the systematics of fluid activity in the subduction zone has not been unraveled yet, such as how much fluid subducts into the mantle, how much fluid is released from the subducting slab, and what kinds of reactions control the dehydration. Due to uncertainties in these fluid activities, there are various perspectives on the nature of subduction system.

We examined the water content variation and the systematics of dehydration reaction in the glaucophanite and eclogite from the Orco Valley area in the Eclogite Micaschist Complex of the Sesia Zone, using the modal analysis and the pseudosection modeling. The application to the conventional geothermobarometry for eclogite yields ca 500°C and 15kb in the southern Orco Valley and 560°C and 17kb in the northern Orco Valley, suggesting that a regional metamorphic gradient (ca 9°C/km) exists in the Orco Valley area.

The result of the modal analysis shows that the eclogites in the southern and northern Orco Valley contain ca 0.9 and 0.8 wt%H₂O, respectively, and the Lws-free glaucophanites in the Orco Valley contain an identical water contents of ca 1.8 wt%. The water content of Lws-bearing glaucophanite is estimated as ca 3.0 wt%. These data suggest that prograde Lws decomposition can supply a significant amount of H₂O (ca 1wt%) from subducting slab by overstepping the Lws decomposition reaction [Lws+Jd/Ab=Czo+Pg+H₂O] at 450°C and 12-13kb. The pseudosection modeling predicts that the water content in the eclogite gradually decreases by a ratio of ca 0.4 wt%/100°C with increasing metamorphic temperature from ca 500 (1.5 wt%H₂O) to 700°C (0.7 wt%H₂O). Therefore, we conclude that a prograde Lws dehydration is a substantial fluid supplier at ca 35-45km depth (12-13kb) in subducting slab.

The metamorphic field gradient of the Orco Valley area is well concordant with the inferred thermal structure along the subducting Philippine Sea slab beneath SW Japan. Recently, the deep low-frequency (DLF) earthquakes and tremors observed at ca 25-45 km depth around the plate boundary below the non-volcanic area of SW Japan. The DLF earthquakes and tremors are considered to be a result in the fluid activity caused by the dehydration in subducting slab. As most of DLF earthquakes and tremors take place at ca 25-45 km depth in SW Japan, where are coincidence with the expected depth of Lws decomposition in SW Japan, we emphasize that the lawsonite decomposition is one of the candidates for causing DLF earthquakes and tremors.

Gravitational trapping of carbon dioxide in deep sea sediments: A geomechanical analysis

J.M. MATTER¹, J.S. LEVINE², D. GOLDBERG¹ and K.S. LACKNER²

¹Lamont-Doherty Earth Observatory of Columbia University, 61 Route 9W, Palisades NY 10964, USA (jmatter@ldeo.columbia.edu, goldberg@ldeo.columbia.edu)
²Earth & Environmental Engineering, 918 SW Mudd, Columbia University, New York, NY 10027, USA (jsl183@columbia.edu, kl2010@columbia.edu)

Carbon dioxide is denser than the surrounding pore water at great depth and relatively cold temperature found in geological formations below the deep ocean floor and thus would be trapped by gravitational forces (House et al. 2006). Gravitational forces will drive the CO₂ from above and below toward the level of neutral buoyancy (Lnb), below which warm CO₂ is less dense than the surrounding pore water and thus will rise and above which the CO₂ is denser than water and thus will sink. CO₂ storage near the neutral buoyancy level is therefore stable. Storage capacity varies with seafloor depth, geothermal gradient, pore water salinity, permeability, and porosity of deep-ocean sediments. Using field data from pelagic sediments from the Atlantic, Pacific, and Indian Oceans, we show how in-situ conditions would affect storage capacity by shifting the level of neutral buoyancy and therefore the sediment depth available for CO₂ accumulation. We also measured permeability and porosity in core samples from relevant sites.

The majority of tectonically stable ocean sediments at the minimum required water depth of 2700m is composed of calcareous sediments or clays. Pelagic clays have very low permeabilities unsuitable for injection. Our data illustrate that pelagic carbonates have low to moderate permeabilities (μD to mD), suggesting that reservoir stimulation techniques such as hydraulic fracturing would be necessary to increase the injectivity. We evaluate the potential for CO₂ injection in calcareous sediments based upon a geomechanical analysis. Young basalts located under pelagic sediments and turbidites may offer attractive alternatives with higher permeabilities for injection.

Ore deposits: An interface between the metallic and light stable isotopes

ALAN MATTHEWS

Institute of Earth Sciences, Hebrew University of Jerusalem, 91904 Israel (alan@vms.huji.ac.il)

The light stable isotopes (H, C, O, S) have proved powerful geochemical tracers of ore deposition processes in a wide variety of areas such as: geothermometry; identifying magmatic-hydrothermal and meteoric hydrothermal fluid systems; sulphide-sulphate fluid equilibria and speciation; the role of bacterial processes. In contrast, the metallic isotopes are most strongly fractionated in chemical sedimentation processes, where the transition metal elements (Fe, Cu, Mo) serve as potential tracers of both biogenic and abiogenic reduction processes and corresponding oxidation reactions. Can these two types of stable isotope system be integrated to promote the understanding of ore deposition processes? Two promising areas appear to be the combination of metallic stable isotopes with sulphur isotopes in sulphide ore mineral deposits and metallic isotopes with oxygen isotopes in oxidized ores. Studies of metal-sulphur isotope covariations are particularly suited to sedimentary ore deposition processes such as banded iron formations, stratiform sedimentary copper deposits, supergene alteration, where they can identify the involvement of bacterial processes and be used to trace redox cycles. However, use of such covariations is not limited to sedimentary processes. Low temperature continental hydrothermal processes, sea-floor hydrothermal systems and even magmatic-hydrothermal systems, may provide unique isotopic signatures. During processes such as supergene oxidation, the combination of metallic isotopes with oxygen isotopes can tell us about the evolution of the fluid-metal system.

One of the potentially important fields for the application of metallic isotopes is the use of speciation-isotope diagrams of the type developed by [1] for sulphur and carbon isotopes. Just as the SO₂–H₂S equilibria potentially control the isotopic composition of sulphide and sulphate minerals in hydrothermal systems, so speciation between oxidized and reduced solution complexes (e.g., Cu²⁺ and CuCl₂⁻) or between oxy- and thio-anion complexes (e.g., MoO₄²⁻ and MoS₂⁻), can help understand the controls of metal isotope compositions in ore deposits.

Examples illustrating the above ideas, taken both from published and our own work, will be presented. Ultimately, the power of metal stable isotopes in ore deposit studies lies in their ability to explore metallic element cycling. Careful combination with the appropriate light stable isotopes can both enhance and refine the insights provided by metal stable isotopes.

OH in mantle olivine: Experiment vs. nature

S. MATVEEV AND T. STACHEL

University of Alberta, Edmonton, Canada.
(smatveev@ualberta.ca; tstachel@ualberta.ca)

Olivine is the principal rock-forming mineral in the mantle lithologies. Its effect structure depends on conditions of crystallization or re-equilibration and thus can be used as an indicator of magmatic and metasomatic processes. Protonated defect structure of olivine, i.e. defect structure in which cation vacancies are charge-balanced by H⁺ bonded to oxygen, is conventionally studied using FTIR (Fourier Transform Infra Red) spectroscopy. It has been shown experimentally that the frequency of OH IR absorption bands depends on a number of parameters, the most important of which have been proposed to be: aSiO₂, aTiO₂, and O₂. Variation of these parameters may have similar effects on OH IR absorption, hampering interpretation of the spectroscopic results.

In order to isolate the major parameters controlling OH IR absorption at the conditions of the lithospheric mantle we studied olivines from mantle peridotitic xenoliths and kimberlitic phenocrysts using FTIR and EPMA. We did not observe correlation between OH IR absorption and TiO₂ content in olivine. Atomic proportion of H typically exceeds atomic proportion of Ti. We assume that Ti does not control the position and concentrations of H in olivine from the lithospheric mantle.

At increasing fO₂, concentration of ferrous iron increases and one anticipates stabilization of hydrous defects associated with Fe³⁺ (lower frequency OH IR absorption). However, spectra indicative of OH associated with Me²⁺ were measured in olivines from contrasting fO₂ environments: spinel peridotites, relatively reduced diamondiferous garnet peridotites, as well as kimberlitic pheno- and xenocrysts. Thus at relatively oxidized conditions of the lithospheric mantle fO₂ does not significantly affect OH occurrence in mantle olivine. At the same time reduced conditions of the adiabatic upper mantle may cause preferential stabilization of the hydrogarnet-type defects (higher frequency OH IR absorption) rather than defects associated with Me²⁺. Hydrogarnet-type defects are significantly more capable of storing OH. In that case oxidation of mantle material at the asthenosphere can cause partial dehydrogenation of olivine and thus assist melting.

We propose that the primary factor controlling OH solubility in olivine at conditions of the lithospheric mantle is aSiO₂. Peridotitic olivine in equilibrium with orthopyroxene (high aSiO₂) should show lower frequency OH IR absorption bands. However many olivine samples from mantle xenoliths show higher frequency OH IR absorption bands suggesting that these samples are not in equilibrium with orthopyroxene. This implies that a significant proportion of available mantle material may have been modified by transporting melts and/or metasomatic fluids, which were characterized by lower silica activities.
Zircon growth and recycling during the assembly of the Tuolumne Batholith, Sierra Nevada, California

J. MATZEL1, R. MUNDIL1, J.S. MILLER2, J. WOODEN3, F. MAZDAB3, S. PATERSON4 and V. MEMETI4

1Berkeley Geochronology Center (jmatzel@gmail.com; rmundil@bgc.org)
2San Jose State University (Jonathan.Miller@sjsu.edu)
3US Geological Survey (jwooden@usgs.gov, fmazdab@usgs.gov)
4Univ. of Southern California (paterson@usc.edu, memeti@usc.edu)

The Cretaceous Tuolumne Batholith represents a classic example of a large (~1200 km²), compositionally zoned pluton and provides a natural laboratory for the study of magmatic processes. Eruptions of large volumes of felsic magma demonstrate that large magma bodies exist in Earth's crust, but the geochemical and geophysical path that links these large magma volumes to the frozen remnants of magma input (plutons) is still obscure. Deciphering the intrusive record of magma systems is essential to understanding the relationship between surface volcanism and the long-term storage and evolution of magma reservoirs. U-Pb zircon TIMS analyses from several locations in the batholith exhibit appreciable dispersion of single crystal or crystal fragment ages (several 10⁷ yrs to 1x10⁸ yrs) and, in addition, display distinctly older ages that likely represent zircon crystals entrained from older parts of the Tuolumne magmatic system. Since techniques aimed at eliminating Pb loss (and thus age scatter) have been employed prior to analysis, we interpret the age dispersion to reflect real variation in the timing of zircon crystallization. Two samples that show a high degree of age dispersion (> 1 Myr) were selected for trace element analysis and Ti-in zircon geothermometry by SHRIMP-RG. Crystallization temperatures ranged from 780-640°C and averaged 695°C (Δν102 ~ 0.75 based on presence of titanite). No clear correlation exists between crystal age and temperature. In most cases, the temperatures from crystal centers were within uncertainty of the temperatures at the rims or show a slight core to rim decrease in temperature. Trace element ratios vary systematically with temperature (e.g. decreasing Th/U ratio with decreasing T) and are attributed to fractionation, although neither sample represents strongly fractionated melt. Low total Zr indicates that the magmas were initially undersaturated in zircon when emplaced, which is also consistent with late zircon crystallization. Entrainment of zircon from older parts of the magmatic system occurred late in the history of the batholith, and recycling of zircon crystals during successive magmatic injections is compatible with progressive growth of a large, long-lived, crystal mush body. Similar studies, applied to magmatic systems where both the plutonic sources as well as the volcanic products can be studied, are expected to shed further light on linking the former with the latter.

On the primitivity of the Wild 2 cometary dust

M. MAURETTE1, G. KURAT2 and C. ENGRAND1
1CSNSM, Bat.104, 91406 Orsay-Campus, France (maurette@csnsm.in2p3.fr)
2University of Vienna, Althanstrasse 14, A-1090, Vienna, Austria (gero.kurat@univie.ac.at)

We were impressed by the analytical results obtained by 183 scientists on a 0.2 μg of dust from the Wild 2 comet (W2-dust) returned by Stardust [1]. What is less impressive is the way the data are interpreted and sold as a "big surprise".

We already argued that the unmelted chondritic dust recovered from the stratosphere and polar ices and snows (micrometeorites or MMs) that we and many other analyzed are cometary dust particles. In 1998, we thus pointed out that cometary dust particles would be similar to MMs, being made of a material related to the CM-type hydrous-carbonaceous chondrites containing refractory phases, kerogen, and being depleted in chondrules [2]. This "ordinary" dust was formed in the inner solar system and then forwarded to the outer solar system by huge surges of nebular gas [3].

The W2-dust analyses confirm these earlier deductions because they establish strong similarities with MMs for: (i) the abundance of Ca-Al-rich inclusions and pre-solar grains; (ii) the H, C, N, and O isotopic compositions; (iii) the chemical composition of the refractory magnesian silicates and of Fe sulfides. These similarities imply that hydrous silicates must also be present in the W2-dust, and that they should be dominated by saponites, which are the major hydrous silicates of unmelted MMs. However, the Stardust team repeatedly emphasized that "hydrous silicates are missing" in the W2-dust. The fate of these missing silicates, which is not discussed, is just pictured in the bulb-shaped aerogel track reported on the cover page of Science [1]. It documents the microscopic explosion of a dust particle containing saponite during its μs deceleration in the aerogel. Only the most massive and refractory particles can be found at the termini of the tracks.

Indeed, saponite contains both OH groups and very labile H₂O, which starts to be released at about 100°C. Consequently, it should be "instantaneously" released during the pulse heating of the particles and form an explosion bulb in the aerogel – with the result that saponite is now missing. In contrast, "dry" crystalline particles produced "carrot"-shaped tracks.

Insights on the enriched isotopic nature of Proterozoic dyke swarms in the Northeastern Superior Province

CHARLES MAURICE1,2, JEAN DAVID1, JONATHAN O’NEIL2 and DON FRANCIS2
1Bureau de l’exploration géologique du Québec, MRNF, 400 Boul. Lamaque, Val d’Or, QC, J9P 3L4, Canada (charles.maurice@mrnf.gouv.qc.ca)
2Earth and Planetary Sciences, McGill University, 3450 University St., Montréal, QC, H3A 2A7, Canada (donf@eps.mcgill.ca; oneil_jo@eps.mcgill.ca)

The origin of the enriched signature commonly seen in continental flood basalts has fueled a long standing debate about the relative roles of sialic crust and lithospheric mantle in the contamination of asthenosphere-derived magmas. Many Proterozoic mafic dykes have the chemical characteristics of continental flood basalts (CFB), displaying light rare earth element and large ion lithophile element enrichments relative to primitive mantle, associated with depletions in Nb and Ta relative to Th and La.

Many Proterozoic mafic dykes have the chemical characteristics of continental flood basalts (CFB), displaying light rare earth element and large ion lithophile element enrichments relative to primitive mantle, associated with depletions in Nb and Ta relative to Th and La.

In the Northeastern Superior Province of Canada (NESP) numerous mafic dyke swarms range in age between 2.51 and 2.00 Ga, with many being ca. 2.21 Ga. The mafic dykes that cut the isotopically-juvenile Archean crust ($T_{DM} = 2.8-3.1$ Ga) of the Riviere Arnaud Terrane in the North have lower La/Nb and Th/Nb ratios, and positive $\varepsilon$Nd values (+4.2 to +0.4). In contrast, the mafic dykes in the older crust ($T_{DM} = 2.9-3.8$ Ga) of the Hudson Bay Terrane, to the South and West, have higher La/Nb and Nb ratios and Th/Nb ratios, and low to negative $\varepsilon$Nd values (+0.5 to -10.5). These differences are independent of age, but rather coincide with the nature of the crust and lithosphere in which the mafic dykes were emplaced. Although enriched alkaline basalts occur along the periphery of the NESP craton (Kenty Lake; 1.96 Ga) and alkaline lamprophyres intrude the craton (Lac Aigneau dykes; 1.94 Ga), these rocks cannot represent the enriched component seen in the mafic dyke swarms, because they are characterized by low La/Nb and Th/Nb ratios coupled with positive $\varepsilon$Nd values (+3.7 to +0.5). These differences are incompatible with the involvement of a lithospheric component in the petrogenesis of the mafic dyke swarms of the NESP and suggest a significant role for old enriched Archean crust ($\varepsilon$Nd$_{3.0 Ga}$ -1 to -20).

Geochemical, lithologic and biotic variations of the K/P boundary record, implications for seiche-like movements as causal factors in the observed mix-up

FLORENTIN MAURRASSE
Department of Earth Sciences, FL International University, Miami, Florida 33199;USA; (maurrass@fiu.edu)

A comparison of temporal and spatial distribution of iridium and various stable isotope records [e.g.1, 2]; in marine deposits affected by the K-P bolide impact, c. 65.0 Ma [3, 4] shows wide discrepancies indicative of unusual conditions of sedimentation. Similarly, the boundary zone displays heterogeneities in texture and microfossil contents, even within short distances of a given basin, as faunal mixing has been, indeed, the hallmark of the boundary layer worldwide. Furthermore, the boundary zone displays considerable variation in thickness within a same area, and most importantly it also includes consistent delicate primary sedimentary structures such as cross-lamination, and rip-up clasts.

These features may occur irrespective of the paleodepths of the basins. Repetitive occurrences of these primary sedimentary structures indicate vigorous multiphase subaqueous flow processes of cohesionless particles. The complexity of the structures together with reversal of directional pattern is consistent with structures related to oscillatory movements [5].

Thus, shock waves generated by the impact and subsequent major crustal readjustments not only triggered tsunamis [6,7], but they apparently generated oscillatory waves such as those observed in seiches, a phenomenon not yet studied in present deep ocean basins. This mechanism may explain the effects of exceptional subaqueous flow processes that led to the sedimentological, faunal and geochemical discrepancies observed at the K-P boundary.

**In situ fluid inclusion analysis: Why bother?**

JOHN MAVROGENES\(^1,2\)

\(^1\)Research School of Earth Sciences, the Australian National University, Canberra ACT 0200, Australia

\(^2\)Department of Earth and Marine Sciences, the Australian National University, Canberra ACT 0200, Australia

In situ studies of solutions in fluid inclusions, both natural and synthetic, are becoming increasingly popular, mostly due to technical advances in recent years. We are now, for the first time, able to directly measure inclusions of hydrous fluids, as well as silicate, sulfide, carbonatite and salt melts. Synchrotron XRF and PIXE allow elemental compositions of individual inclusion, but are strongly dependant upon independent estimates of inclusion geometries and depths. LA-ICPMS provides high precision elemental ratios of inclusion compositions, but requires a priori knowledge of one element within each inclusion as an internal standard. Thus synchrotron XRF, PIXE and LA-ICPMS all have specific difficulties that are rarely admitted publicly.

Synchrotron absorption studies provide the only means to measure oxidation states and bonding within inclusions at high P and T. This technique, although not straightforward, is likely to be the only way to directly measure molecules in melts and hydrous solutions. The small sample size of individual fluid inclusions, however, may limit how much information we can extract from them. Hydrothermal cells and diamond anvils may provide better data due to longer path lengths through solutions, but absorption by window materials may be a limiting factor here.

We are only now getting to the point where we can routinely measure inclusion compositions. But what will we really learn with this new capability? If one cannot connect a specific inclusion to a geological event, what is the point? So far, most studies have concentrated on highly saline brines, which contain very high metal contents. However, most ore-forming fluids contain very low levels of dissolved metals, and until we can detect these, we may not be unravelling ore-forming processes, which is our obvious goal.

**Characterisation of Methanotrophic bacteria in volcanic soils through time-series \(^{13}\)CH\(_4\) PLFA labelling**

P.J. MAXFIELD\(^1\), E.R.C. HORNIBROOK\(^2\) AND R.P. EVERSHEDET\(^3\)

\(^1\)Organic Geochemistry Unit, Bristol Biogeochemistry Centre, School of Chemistry, University of Bristol, Cantock’s Close, Bristol, BS8 1TS, UK (r.p.evershed@bristol.ac.uk)

\(^2\)Bristol Biogeochemistry Research Centre, Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queens Road, Bristol BS8 1RJ, UK (ed.hornibrook@bristol.ac.uk)

Methanotrophs are a unique group of microorganisms in the Earth system acting as both a sink for atmospheric CH\(_4\) (high affinity methanotrophs) and a robust barrier against CH\(_4\) flux to the troposphere from anoxic environments (low affinity methanotrophs). As they have yet to be successfully cultured few details are known about high affinity methanotrophs with the main evidence supporting their activity from indirect CH\(_4\) oxidation rate studies. Moreover, the fate of methanotrophically fixed carbon in the extensive range of natural and anthropogenic environments that they inhabit is unknown.

Through the use of compound-specific \(^{13}\)C stable isotope analysis of microbial biomarker PLFAs we have simultaneously assessed high affinity methanotropic biomass and taxonomic identity from a range of different mineral soils under atmospherically relevant CH\(_4\) concentrations (Maxfield et al., 2006). This paper presents the first detailed investigation of high affinity methanotrophs in volcanic soils (andisols) from Tenerife. The results show substantial levels of \(^{13}\)C incorporation following incubation under 2 ppmv \(^{13}\)CH\(_4\), indicating an extremely high abundance of methanotrophic bacteria in these environments. This suggests that Andisols, a previously unstudied soil class with respect to methanotrophic bacteria, may oxidise significant amounts of atmospheric methane despite their low areal coverage globally. The preliminary fate of methane-derived carbon in soils will also be considered, as will the relationship between these findings and previously studied temperate soils (Evershed et al., 2006).

The structure of REE aqua and chloroaqua complexes in hydrothermal fluids

ROBERT A. MAYANOVIC1, ALAN J. ANDERSON2, WILLIAM A. BASSETT3 and I-MING CHOU4

1Missouri State University, Springfield, MO (robertmayanovic@missouristate.edu)
2St. Francis Xavier Univ., Antigonish, Nova Scotia, Canada (aanderso@stfx.ca)
3Cornell Univ., Ithaca, NY (WAB7@cornell.edu)
4MS 954, U.S. Geological Survey, Reston, VA (imchou@usgs.gov)

Our understanding of the association of rare earth ions with ligands common in the Earth’s crust (e.g. chloride, fluoride, phosphate, and carbonate ions) at elevated pressures (P) and high temperatures (T) is incomplete. Data on the stability and structure of REE ion complexes at elevated P-T conditions are necessary in order to understand fully the geochemistry of hydrothermal rare earth mineralization. We discuss structural data for several rare earth ions measured using synchrotron x-ray absorption spectroscopy (XAS) in aqueous solutions under elevated P-T conditions on the PNC-ID 20 beam line at the Advanced Photon Source, Argonne National Laboratory. Analysis of XAS spectra measured from Eu3+, Gd3+, and Yb3+ ions, at concentrations ranging from 0.006 to 0.07 m in 0.16 m HNO3 aqueous solutions, shows that the number of H2O ligands of the Gd3+ aqua ion decreases at a rate (0.41/100 °C) which is roughly half of the rate of H2O-ligand reduction for the Yb3+ aqua ion (0.84/100 °C) and for the Eu3+ aqua ion (0.77/100 °C) over the 25 to 500 °C temperature range. These results suggest that the Gd3+ aqua ion is more thermodynamically stable than the Yb3+ and Eu3+ aqua ions. We conjecture that this may be due to the tetrarad effect, as evidenced in a strengthening of the bonding of aqueous ion complexes derived from enhanced quantum mechanical interelectronic repulsion energy of the half-filled 4f electronic shell configuration of the Gd3+ ion. XAS measurements of Nd3+, Gd3+, and Yb3+ ions, at concentrations ranging from 0.006 to 0.1 m in low pH chloride (0.02 – 0.3 m) aqueous solutions reveal that significant association between these REE ions and the chloride ligand occurs in the 300 to 500 °C temperature range forming stepwise inner sphere chloroaqua complexes of the type REE(H2O)δ− nCl+n−δ+, where δ = 7 – 8 and the number of Cl− ligands (n) increases steadily with temperature from an average of roughly 0.5 to a value close to 2. This demonstrates that chloride species may be important for transport of REE in low pH chloride-bearing hydrothermal fluids at elevated temperatures (300 to 500 °C). Our results are found to have negligible pressure dependence for the pressure range of this study. The structural results for the REE chloroaqua complexes under elevated P-T conditions are discussed in terms of variability (or lack thereof) across portions of the REE series.

Identifying sources of riverine sulfate by combining hydrological, chemical and isotopic approaches

BERNHARD MAYER
Department of Geology & Geophysics, University of Calgary, Alberta, Canada T2N 1N4 (bmayer@ucalgary.ca)

A series of case studies will be presented in which sulfate in surface water systems was sampled frequently, 34S and δ18O values were obtained, and interpreted in conjunction with hydrological and chemical data. Using this approach in selected forested headwater catchments in New Hampshire, New York, and Vermont (USA), it was demonstrated that a significant portion of stream water sulfate during base flow was derived from weathering of bedrock, particularly in catchments with sulfur-rich lithology. During storm events after a dry summer season, sulfate concentrations in stream water increased significantly and δ34Ssulfate decreased to minimum values in some catchments. This suggests that sulfate derived from oxidation of sulfide minerals, e.g. in wetland areas or the hyporheic zone, contributed to the increased sulfate load in these streams following storm events. Monitoring of stream water during spring snowmelt events at the Sleepers River Research Watershed (Vermont, USA) revealed elevated contributions of sulfate from pedospheric sources, but little direct contribution of sulfate from the melting snowpack.

Investigations in two large watersheds in the Rocky Mountains of Alberta (Canada) indicated that riverine sulfate in headwaters was mainly derived from evaporite dissolution. In the agriculturally dominated downstream portions of the watersheds, oxidation of pyrite in tills was identified as an additional source of riverine sulfate evidenced by increasing sulfate concentrations and decreasing δ34S values. Using a combination of hydrological, chemical and isotopic approaches, it was also demonstrated that urban centers, such as Calgary in southern Alberta, had a significant impact on riverine sulfate loads that was evident from the distinct isotopic composition of sulfate released from the waste water treatment plant.

In watersheds with forested, agricultural and/or urban land use, there is a variety of natural and anthropogenic sources of riverine sulfate. The relative contributions of these sources to sulfate in rivers and streams can vary significantly depending on hydrological conditions that have distinct seasonal patterns. To identify these different sources and to assess their relative contributions, it is essential to determine the isotopic composition of sulfate from spatially distributed sites along headwater creeks, rivers or streams under different hydrological regimes. These isotopic data, when combined with hydrological and chemical results, provide information that can be used to markedly improve the quantification of riverine sulfate sources.
The geochemistry, mineralogy and consideration of AMD of Karmozd coal mine and Zirab coal cleaning factory, Mazandaran, Iran

S.A. MAZAHERI AND M. GHOLIPOUR
Geology Department, Faculty of Sciences, Ferdowsi University of Mashhad, Mashhad 91775-1436, Iran. (mazaheri@ferdowsi.um.ac.ir)

The Karmozd mine and Zirab coal cleaning factory in Mazandaran Province are one of the largest and oldest coal extraction and coal concentration in Central Alborz Coal Basin. These coals are classified as low sulphur, low ash coals. Mineralogy and geochemistry studies show that excluding P2O5, all other main oxides are related to the minerale within the coal layers. The concentration of some major, trace and rare elements such as Ti, Mn, Sr, Ba, Nb, Ce, Zr, Rb, V, Cr, Co, Ni, Cu, Zn, Pb, Mo, W, Th, and U in Karmozd are much more higher compared to the most coals in the world.

Two types of drainage exists in Karmozd: Acid drainage of Mg-SO4 type (pH≈4.59) and alkali drainage of Na-HCO3-SO4 type. Hydrogeochemistry modeling indicates that minerals such as jarosite, alunite, iron and aluminum oxides and hydroxides are basically oversaturated, whereas carbonate minerals like calcite, dolomite and aragonite are undersaturated. Bledite and secondary minerals are formed in arid seasons due to evaporation of hydrosulphate solutions. The river water tends to change from Ca-HCO3 type to (Na-Ca-Mg)-HCO3-SO4 type in arid seasons. Potential consideration of water shows that in acid mine drainage: EC, TDS, SO4, PO4, NO3, Mg,y) Fe, Sr, As, and Mn and in neutral to alkali mine drainage (as well as seepage water from tails and coal cleaning factory) SO4, PO4, Ca, As, Sr, Sb and Bi are more than standard value, which may leads to surface and underground water pollution in this region.

According to acid mine drainage management standard methods, limestone pond is suggested in order to control AMD in Karmozd. However, because the Zirab coal cleaning factory tail dumps are discharged in the riversides, using precipitation ponds and constricted wetlands seems to be suitable controls.

Carbon dioxide degassing and estimation of thermal energy release from volcanic lakes

A. MAZOT1, A. BERNARD2 AND Y. TARAN1

1 Instituto de Geofísica, Universidad Nacional Autónoma, Ciudad Universitaria, 04510 Coyoacán, D.F., México (amazot@geofisica.unam.mx)
2 Department of Earth and Environmental Sciences, CP 160/02, Université Libre de Bruxelles, 50 Ave. Roosevelt, 1050 Brussels, Belgium (abernard@ulb.ac.be)

Introduction

Periodical surveys are carried out in geochemistry since 1993 to understand the hydrothermal system of Kelud volcano (Indonesia). The last eruption of Kelud volcano was occurred in 1990 and it contains a crater lake with near neutral waters (pH≈6): a part of CO2 is dissolved as bicarbonates, and another part of CO2 escape through the lake as bubbles and by diffusion to the surface.

CO2 flux degassing

From 2001 to 2006, measurements of CO2 flux emitted by the surface of the lake were performed by using the accumulation chamber method (Chiodini, 1998) modified in order to work at the surface of a crater lake. Two statistical methods were used to process data: the graphical statistical approach (Sinclair, 1974) and stochastic simulation methods (Deutsch and Journel, 1998). The results of graphical statistical approach permit to quantify the different degassing processes that are acting at the lake surface: one corresponding to CO2 fluxes resulting from rising bubbles close to the lake shore (from 2633 to 9072 g/m2/d); the second corresponding to CO2 fluxes from rising bubbles in the middle of the lake (from 478 to 945 g/m2/d); and the last corresponding to equilibrium diffusion of dissolved CO2 at the water-air surface (from 151 to 209 g/m2/d). Total CO2 emission rate estimated by stochastic simulation ranges from 105 t/d for 2001 to 35 t/d for 2006.

Thermal energy

Thermal energy released by the lake was estimated by using physical characteristics of the lake and meteorological data (wind speed, rainfall rate). The results of gases analysis and CO2 fluxes have provided a new constraint in the quantification of the input of steam and brine from the hydrothermal system. The thermal flux decreased from 200 MW (2001) to 60 MW (2006) and estimated inflow steam from 12 to 4 kg/s and inflow brine from 429 to 235 kg/s.

References

Provenance studies, which provide crucial insight into crustal evolution and palaeogeography, are particularly important in deformed and metamorphosed cover sequences that may be displaced during orogeny thereby obscuring the link with their original basement. Of the various sedimentary provenance techniques available (e.g. whole-rock major and trace element analyses and single grain U-Pb zircon dating), none can be described as the definitive tool and as such integrated, multi-method approaches are necessary.

This contribution presents the first in situ ion microprobe U-Pb study of detrital titanite, applied in conjunction with petrography, whole-rock Sm-Nd and U-Pb detrital zircon data. These techniques were used to investigate the provenance of two enigmatic, probable Neoproterozoic, metasedimentary cover sequences in the Inner Hebrides, SW Scotland – the Colonsay Group, which unconformably overlies the Palaeoproterozoic Rhinns Complex on Islay and the Iona Group, unconformably overlying Archaean Lewisian gneisses on Iona. U-Pb detrital zircon data point to the Rhinns Complex (c. 1780 Ma) as the major source of both successions and are consistent with whole-rock Sm-Nd data. Detrital titanite data, for the most part, support predominant derivation from the Rhinns Complex, but yield younger maximum ages, for the most part, support predominant derivation and are consistent with whole-rock Sm-Nd and U-Pb detrital zircon data. These techniques were used to investigate the provenance of two enigmatic, probable Neoproterozoic, metasedimentary cover sequences in the Inner Hebrides, SW Scotland – the Colonsay Group, which unconformably overlies the Palaeoproterozoic Rhinns Complex on Islay and the Iona Group, unconformably overlying Archaean Lewisian gneisses on Iona. U-Pb detrital zircon data point to the Rhinns Complex (c. 1780 Ma) as the major source of both successions and are consistent with whole-rock Sm-Nd data. Detrital titanite data, for the most part, support predominant derivation from the Rhinns Complex, but yield younger maximum depositional ages of c. 942 Ma and c. 1482 Ma for the Colonsay and Iona groups, respectively. One sample (from the Dun Gallain Grit Formation of the Colonsay Group) exhibits a markedly different titanite age distribution to that of the zircon, with a pronounced peak at c. 1.0 Ga. This difference could reflect additional source contributions, lacking in zircon but containing titanite. Alternatively the titanite may be recording metamorphic events in the source(s). As detrital titanites from this sample are found overgrowing ilmenite (implying a metamorphic origin) the latter explanation seems more plausible. The pronounced peak at c. 1.0 Ga suggests that these titanites are recording Grenville events in the source(s).
Kaersutite in the Chassigny martian meteorite: How much water?

Francis M. McCubbin¹, Hanna Nekvasil¹, Alexander Smirnov² and Donald H. Lindsley¹

¹Department of Geosciences, Stony Brook University, Stony Brook, NY 11794-2100; (fmccubbi@ic.sunysb.edu)
²Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Rd., N.W, Washington, DC 20015

Kaersutite (Ti-rich amphibole) occurs within olivine-hosted polyphase melt inclusions within the Chassigny martian meteorite. Extensive work has been conducted to assess the compositional characteristics of this mineral because of the potential implications for water on Mars (i.e. Johnson et al., 1991; Monkawa et al., 2006; Watson et al., 1994). Microprobe analyses of F and Cl contents of this kaersutite (Johnson et al. 1991) yielded 0.50 and 0.10 wt.% respectively. These low values led to the presumption that much of the amphibole O(3) site was filled with OH-. However, Watson et al. (1994) found very little water in the kaersutite (~0.15 wt.% H₂O), implying that the kaersutite O(3) site is largely occupied by O²-. However, Fe micro-XANES data collected by Monkawa et al. (2006) showed that Fe³⁺ comprised only ~5% of the Chassigny kaersutite, which is uncommon for typical terrestrial oxy-rich kaersutites.

When all of the above published data are considered, a structural formula for the Chassigny kaersutite can be calculated based on normalization to 24 anions [best normalizatin scheme for well characterized O(3) occupancy]. The resulting structural formula yields an over-occupied A-site (by ~ 11-15%), which is consistent with having too much O²⁻ in the O(3) site. This inconsistency suggests either that at least one of the above published data is inaccurate or that the Chassigny kaersutite is not currently representative of its chemical state at the time of crystallization. The first case requires (i) a higher concentration of monovalent anions is present within the O(3) site to decrease the apparent amount of O²⁻ in O(3), (ii) a higher concentration of Fe³⁺ in the M(1-4) sites to diminish the effects of the extra negative charge imposed by O²⁻, or (iii) a combination of both. The second case would imply that the above data are accurate and the Chassigny kaersutite has changed to an unstable or charge-imbalanced phase subsequent to crystallizing within the melt inclusions. Such a change may have been induced by the shock event that removed the Chassigny dunite from the martian surface (dehydroxylation?). Analyses are ongoing to further assess these possibilities.

Coral reefs and global change: the roles of increasing ocean acidity, ocean temperatures, sea-levels and direct human impacts

Malcolm T. McCulloch

Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia (Malcolm.McCulloch@anu.edu.au)

Although coral reefs make up less than 1.2% of the world’s continental shelf area, they represent a disproportionately large and essential resource to people as well as being of immense ecological value. Coral reefs are however sensitive to the threats from global climate change as well as direct human impacts from degradation of their local marine environment, both of which are now occurring at unprecedented rates. Higher levels of atmospheric CO₂ from fossil fuel burning are causing global warming, but also importantly increasing the acidity of the world’s oceans. Increasing ocean acidity and the resultant decrease in the carbonate saturation state of seawater, has the potential to cause substantial reductions in coral calcification. Warming of the world’s oceans has also increased the frequency of unusually warm events resulting in widespread mass coral bleaching, such as occurred in 1998 and 2002. These effects, and the apparent lack of adaptability of corals, is more than counter-balancing any possible beneficial effects from climate change such increased calcification and reduced uptake of CO₂ with higher sea surface temperatures as well as increased accommodation space for coral growth from rising sea levels.

However, arguably the most severe impacts on coral reefs are still those that arise from direct human activities. Locally, landuse changes in river catchments, wetlands and estuaries is leading to increased supplies of sediment and nutrients to many inshore coral reefs. In some cases these, together with pressures from other activities such as trawling and overfishing are now resulting in an evolutionary trajectory that may ultimately result in an abrupt phase shift from a coral to macro-algae dominated ecosystem. It is thus clear that the long-term sustainability of coral reefs is not only dependent on the still poorly understood effects of global climate change and coral adaptability, but also on increasing the resilience of reef systems by mitigating direct human impacts.
Microbes, sedex deposits and siderophile seawater at ~1.65 Ga in northern Australia

PETER MCGOLDRICK1, TIMOTHY LYONS2 AND POUL EMSBO3

1CODES Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Tas 7001, Australia; (p.mcgoldrick@utas.edu.au)
2Department of Earth Sciences, University of California - Riverside, Riverside, CA 92521-0423, USA; (timothy.lyons@ucr.edu)
3United States Geological Survey, Denver, CO 80225, USA; (pemsbo@usgs.gov)

Late Palaeoproterozoic to earliest Mesoproterozoic sequences in northern Australia host nearly a quarter of the world’s zinc reserves [1]. Individual sedex (‘sedimentary-exhalative’) deposits may contain tens of millions of tonnes of base metals. Furthermore, the deposits and their primary dispersion halos contain several orders of magnitude greater amounts of iron (as pyrite and/or iron carbonate) than base metals [2]. This talk will discuss the origin of northern Australian sedex zinc deposits in the light of new ideas about the oxidation state and sulfur content of Proterozoic oceans [3,4].

These deposits are thought to form from oxidised fluids that already contained dissolved S (as sulfate) or obtain sulfate when the exhaling fluid mixed with seawater, or both [1]. Sulfide was produced through biogenic reduction at the site of ore deposition and local water column euxinia must have been important to fix (and preserve) base metal- and Fe-sulfides in the sediments. However, Fe enrichments expressed as carbonates, rather than sulfides, imply S-poor (and perhaps CO\textsubscript{2}-rich) bottom waters. Such waters may have been anoxic, but were not euxinic.

We will present textural evidence from distinctive bottom precipitated carbonates, as well as S isotope data (sulfide and CAS) from the mineralised and unmineralised sequences, that support arguments for a low-S reduced ocean at this time. The extent of the influence of giant ore-forming exhalative systems on coeval ocean chemistry will be discussed.

Microscale controls on contaminants at the Hanford Site

J.P. MCKINLEY1, J.M. ZACHARA1 AND S.M. HEALD2

1Pacific Northwest National Laboratory, Richland, WA 99354, (james.mckinley@pnl.gov, John.Zachara@pnl.gov)
2Argonne National Laboratory, Argonne, IL, 60439, (heald@aps.anl.gov)

Hanford was the site of intensive plutonium production from 1943 to 1989, the operation of reactors, chemical processing facilities, and waste storage and disposal facilities resulted in environmental contamination on a large scale. The vadose-zone mobility of these contaminants was controlled by microscale reactions with unconsolidated surface sediments. Waste-sediment interactions modified migrating solution compositions along the flow path, resulting in immobilization by precipitation or sorption. We used autoradiography, x-ray microprobe, electron microprobe, and scanning electron microscopy to determine the microscale controls on mobility for U, \textsuperscript{90}Sr, \textsuperscript{137}Cs, and Cr.

Uranium diffused into microscale fractures in granitic sediment clasts, and precipitated as sodium boltwoodite. The reaction was sustained by dissolution of silica from feldpars and by continued diffusion of uranyl from the pore-filling waste solution. Sequestration of uranyl in microfractures implied a limited possibility of subsequent dissolution and remobilization. \textsuperscript{90}Sr was entrained in Na\textsuperscript{+} rich solutions that displaced Ca\textsuperscript{2+} from ion exchange sites on sediment smectites, causing saturation and Sr coprecipitation with secondary calcite, suggesting that remobilization by subsequent dissolution would be moderated by exchange with Na\textsuperscript{+}. \textsuperscript{137}Cs was found to be bound to interlayer sites on biotite and muscovite. The extent of weathering within the micas was critical to the penetration of \textsuperscript{137}Cs; more weathered biotites included internal concentrations, while muscovite held \textsuperscript{137}Cs predominantly along the muscovite clast boundaries. Chromate was observed associated with aluminosilicate coatings on sediment clasts, and as concentrated, reduced precipitates in interclast space. The mobility of these contaminants was limited by reaction within distinct reactive components not evident during macroscopic investigations.
Evaluating environmental response trends using an integrated paleolimnological approach

1Department of Geological Sciences, Michigan State University, East Lansing, MI 48824, USA
2Department of Geography, Michigan State University, East Lansing, MI 48824, USA
3Geological Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria
4Department of Zoology, Michigan State University, East Lansing, MI 48824, USA

We examine the hypothesis that ecosystems highly perturbed by human activities cannot return to their original unperturbed state and with the influence of climate change, new ecosystem balances are obtained. A problem is that ecosystems are perturbed by various stressors that operate at different timescales and intensities. Our approach is to integrate observations of various ecological/environmental indicators over time. An investigation of lacustrine sediments was used to examine this hypothesis and determine rates of response and recovery from environmental stressors.

The study area is Muskegon Lake (Great Lakes region, USA) which is in a watershed highly perturbed by human activity since the early 1800s. Logging, dams, agricultural runoff, urbanization and industry have resulted in altered hydrology, disrupted biological communities and chemical contamination. Sediment were analyzed for vertical profiles of pollen stratigraphy, diatom community structure, 210Pb activity (sedimentation rates, age, focusing), and corresponding geochemistry that includes a suite of elements including trace metals and nutrients.

Three distinct paleoecological phases are represented in the sediment geochemistry chronology and diatom community structure of the core. Select relationships observed include: 1) Top section (<16cm depth) shows diatom species indicative of high nutrient conditions, specifically, Achnanthes minutissimum and Amphora pediculus, which correspond to increasing phosphorus concentrations near the surface; 2) The 60 – 90cm depth reflects an increase in Cocconeis placentula and C. placentula v. euglypta, that predates the peak in anthropogenic loading of lead and mercury, after which, both species decline; 3) Bottom of core (>100cm depth) is abundant in Cavinula scutelloides, benthic diatom species associated with cooler climate (Little Ice Age), Ophephora martyi, and geochemistry that reflects apparent background conditions.

Preliminary results are consistent with the hypothesis and are interpreted to indicate that ecosystems will work to attain new balances in the Great Lakes region as climate changes, but the magnitude of human disturbances further influences these new balances. It is hoped that this integrated approach will facilitate not only a better understanding of ecosystem response to stressors, but also a more realistic assessment of new states of balance after the stressors are removed.

LIBS analysis of gem beryls: Single-pulse, double-pulse, and provenance determination

C.E. McManus1, N.J. McMillan1, R.S. Harmon2, F.C. Delucia3 and A.W. Mizolek3

1New Mexico State University, Las Cruces, NM, (katedowe@aol.com, nmcmilla@nmsu.edu)
2Army Research Office, Research Triangle Park, NC
3Army Research Laboratory, Aberdeen Proving Ground, MD

Laser-induced Breakdown Spectroscopy (LIBS) is an attractive emerging tool for chemical analysis, including potential for real-time, in-field, minimally destructive analysis. LIBS is simultaneously sensitive to all elements, especially for those with low atomic weights. Based on the premise that every material produces a unique broadband LIBS emission spectrum, averaged LIBS spectra (200-980 nm) were collected for a wide variety of samples of the cyclosilicate gem beryl (Be3Al2Si6O18). Spectra were collected for single-pulse LIBS in air and Ar atmospheres, and for double-pulse LIBS in air. A methodology for comparing spectra was developed to determine provenance of gem beryls based on the premise that specimens from the same mine, mine field, or tectonic region should share a common geochemical signature. Analysis of over one hundred beryls from 27 localities worldwide demonstrates that this should be possible, given the appropriate database. However, ionic substitutions in beryl are sufficiently complex that within-pegmatite variations controlled by magmatic differentiation and subsequent recrystallization add a significant amount of chemical variability to the beryls. Despite this complexity, the analytical and data processing protocols demonstrate that the provenance of beryls can be successfully identified at the scale of a pegmatite mine, if the database contains a sufficient number of samples to capture the chemical variability in the field. The precision of provenance studies also depends on the quality of geographic metadata associated with each sample.
Crustal contamination in the British and Irish Palaeogene Igneous Province: Mechanisms, timing and implications for the formation of granitic magmas

F.C. MEADE1, V.R. TROLL1, D.M. CHEW1, R.M. ELLAM2, L. FONT3 AND J.P. CHADWICK1

1Department of Geology, Trinity College Dublin, Ireland. (meade@tcd.ie)
2Scottish Universities Environmental Research Centre, East Kilbride, Scotland.
3Department of Earth Sciences, University of Durham, UK.

Old and lithologically variable terranes, such as those in the northern British Isles, preserve distinct and diverse crustal isotopic end-members. Similarly, individual crustal lithologies comprise various isotopic sinks, representative of various sources. Hence, while a partial melt/restite of these crustal lithologies may not be fully representative of the original protolith, it can be identified individually, further constraining crustal contamination. Therefore a magma’s course may be traced isotopically, providing a picture of a granite’s ascent and storage at both a local and crustal scale. Samples from the Drumadoon Igneous Complex, Isle of Arran, Scotland, and the Carlingford Igneous Centre, NE Ireland, were analysed for major and trace elements and Sr and Nd isotopes, aiming to reveal both magma chamber-scale processes and larger-scale crustal pathways. The Arran data point towards major involvement of the Grampian terrane, despite the Drumadoon Igneous Complex being within the Midland Valley. Therefore, while the magmas originated at depth on the northern side of the Highland Boundary Fault (HBF), they have crossed this boundary during their evolution and ascent, most likely during shallow-level emplacement. The HBF has a sub-vertical orientation, therefore the magma is unlikely to have taken a direct vertical traverse through the crust, but rather experienced significant lateral transport. At Carlingford, all samples trend markedly towards local Silurian crust, reflecting the involvement of a single crustal end-member. Nevertheless, our data imply contamination was not straightforward. We see a time sequence of variably overprinted processes, from initial contamination by crustal partial melts, to bulk contamination, and final assimilation of the remaining restite during transport and emplacement. At both centres, granitic magmas appear to result from high levels of contamination during differentiation, producing a characteristic bimodal “Bunsen-Daly Gap”. Significantly, the intermediate compositions that bridge this gap at Drumadoon and Carlingford are not the products of fractional crystallisation, but rather appear to be the result of both mixing of end-member compositions and variable amounts of crustal contamination during storage, transport and emplacement.

Silicon isotopic fractionation: Assessments from first-principles methods

M. MEHEUT1, M. BLANCHARD1, M. LAZZERI1, E. BALAN1,2 AND F. MAURI1

1IMPMC, Université Paris VI, Paris, France
2IRD –UMR CEREGE, Aix en Provence, France

Equilibrium isotopic fractionation between solids is a thermodynamic property, which is determined by the vibrational properties of the system. In this work, we employ an ab initio method (Density Functional Perturbation Theory) to obtain the complete phonon dispersion, which in turn, is used to calculate the free energy of a material of a given isotopic composition. Finally, the equilibrium isotopic fractionation is determined from the difference in free energy of materials of different isotopic compositions. We use PBE functionals, combined with the use of pseudo-potentials and planewave basis sets. This methodology has proved to be successful in reproducing the physical and chemical properties of complex systems. Within this framework, we have recently developed a methodology to predict equilibrium fractionation factors as a function of temperature [1].

Silicon is a major component of Earth crust. Measurements of various isotopic compositions in Nature show that, in general, the silicon composition follows the oxygen composition, and shows a positive correlation with silicon content [2]. Further observations, as well as theoretical arguments, predicted that silicon isotopic fractionation properties could be related to the degree of polymerization of silica units in silicates[3].

In this study, we have focused on the study of the systematic trends in Si fractionation, and on its relationship with oxygen fractionation or silicate polymerization. Our work consists in a comparative study of materials presenting several degrees of silicate polymerization: nesosilicates (forsterite), inosilicates (clinoenstatite), phyllosilicates (kaolinite and lizardite), and tectosilicates (quartz). Oxygen isotopic fractionation has been computed and compared to existing experimental data with which they agree well given the calculation uncertainty. Silicon isotopic fractionation has also been computed and compared to their oxygen counterparts. Silicon fractionation between quartz and other materials is systematically positive and range from 0.2 to 0.8 permil at 1000°C. Beyond that, they roughly follow the trends of oxygen fractionation. Nevertheless, a clear correlation between silicate polymerization and silicon fractionation has not been observed.

Iron sulfide formation under low pH conditions in sulfate reducing enrichment cultures obtained from acidic pit lake sediments

JUTTA MEIER, ANGELA PIVA AND DANIELLE FORTIN
Department of Earth Sciences, University of Ottawa, 140 Louis Pasteur, Ottawa, ON, Canada K1N 6N5 (jmeier@uottawa.ca, apiva027@uottawa.ca, dfortin@uottawa.ca)

Dissimilatory sulfate reduction often plays a key role in bioremediation systems treating acid mine drainage as it leads to alkalinity generation and precipitation of metal ions. However, both, microbial sulfate reduction and metal sulfide formation, are pH dependent and are inhibited under low pH conditions. The aim of this study was to investigate iron sulfide formation under sulfate reducing conditions in systems mimicking low pH environments. Experiments were performed at 18°C with indigenous sulfate reducing populations originally enriched from sediments of an acidic pit lake. The artificial pore water media contained elevated concentrations of sulfate (20 mM), Ca (6 mM), Fe(II) (5 mM), Al (4 mM), and Mg (1 mM) and a H2/CO2 gas mixture was used as electron donor/carbon source. The pH was initially set to pH 3.3, 3.8, 4.8, and 5.9. Over an incubation time of 12 weeks, pH, concentrations of soluble Fe(II), sulfate, and sulfide, and partial pressures of H2 and CO2 were monitored. In the less acidic systems (pH 4.8 and pH 5.9), sulfate reduction started shortly after inoculation. In the systems with an initial pH of 5.9, immediate precipitation of iron kept the concentration of free sulfide very low (< 30 µM), whereas in the systems initially set at pH 4.8, free sulfide concentrations built up to 300 µM during iron precipitation. In the more acidic systems, sulfate reduction occurred after a lag phase of 20 – 40 days but it proceeded at a much higher rate than in the less acidic systems. A decrease of soluble Fe(II) was only observed at pH > 4.3 when the amount of sulfate reduced exceeded 5 mmol per ml of culture medium. The results show that free sulfides form at low pH when high concentrations of free sulfide are present. Sulfate reducing prokaryotes thriving under these conditions need not only to be acidotolerant but must also tolerate high concentrations of free sulfide. Different cell morphologies revealed by microscopic observations as well as microbial community analysis based on 16S rRNA gene amplicons suggest that different sulfate reducing species were enriched. Mineral precipitates formed in the different system will be characterized by electron microscopy (SEM/TEM). Geochemical equilibrium modeling will be used to calculate saturation indices and predict iron-rich mineral formation in the various systems.

Determination of siderophile and chalcophile elements in peridotites by sector field ICP-MS

L.C. MEIER, D. VAN ACKEN, M. FISCHER-GÖDDE, F. WOMBACHER AND H. BECKER
Institut für Geologische Wissenschaften, Freie Universität Berlin, Malteserstr. 74-100, 12249 Berlin, Germany (fwo@zedat.fu-berlin.de; hbecker@zedat.fu-berlin.de)

Obtaining complete and accurate data sets on all highly siderophile elements in peridotites and related rocks is challenging because of digestion issues, low abundances and the monoisotopic nature of Au and Rh. Similarly, moderately siderophile and chalcophile elements such as Mo, Ag and Cd are poorly constrained in such rocks, again because of digestion issues, low abundances and a wealth of interferences in ICP-MS. Here, we report initial results on highly siderophile elements including Rh and Au and a new approach for the precise analyses of some moderately siderophile and chalcophile elements. Analyses are carried out at the Freie Universität Berlin using a Thermo Element XR sector field ICP-MS equipped with an Aridus desolvating system, glass spray chambers and microconcentric nebulizers.

The analysis of PGEs, Re and Au follows a modification of previously published protocols (Meisel et al., 2003, JAAS 18, 720-726). Up to two g of powdered samples are digested in inverted aqua regia using carious tubes or a high pressure asher. Osmium is separated by solvent extraction and analyzed by TIMS, the other PGEs and Re are separated from the rock matrix in 0.2 M HCl using cation exchange resin. Rhenium and all PGEs except Rh are quantified by isotope dilution (ID). Rhodium is quantified relative to Ir by using the Ir abundance from the ID analyses and a response factor derived from a Rh-Ir calibration solution.

Gold abundances have been determined by the standard addition method for two samples, a serpentinitized herzolite reference material (UB-N) and a Al-rich peridotite (TUR-7) from France. Four rock powder aliquots were spiked with 0, 2, 4 and 6 ng Au before carius tube digestion. Prior measurement, the samples were centrifuged and diluted with 0.5M HCl to a solution weight 50 times the initial sample weight. During the analysis, drift was compensated for by internal normalisation to sample Ir. Very good correlations were obtained despite the independent digestions for each aliquot, which suggests that Au and Ir are homogeneous at the 2g sample scale and that the digestion method is reproducible. The Au abundance in UB-N and TUR-7 was found to be 1.49 (+0.04; -0.05) and 1.34 (+0.11; -0.20) ng/g at the 95% confidence level.

The abundances of many moderately siderophile and chalcophile elements are poorly constrained in the Earth’s mantle. To obtain high precision data, we started to prepare enriched isotope spikes and developed a chemical separation protocol for Cu, Zn, Ga, Mo, Ag, Cd, In, Sn, Te, W and Tl.
Hardpan formation in mine tailings: Reactive transport modelling of column experiments

J.A. MEIMA, T. GRAUPNER AND D. RAMMLMAIR

Federal Institute for Geosciences and Natural Resources (BGR), Stilleweg 2, 30655 Hannover, Germany (jeannet.meima@bgr.de; torsten.graupner@bgr.de; dieter.rammlmair@bgr.de)

Hardpan formation in low-sulphide low pH mine tailings was studied using laboratory column experiments. The main reactive components of these tailings are metal-sulphides and sheet-silicate minerals like biotite (Graupner et al., 2007). Artificial rain water was allowed to enter at the bottom of a 5 cm Ø column, which was filled with 35 cm of loamy tailings beneath a 15 cm layer of fine-grained quartz sand. Upward capillary transport of water followed by evaporation at the top of the column resulted in partially saturated conditions within the upper part of the column, an upward directed transport of solutes and colloids into the quartz sand, as well as the formation of a hardpan at the capillary fringe.

Figure 1: Bulk chemical profiles after 146 days (circles: measured data, lines: reactive transport model (single porosity model, transport of solutes only))

The reactive transport code FLOTRAN (Lichtner, 2005) was used to model the relevant reactive transport processes leading to the formation of the observed hardpan. The observed concentration profiles (Fig. 1) cannot be explained by reactive solute transport on the basis of single porosity models. A dual porosity approach, which considers mobile and immobile pores, is required to explain the observed retention of e.g. aluminium, zinc, and copper within the quartz sand layer. Furthermore, the observed extremely high transport rates for e.g. aluminium can only be explained assuming colloid and/or mechanical transport. These additional processes would positively affect hardpan formation rates.

Identifying the sources of PGE, Re and Sb in road dust and soils along highways

T. MEISEL AND V. STOTTER

General and Analytical Chemistry, University of Leoben, A-8700 Leoben (thomas.meisel@mu-leoben.at)

Automobile catalytic converters are a known source of Rh, Pd and Pt deposited in road dust and soils along highways. Since Ir is now also used in catalytic converts an increase in concentrations in the environment could be detectable. In addition Os, which can occur in toxic species, with a close to Earth mantle isotopic composition was detected in car exhaust. Thus a almost the whole range of PGE in the environment are related to anthropogenic emissions. In this work we studied soils from an Austrian highway section sampled in 2002, 2005 and 2007. Soils, grass and road dusts where analyzed for platinum group elements (Ru, Rh, Pd, Os, Ir and Pt), Re, Sb and the 187Os/188Os isotopic composition. Samples where taken in 0, 2 and 10 m distance and in 0-5 and 5-10 cm respectively. In addition to trace element concentration data, magnetic susceptibility of the soils were measured.

The combination of all data and information allow the following observations. Very strong correlations between Re, Sb, Cu and magnetic susceptibility point to brake liners as the source of the enrichments observed in the top layers of the soils close to the highway. The strong increase of Ru, Pd and Pt enrichments within the last 5 years is clearly a attributed to catalytic converters. The high Ru, Os and Ir concentrations of soils close to the highway are explained by the use of serpentinite gravel from a quarry close to the sampling site used for the construction of the highway dam. Since a very strong correlation between Os isotopic composition and the inverse concentration of Os exists a mixing of two endmembers is evident. The two endmembers coincide with estimations of upper mantle and a continental crustal composition. A mixture with a third component representing the composition of catalytic converter can be excluded based on the current data. Either the concentrations of Os are too low to be detected or Os occurs in a volatile species that is easily dispersed compared to the Rh, Pd and Pt which are associated with Al-Ce bearing particles. Since Ir/Os and Ru/Os ratios are similar to mantle estimates and their concentrations relatively high, an anthropogenic source of Ir cannot be detected at this site.

In conclusion we can attribute the observed distributions of measured trace element concentrations to the following sources: automotive converters (Rh, Pd and Pt), brake liners (Sb, Cu and Re?) and serpentinite gravel (Ru, Os and Ir).
Equilibrium experiments and theoretical studies in the MgO-SiO$_2$-H$_2$O system at high pressures: Clarification of stabilities and thermodynamic properties of phase A, clinohumite and chondrodite

E. MELEKHova$^1$, M.W. SCHMIDT$^1$, P. ULMER$^1$, J.A.D. CONNOLY$^1$ AND P.I. DOROGOKUPETS$^2$

$^1$Inst. Of Mineral. and Perol., ETH Zurich, CH-8092, Switzerland (elena.melekhova@erdw.ethz.ch)
$^2$Inst. Of Earth’s Crust, SB RAS, Irkutsk, Russia

The stabilities of clinohumite, chondrodite and phase A were investigated in phase equilibrium experiments using a rocking multi-anvil apparatus at pressures of 7.5-12.5 GPa and 800-1350 °C. The rocking technique, i.e. regular inversion of the experimental apparatus including the capsule, results in nearly homogeneous run products. This overcomes the problem of experimentally producing more phases than can be in equilibrium and thus allows unequivocal determination of stability fields.

Seven reactions were bracketed by equilibrium experiments (every starting material consisted of crystalline phases both, products and reactants).

Our results show that phase A, clinohumite and chondrodite have wider P-T stability fields when compared to the previous studies. More over, above 10 GPa, clinohumite has a lower temperature stability compared to chondrodite. These results contradict works by Wunder, (1994) and Kawamoto, (2004).

Thermal expansivities for clinohumite and chondrodite and the C$_P$ function of chondrodite were predicted from the Debye model. Thermal expansivities correspond to 2.64 ·10$^{-5}$ and 2.71 ·10$^{-5}$ K$^{-1}$, respectively. Standard state entropy and enthalpies for phase A, clinohumite and chondrodite were deduced from the fluid absent reactions by mathematical modelling.

Effect of montmorillonite dissolution on U(VI) sorption in bentonite

A. MELESHYN$^1$, M. AZEROUAL$^1$, T. REECK$^1$, G. HOUBEN$^2$, B. RIEBE$^1$ AND C. BUNNENBERG$^1$

$^1$Center for Radiation Protection and Radioecology, Leibniz University of Hannover, Germany (meleshyn@zsr.uni-hannover.de)
$^2$Federal Institute for Geosciences and Natural Resources, Hannover, Germany (Georg.Houben@bgr.de)

Along with the fulfilling of other safety functions relevant for the final disposal of radioactive waste, bentonites should also retard the release of radionuclides in case of groundwater inflow. This study shows that U(VI) interaction with bentonite depends on its aqueous complexation and is strongly influenced by the dissolution of montmorillonite.

Results and Discussion
A comparison of the time-dependent changes in Mg and U(VI) supernatant concentrations as a result of clay-solution contact at circumneutral conditions reveals their strong correlation. SEM-EDS and FEM analyses of the bentonite samples indicate further that U(VI) is adsorbed at montmorillonite edges, which supports the findings of previous studies (Catalano and Brown, 2005). Time-dependent changes in the solubility of colloidal silica evidence silica release from montmorillonite and its relation to Mg release occurring at montmorillonite edges as well.

Application of the periodic bond chains (PBC) theory (Hartman and Perdock, 1955) to the observed data and taking into account the mechanism of alkali feldspar dissolution (Oelkers et al., 1994) allows to suggest the following mechanism of the non-stoichiometric montmorillonite dissolution as related to U(VI) adsorption on its edges: (1) surface complexation of U(VI) with Mg edge sites; (2) detachment of Mg; (3) surface complexation of U(VI) with Al, Fe edge sites; (4) diffusion and release of Mg from the outermost but one PBC; (5) hydrolysis of Al-O-Si bonds and release of Al; (6) Si release after dissolution of at most three PBCs. Taking into account the proposed mechanism of orthosilicate dissolution (Casey and Westrich, 1992), we hypothesize that the preferential complexation of dissolved U(VI) with Mg edge sites may be explained by very similar rates of water exchange on UO$_2$(H$_2$O)$_5^{2+}$ and Mg(H$_2$O)$_6^{2+}$.

Conclusions
The study proposes a mechanism of montmorillonite dissolution as related to U(VI) adsorption, which provides molecular scale information about the involved processes.

Oldest terrestrial diamonds in zircon from Jack Hills, Western Australia

M. MENNEKEN1, A.A. NEMCHIN2, T. GEISLER1, R.T. PIDGEON2 AND S.A. WILDE2

1Institut für Mineralogie, Westfälische Wilhelms-Universität Corrensstr.24, 48149 Münster, Germany
2Department of Applied Geology, Western Australian School of Mines, Curtin University of Technology, Bentley, WA, 6102, Australia

Recent geochemical and mineralogical studies of >3,900 Myrs old, detrital zircons from the Jack Hills metasedimentary belt, Yilgarn Craton, Western Australia, implied that granitic, continental crust and oceans on the Earth already existed as early as 4,400 Ma. However, this hypothesis is still a matter of debate as it contrasts with the conventional view that early Earth’s evolution was dominated by mafic and ultramafic magmatism. Importantly, we have now discovered diamond inclusions in Jack Hills zircons using micro-Raman spectroscopy. The ages of the diamond-bearing zircons range from 3 to >4 Ga, thus providing a completely new dimension in the formulation of ideas regarding the evolution of the early Earth. This spread of ages indicates that either the conditions required for diamond formation were repeated several times during early Earth history or that there was significant recycling of ancient diamond. Most diamonds are surrounded by graphite, suggesting a retrograde diamond-to-graphite transformation. Graphite is known to be associated with metamorphic diamonds formed during ultra-high pressure (UHP) metamorphism. This, together with other mineralogical features, demonstrates that the Jack Hills diamonds most closely resemble diamonds formed during UHP metamorphism. Unless conditions on the early Earth were unique, this implies the presence of a relatively thick continental lithosphere and that crust-mantle interaction occurred on Earth as early as ~4.2 Ga.

Organic speciation of hydrocarbon-derived carbonate chimneys (Gulf of Cadiz, SW Iberia)

C. MENOR-SALVÁN1, M. RUIZ-BERMEJO1, R. MERINERO2, R. LUNAR2 AND J. MARTÍNEZ-FRIAS1

1Centro de Astrobiología (CSIC-INTA). Ctra. Torrejón-Ajalvir km. 4.2, Torrejón de Ardoz. E-28850 (Spain); menorsc@inta.es
2Departamento de Cristalografía y Mineralogía, Facultad de Ciencias Geológicas, Universidad Complutense de Madrid, 28040, Madrid, Spain

Dolomite-rich chimneys associated with hydrocarbon-rich fluid venting were discovered in September 2000 in the Gulf of Cadiz. Chimneys show a wide variety of shapes and range in size from several centimetres to a few decimetres. Basically, they are made of a fine groundmass of major Fe-rich dolomite, ankerite and calcite, small grains of quartz and phyllosilicates, and foraminifer tests and ostracod shells. The possibility of anaerobic oxidation of methane mediated by a community of anaerobic methanotrophic archaea and sulphate reducing bacteria, along with the proposal that the iron oxides and sulphides, present in the carbonate matrix of the chimneys, are probably formed by biomineralization processes justify the organic speciation of samples and study of biomarkers. We found linear hydrocarbons with C<20, isoprenoids but not hopanoids and PAHs as indicators of petroleum or anthropogenic contaminations. It is interesting the presence of a complete series of terminal monochloroalkanes in the same C range of the n-alkanes found in the sample (Fig. 1.) We suggest that chloroalkanes were formed during the hydrothermal process in the seafloor.

Figure 1: SPME-GC/MS chromatogram showing the 1-chloro-n-alkanes profile in hydrothermal chimney samples.
Generating the aromatic world: Synthesis of aromatic compounds in icy environments

C. Menor-Salván, M. Ruiz-Bermejo, S. Osuna Esteban and S. Veintemillas Verdaguer
Centro de Astrobiología (CSIC-INTA). Ctra. Torrejón-Ajalvir km. 4.2, Torrejón de Ardoz. E-28850 (Spain); (menorsc@inta.es)

The aromatic hydrocarbons are recognized as astrophysically important molecules and their presence in interstellar ices may contribute to the materials incorporated into planets, satellites, asteroids and comets. Ultimately, PAHs are recognized as key molecules in the study of the origin of life, due to their photochemical properties that could allow to PAHs to play the role of primitive pigment systems that drive synthesis of amphiphilic compounds; assemblies based on aromatic hydrocarbons were proposed as components of informational polymers, containers and mediators in metabolic pathways (1). The availability and stability of such aromatic compounds plus their capacity for self-assembly driven by pi-pi stacking interaction and weak forces made the aromatic hydrocarbons good building blocks for protocellular structures. Indeed, it has been demonstrated that amphiphilic polycyclic aromatic compounds are capable to self-assemble and form bilayer structures (2). We demonstrate that complex mixtures of aromatic compounds could be synthesized in cold systems with water ice and methane as carbon source. Using spark discharges as energy source and generating a “ice reactor” by means of a cycle of freezing-melting we found benzene derivatives as acetophenone, benzaldehyde and benzonitrile and PAHs.

Dating carbonate rocks with in situ produced cosmogenic $^{10}\text{Be}$: Why it often fails

S. Merchel¹, R. Braucher¹, L. Benedetti¹, O. Grauby² and D. L. Bourles³
¹CEREGE, CNRS UMR 6635, Université Aix-Marseille III, F-13545 Aix en Provence, France (merchel@cerege.fr)
²CRMCN-CNRS, F-13288 Marseille cedex 9, France

In situ produced cosmogenic $^{10}\text{Be}$ has proved to be valuable tools for environmental and Earth sciences. Progress in the field of accelerator mass spectrometry (AMS) allows the determination of radionuclide concentrations as low as of $10^3$-$10^5$ atoms/(g rock) that makes quantifying Earth’s surface processes possible. However, surface dating of carbonate rocks using the cosmogenic radionuclide $^{10}\text{Be}$ is still problematic. In order to investigate the reasons for this, we have performed extensive step-wise leaching of calcite-rich samples. Results on different grain size fractions clearly indicate the sources of atmospheric $^{10}\text{Be}$ being small clay minerals. We demonstrate that partial-leaching procedures that result in moderate pH levels will not release $^{10}\text{Be}$ (in-situ produced or atmospheric) due to the instant re-absorption on grain surfaces. Under strongly acidic conditions all absorbed atmospheric $^{10}\text{Be}$ is leached from aluminosilicates giving abnormally high $^{10}\text{Be}$ concentrations and consequently exposure ages that are too old (Merchel et al., submitted).

Now, that we understand the main obstacles in analysing $^{10}\text{Be}$ from carbonate rocks, the next steps are clear: We need to concentrate on samples that do not contain clay minerals. This might require working on coarser grain size fractions or recrystallized material. Or we need to find a way to physically and/or chemically separate clay minerals from carbonates before dissolving them. This task is most challenging because clay is generally much more resistant to chemicals than carbonate minerals. After testing several analytical methods, i.e. XRD, IR, TEM-SAED, ICP-OES, SEM-EDX, we are still searching for a “simple and fast” method which could quantify clay concentrations in our samples and could help monitoring the efficiency of future separation procedures.

Acknowledgments: We thank I. Schimmelpfennig, L. Palumbo and P.H. Blard for their help during field work. D. Borschnek is thanked for performing XRD, H. Miche for ICP-OES, and G. Camoin for optical microscopy at CEREGE. We also acknowledge the good collaboration with J. Huth (MPI for Chemistry, Mainz) in respect to SEM-EDX measurements. The AMS measurements at Gif-sur-Yvette would not be possible without G. Aumaitre.

New spectroscopy developments to study water in basaltic melts

M. MERCIER1, A. DI MURO2, N. MÉTRICH1, G. MONTAGNAC3, D. GIORDANO4, P. LESNE5 AND R. CLOCCHIATTI1

1LPS, CNRS-CEA, Saclay, France (maxime.mercier@cea.fr, nicole.metrich@cea.fr, roberto.clochiatti@cea.fr)

4DGS, Univ. Roma III, Italy (dgiordan@uniroma3.it)
5ISTO, Orleans, France (lesne@cnrs-orleans.fr)

Micro-Raman spectroscopy is a powerful technique to assess the water content and diffusion profiles in silicate glasses, at micrometer scale. The potential of Raman spectroscopy to quantify water has been recently demonstrated for hydrous, silicic glasses [e.g., 1-2]. However, Raman analysis of hydrous, basaltic glasses is more delicate. We examine here the effects of laser beam (heating and oxidation) on these glasses and the dependence of Raman calibrations on iron redox state and compositions of glasses. We studied 28 dry natural glasses having a large range of polymerization degree (NBO/T: 0 to 1.17), 2 sets of basaltic glasses with variable Fe3+/ΣFe ratios and 4 sets of synthetic hydrous mafic glasses (H2O: 0.4 to 5.3 wt%). In order to prevent analytical condition bias, Raman calibration for water (internal calibration) has been based on the ratio of the H2O total stretching band (3500 cm−1) relative to spectral features (LF: 490 cm−1 and HF: 960 cm−1) of the glass network. Internal calibration is glass composition dependent. Our results on dry glasses demonstrate that the ratios between LF and HF spectral bands correlate with the sum of structural modifiers (SM). It thus allows us to predict the composition dependency of Raman internal calibrations. Moreover, the iron oxidation state of basaltic glasses does not influence the Raman calibrations. We demonstrate that internal calibration of water is reliable, using the HF and LF bands, respectively, for depolymerised and polymerised glasses.

Growth of calcium carbonates in gels in the presence of organic and inorganic additives

C. MERKEL1, G. JORDAN1, C.M. PINA2, L. FERNÁNDEZ-DÍAZ2 AND W.W. SCHMAHL1

1Department of Earth and Environmental Sciences, Section of Applied Crystallography and Materials Science, Ludwig-Maximilians-Universität München, Germany (Casjen.Merkel@lrz.uni-muenchen.de)

Biomineralisation provides a great variety of crystal morphologies. For example the brachiopod Mergelia Truncata [1] forms extremely tortuous strands of calcite crystals. In order to understand the biologically induced crystal morphologies, the growth of crystals in gels is an excellent method to study the influences of additives on the morphology of the growing crystals. Different striking effects on the morphology of calcite crystals have been shown for inorganic [2] as well as organic additives [3] using this method. Additionally, biomineralisation often results in crystals with incorporated cations (e.g. Mg2+ in calcite [1]). The focus of this work, therefore, is the investigation of the combined influences of organic and inorganic additives on the crystal morphologies and polymorph formation of calcium carbonate. We used acrylamide as well as sodium silicate hydro-gels with MgCl2, SrCl2, aspartic acid, and succinic acid as additives. The crystals were investigated using XRD, micro-raman spectroscopy, and SEM. We obtained vaterite, aragonite, and calcite polymorphs. The crystal morphologies range from spheres (Fig. 1) and morphologies known from inorganically grown crystals (rhombohedra, aragonite twins) to crystals with strongly distorted morphologies such as dumbbell-shaped crystals. The experiments show that the combined influences of inorganic and organic additives are able to change the growth behavior of calcium carbonate, generating a variety of crystal morphologies.

**40 Ar/39 Ar ages and geochemistry of Maranhão CAMP tholeiites (Brazil): Implications for low and high-Ti basalts sources**

R. Merle1, A. Marzoli1, C. Verati2, H. Bertrand3, M. Chiaradia4, G. Bellieni1 and M. Ernesto3

1Università di Padova, Italia (renaud.merle@unipd.it)
2Géosciences Azur, France (verati@unice.fr)
3ENS-Lyon and UCBL, France (herve.bertrand@ens-lyon.fr)
4Université de Genève, Suisse (chiaradia@terre.unige.ch)

The Central Atlantic magmatic province (CAMP) emplaced at the Triassic-Jurassic boundary, is composed of prevailing low-Ti (TiO2 < 2.0 wt%) and of rare high-Ti basalts (TiO2 > 2.0 wt%). The latter are generally confined to the circum-Atlantic regions of northernmost South America (French Guiana, Surinam and Cassiporé area of Brazil) and of western Africa (Liberia, Sierra Leone). Here we report first separates for intermediate-Ti (198.5 ± 0.8 Ma) and to the mean 40Ar/39Ar age of the brazilian CAMP (mean 199 ± 2.4 Ma).

The Maranhão tholeiites are generally evolved basalts to basaltic andesites (MgO = 2.6-7.9 wt%). Three chemical groups are defined: low-Ti (TiO2 ≈ 2.0 wt%), high-Ti (TiO2 > 2.0 wt%), and intermediate-Ti tholeiites (TiO2 ≈ 2.1 wt%; K2O ≈ 0.3 wt%). The three chemical groups display almost flat to slightly enriched REE patterns precluding a garnet-bearing source. In particular, the intermediate-Ti tholeiites display almost flat REE patterns (LaCN/YbCN ≈ 2.1) relative to low-Ti (LaCN/YbCN = 3.5-4.0). The high-Ti tholeiites are more enriched in LILE and LREE (LaCN/YbCN = 4.4-5.0). All the low-Ti tholeiites display strong negative Nb and positive Pb anomalies, which are indicative of crustal assimilation. By contrast, such effects of crustal contamination.

**Chromitite alteration in serpentinite mélanges of Nurali and Kalan massifs (Russia)**

Anna Merlini1, Giovanni Greco2 and Valeria Diella3

1University of Milan (anna.merlini@unimi.it)
2University of Milan (giovanni.greco@unimi.it)
3CNR, IDPA, Section of Milan (valeria.diella@idpa.cnr.it)

Studies on the genesis and evolution of Cr-mineralization in ophiolites usually do not consider the metamorphic processes that influenced the mineralization in later stages. Kalkan and Nurali chromitites from Urals mélanges exhibit different alteration. During post-serpentinization reactions Al diffuses out of magmatic spinel leaving behind a ferritchromite and promoting the formation of chloride aureoles (Mellini, 2005). Kimball (1990) describes the alteration of spinel to ferritchromite and the formation of chloride by the reaction:

\[
\text{MgAl}_2\text{O}_4 + 4\text{MgO} + 3\text{SiO}_2 + \text{H}_2\text{O} = (\text{Mg}_3\text{Al})(\text{AlSi}_2\text{O}_8)(\text{OH})_8
\]

Studies on the genesis and evolution of Cr-mineralization in ophiolites usually do not consider the metamorphic processes that influenced the mineralization in later stages. Kalkan and Nurali chromitites from Urals mélanges exhibit different alteration. During post-serpentinization reactions Al diffuses out of magmatic spinel leaving behind a ferritchromite and promoting the formation of chloride aureoles (Mellini, 2005). Kimball (1990) describes the alteration of spinel to ferritchromite and the formation of chloride by the reaction:

\[
\text{MgAl}_2\text{O}_4 + 4\text{MgO} + 3\text{SiO}_2 + \text{H}_2\text{O} = (\text{Mg}_3\text{Al})(\text{AlSi}_2\text{O}_8)(\text{OH})_8
\]

with MgO, SiO2 and H2O coming from the fluid.

At Kalkan post-serpentinization processes led to the formation of chloride and ferritchromite by reaction of fluid with spinel and serpentine, with MgO and SiO2 coming from serpentine. Only rare serpentine relics testify the serpentinization stage. At Nurali no evidences of chloride and ferritchromite formation have been observed and post-serpentinization processes led to partial reabsorption of chromite. Serpentinization did not affect chromite and led to the formation of magnetite as coronae around chromite crystals or as small scattered magnetite grains in the matrix. According to the mineral chemistry of involved phases we propose the following reaction for ferritchromite formation:

\[
2(\text{Mg}_{0.60}\text{Fe}_{0.40})(\text{Cr}_{1.10}\text{Al}_{0.70})\text{O}_4 + 3/2(\text{Mg}_{0.57}\text{Al}_{0.43}\text{Fe}_{0.10})\text{Si}_2\text{O}_5\text{(OH)}_4 + \text{H}_2\text{O} + 1/12\text{O}_2\rightarrow 7/6(\text{Fe}_{0.60}\text{Mg}_{0.40})(\text{Cr}_{1.85}\text{Fe}_{0.15}\text{Al}_{0.00})\text{O}_4 + 1/2(\text{Mg}_{0.18}\text{Fe}_{0.82}\text{Al}_{0.00}\text{Si}_{0.00}\text{O}_{16})(\text{Al}\text{Si}_2\text{O}_8)\text{(OH)}_8
\]

Magnetite formation during serpentinization without involving chromite can be described by the reaction:

\[
4(\text{Mg}_{1.8}\text{Fe}_{0.2})\text{SiO}_4 + 2(\text{Mg}_{0.6}\text{Fe}_{0.4})\text{Si}_3\text{O}_5 + 6\text{H}_2\text{O} + 1/6\text{O}_2\rightarrow 3\text{Mg}_2\text{Si}_3\text{O}_8\text{(OH)}_4 + 1/3\text{Fe}_2\text{O}_4
\]

Interactions of U(VI) and Eu(III) with natural bacterial isolates

M.L. MERROUN, A. GEISSLER, M. NEDELKOVA AND S. SELENSKA-POBELL
Institute of Radiochemistry, Forschungszentrum Dresden-Rossendorf, Dresden, Germany (m.merroun@fzd.de)

The presence of the actinides uranium, plutonium, neptunium, americium and curium as well as of lanthanides in radioactive wastes is of major concern because of their potential for migration from the waste repositories and long-term contamination of the environment. It was demonstrated that abiotic processes strongly affect the migration of these elements in the environment. However, it is becoming increasingly evident that microbial processes are of importance as well. Microbial processes will act immobilizing or mobilizing radionuclides, depending on the type of process and the state of the microbes. The present work investigated the interaction of bacterial strains isolated from different uranium contaminated sites as well as from groundwater at a deep-well monitoring site of the radioactive waste repository Tomsk-7, Siberia, Russia with U(VI) and Eu(III) (as non radioactive analogue of the trivalent actinides). A highly multidisciplinary approach consisting in a combination of wet chemistry (batch sorption), microbiological, spectroscopic (EXAFS, XANES, TRLFS) and microscopic techniques (TEM/EDX) is used. The results of this work will help in understanding the role of microbiological process in the chemical behavior of actinides in geological and environmental context for future nuclear waste disposals as well as in the optimization of bioremediation processes using these natural bacteria.

Seasonal element and Sr isotope ratio variations in Late Miocene corals from Crete, Eastern Mediterranean

R. MERTZ-KRAUS¹,², T.C. BRACHERT¹, S.J.G. GALE², B. STOLL² and K.P. JOCHUM²
¹Institut für Geowiss., Johannes Gutenberg-Universität, 55099 Mainz, Germany (mertzre@uni-mainz.de)
²Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (sig@mpch-mainz.mpg.de)

Trace and minor element profiles of coral skeletons may be used to infer temporal changes in environmental conditions. In paleoclimate and paleoenvironmental studies diagenetically unaltered materials are required which are generally only available from Pliocene or younger localities. However, exceptionally well-preserved Porites corals of Late Miocene age (~9 Ma) can be found on Crete (Eastern Mediterranean) which have retained their original aragonite mineralogy. Previous stable isotope (δ¹⁸O, δ¹³C) profiles yielded geologically significant seasonal signals, similar to those found in present-day corals.

Here, we report element profiles of these corals by laser ablation along the axis of maximum growth at a spatial resolution of 500 µm, corresponding to eight to eleven samples per year. Analyses were done using a 213 nm Nd:YAG laser coupled to an Element2 ICP-MS (ThermoFisher). In addition, two Sr isotope profiles of several years each were measured by TIMS by microdrilling (0.8 mm bit) at a resolution of ~4 samples per year.

The ⁸⁷Sr/⁸⁶Sr ratios mostly cluster closely around 0.7089 which confirms the ~9 Ma-old age of the corals, and suggest a working connection of the Eastern Basin to the open ocean at that time. Nevertheless, several isotopic excursions to lower values are seen in the profiles, which could be interpreted in terms of a semi-closed basin with Nile-like (unradiogenic) influence.

Variations in many lattice-bound elemental ratios (e.g. Sr/Ca, U/Ca) co-vary with those of δ¹⁸O, and thus closely reflect sea surface temperature (SST) seasonality. Other element ratios in the profiles (e.g. Al/Ca, Ba/Ca, Mn/Ca, Zn/Ca) do not correlate with δ¹⁸O (and thus SST), but do however exhibit strong peaks in the winter months. Therefore, this signal cannot plausibly originate from diagenetic alteration or post-growth contamination. Rather, the Al, Ba, Mn and Zn most likely represent seasonal terrigenous input into the coral reef environment syn-genetically incorporated into skeletal porosity during coral growth, though the exact mechanism of sediment inclusion remains unclear in detail. However, because of its winter dominance, we interpret it in terms of variations in riverine suspended load from Crete into the near-shore environment of the corals caused by winter rainfall. If so, our profiles are a proxy for the frequency and/or severity of winter storm events in the Eastern Mediterranean during the Late Miocene.
Petrogenesis and tectonic evolution of the meso-Proterozoic felsic volcanic suite of the Sakoli Group in the Bhandara Craton, Central India

D.C. MESHRAM1 AND D.B. YEDEKAR2

1Department of Geology, University of Pune, India (demeshram@unipune.ernet.in)
2School of Earth Sciences, Swami Ramanand Teerth Marathwada University, Nanded, India

The Sakoli supracrustal rocks encompassing an area of about 3600 sq km known as ‘Bhandara Triangle’ of Central India are surrounded by the Amgaon granitic gneisses forming the basement for Sakoli Group with highly tectonised contact. Chemically the felsic volcanics of Sakoli Group lie in rhyolite-rhyodacite field and the relationship of Zr/TiO2 vs Nb/Y shows that felsic pyroclastics are relatively less evolved members of the felsic suite that fall in the rhyodacite-dacite-trachyte field. Other members of the felsic suite shows a spread in comendite-pantellerite-trachyte field. The pyroclastics are the least alkaline, hence least evolved members of the felsic suite, while the lavas emplaced at conduit are most evolved.

The geodynamic setting of the felsic lavas is interpreted by using various discrimination diagrams and ratios of incompatible elements. The La/Yb vs Sc/Ni discriminant function shows that the felsic suite was evolved in ‘continental margin arc’ to ‘evolved oceanic arc’ like mixed setting. The La/Yb vs Yb discrimination indicates extensional set up for the pyroclastics and the La/Yb vs Th/Yb functions suggest that the lavas were evolved in immature transitional to marginal arc setting with evolutionary trends towards Andean (continental) arc. Overall the ratios of incompatible trace elements for the felsic volcanics indicate a continental marginal arc to marginal extensional basin set up, suggestive of a back arc rifting at the continental margin. Pyroclastics in general have highest LREE enrichment as well as high HREE content of the felsic suite. Hydrothermally altered Pyroclastics have HREE levels compatible to felsic suite, but the depleted middle and LREE are similar to the REE pattern of granite dykes from the area. The hydrothermal fluids that caused this alteration may hence be related to granite emplacement. The hydrothermal fluids have been enriched in HREE possibly because these fluids were generated by partial melting of the residuum of the first partial melt that generated felsic magma.

Overall REE pattern and incompatible trace element ratios suggests that the magma for the Sakoli felsic volcanic suite was generated by a mixed process. An initial enriched mantle partial melting event unrelated to the subduction process generated primary melt. Its emplacement at deep continental levels, possibly related with subduction regime that generated a subsequent deep continental crustal partial melt. Mixing up of both the melts resulted in the mixed transitional character of the felsic suite. The resultant mixed melt possibly had short, shallow crustal residence after initial emplacement and fractionation.

Submicrometer organic grains: Widespread constituents of the early Solar System

SCOTT MESSENGER1, KEIKO NAKAMURA-MESSENGER1,2, LINDSAY KELLER1, GRACIELA MATRAJ1, SIMON CLEMETT2 AND MOTOO ITO1

1Robert M Walker Laboratory for Space Science, NASA Johnson Space Center, Houston TX
2ESCG/ Jacobs Engineering, Houston, TX 77058 USA
3Dept. of Astronomy, University of Washington, Seattle, WA

Primitive meteorites and interplanetary dust particles (IDPs) contain remnants of interstellar organic matter, marked by anomalous H and N isotopic ratios [1]. These isotopic anomalies are attributed to mass fractionation during chemical reactions at cryogenic temperatures (10 – 100K) in a cold molecular cloud. Significant variations in the chemistry and isotopic compositions of organic compounds within and between these samples suggest varying histories of alteration and dilution of the presolar components.

Recent studies have reported large H and N isotopic anomalies preserved in sub-µm organic inclusions in both meteorites and IDPs [2]. In the Tagish Lake meteorite, the largest H and N isotopic anomalies are associated with sub-µm, hollow organic globules [3]. The common physical, chemical, and isotopic characteristics of these globules suggest that they formed before being incorporated into their parent meteorite. These organic globules probably originated as organic ice coatings that formed on preexisting ice or mineral grains in a cold molecular cloud. Radiation driven photochemistry may have processed them into refractory organic grains. This model implies that submicrometer organic grains were widely distributed throughout the solar nebula during the epoch of planet formation.

Submicrometer organic particles were detected by the Giotto and Vega encounters with comet Halley, termed CHON particles based on their major element chemistry. The first direct samples of cometary dust (comet Wild-2) were returned by the Stardust spacecraft in January 2006. These samples exhibit widely varying, fine grained mineralogy similar to anhydrous IDPs, including submicrometer carbonaceous grains. The submicrometer organic grains from comet Wild-2 exhibit H and N isotopic anomalies of similar magnitude to those commonly observed in primitive meteorites and IDPs [4,5].

Isotopically anomalous, submicrometer organic grains have now been observed in meteorites, IDPs, the Oort-cloud comet Halley, and the Kuiper-belt comet Wild-2, suggesting that such grains were prevalent throughout the protoplanetary disk.

Trace element and volatile signature of Etna magma source(s): A melt inclusion approach

N. MÉTRICH1, V. KAMENETSKY2, P. ALLARD1 AND M. POMPILIO3

1Laboratoire Pierre Sue, CEA-CNRS, Saclay, France (nicole.metrich@cea.fr; patrick.allard@cea.fr)
2University of Tasmania, Australia (Dima.Kamenetsky@utas.edu.au)
3INGV, Pisa, Italy (pompilio@pi.ingv.it)

OIB-type alkaline magmatism at Mt Etna is related to mantle upwelling and tensional tectonics at the collision boundary of the African and European plates, promoted by differential roll-back of subducting Ionian oceanic lithosphere. During the last 4 ka Mt Etna produced rare H2O, Ca-rich picrite magma [1] and recurrently, water-rich basalts-trachybasalts variably enriched in alkalis [2]. Trace elements, Cl H2O and CO2 have been analyzed in the olivine-hosted melt inclusions in order to better constrain magma genesis, the mantle source processes and the evolution of the volcano plumbing system. Both picritic and basaltic melt inclusions display closely similar Th/U, La/Th, Ce/Th, Ta/Nb ratios indicating their derivation from a bulk HIMU-type OIB mantle source. However, the Ca-rich picritic magma is distinguished by a stronger negative anomaly in Nb, high U/Nb, Cl/Ce, H2O/Ce ratios, and moderately high Ce/Pb, Ba/Th and Sr/Nd ratios which evidence the imprint of a subduction-derived fluid component. This imprint is diluted in historic and present-day basalts that show moderate water enrichment and nearly constant H2O/Ce and Nb/U ratios. A main feature is the decoupled behaviour of alkalis and volatiles (H2O-Cl). Compared to historic basalts, the present-day magmas are significantly enriched in alkalis, but preserve alkalis/La ratios similar to those of the picrite. This suggests the separate involvement of an alkali-rich component during either mantle processes (melting, magma production rate) or interactions with the lower crust, as will be discussed.

The process of biomineralization involves exquisite control of organic and mineral components by biological systems [1-3], which harness chemistry and physics, drawing the attention of material scientists, geochemists, physicists, and biologists [4-5]. The key to understanding biomineralization is in the interaction, at the molecular level, between the organic and mineral components [4]. In this study we employ x-ray absorption near edge (XANES) spectromicroscopy to investigate bond changes and electronic structure of both calcium carbonate mineral crystals and peptides at the OMI. We acquired XANES spectra from calcium carbonate crystals grown in the presence of three nacre-inspired peptides (AP7N, AP24N, n16N) and a sea urchin spicule matrix protein, LSM34.

All model biomineral systems examined show disruption of surface C–C bonds in calcite and the enhancement of the peak associated with C–H bond, indicating ordering of the amino acid side chains. We show that these changes do not occur when Asp and Glu are replaced in the n16N sequence with Asn and Gln, respectively, demonstrating that the Asp and Glu amino acids participate in peptide-mineral molecular associations.

Biominerals in general [1-4] and nacre, or mother-of-pearl, in particular [5-8] attract the attention of scientists in biology, material science, and geochemistry because of their remarkable mechanical properties and the fascinating mysteries that still surround the formation mechanisms of these materials.

The structure and formation of aragonitic mollusk shell nacre are widely studied but still poorly understood. In this work we analyze Haliotis rufescens (red abalone) nacre with synchrotron spectromicroscopy, using linearly polarized soft-x-rays as illumination, and x-ray absorption near-edge structure (XANES) spectroscopy. We demonstrate high imaging contrast between adjacent individual nacre tablets, dependent on their crystal orientation with respect to the polarization vector. We compare data from previous reports and our new data with models for columnar nacre growth and polarization vector. We compare data from previous reports and our new data with models for columnar nacre growth and polarization vector.

Experimental study on the B-isotope fractionation between tourmaline and fluid: A re-investigation

C. MEYER, B. WUNDER, A. MEIXNER, R. ROMER AND W. HEINRICH

GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (whsati@gfz-potsdam.de)

The boron isotopic composition of magmatic and metamorphic tourmaline shows a wide spread in δ11B-values which may range up to 40‰. Fractionations of boron isotopes between tourmaline, fluids, and melts have been used to infer quantitative information on fluid-rock and melt-rock processes in which tourmaline is involved. However, experimental data on ∆11B_{tourmaline-fluid} are scarce and restricted to hydrothermal experiments by Palmer et al. (1992) performed at 350 to 750°C and 50 to 200 MPa.

We reinvestigated the boron isotopic fractionation between tourmaline and fluid by hydrothermally synthesizing dravite with excess fluid between 400 and 700°C at 200 MPa, and at 500°C, 500 MPa using different synthesis techniques. One series used oxides, water and boric acid (90% excess) in a single capsule; the other boric acid (10% excess) and a two-chamber capsule (von Goerne et al. 1999). Run products were characterized by XRD with Rietveld refinement, SEM, EMP and P-TIMS.

Dravitic tourmaline was always the main solid phase sometimes accompanied by traces of other phases, which essentially are boron-free. Dravites from the first series are uniform in size (about 20 µm long), the second series produced a bimodal distribution consisting of small dravite aggregates plus large needles up to 350 µm long. Fractionation of boron isotopes between tourmaline and fluid from the first series give consistent results of -0.4‰ at 700°C and -2.6‰ at 400°C. The temperature dependence is approximated by ∆11B_{tourmaline-fluid} = -3.82 (1000/T[K]) + 2.88, R2 = 0.61.

Quantification and geochemical characterization of total mass fluxes in river catchments of the Rhenish Massif and the Black Forest, Germany

HENNING MEYER, RALF HETZEL AND HARALD STRAUSS
Geologisch-Paläontologisches Institut, Westfälische Wilhelms-Universität Münster, Germany
(hmeye_02@uni-muenster.de)

We aim to constrain long-term erosion rates from the concentration of cosmogenic \(^{10}\text{Be}\) in stream sediments in order to quantify the Late Quaternary denudation history of mountain ranges in central Europe. Four different catchments in Germany, ranging in size from 8 to 379 km² are being investigated. Two of them, the Aabach and Möhne catchments in the Rhenish Massif, drain predominantly low-grade Paleozoic metasediments. The other two, the Gutach and Acher catchments in the Black Forest are situated in late Paleozoic granites. Initial samples from river catchments in the Rhenish Massif yield preliminary erosion rates between 30 and 50 mm/ka. These spatially-averaged erosion rates integrate over the past 10 to 20 ka. Central to our investigation are questions concerning the relative importance of lithology and catchment relief on long-term erosion rates.

Short-term erosion rates for all catchments will be quantified by combining the amounts of suspended and dissolved loads in water samples with water discharge data and basin area. By analyzing the stable isotopic signatures \(\delta^{34}\text{S}\) and \(\delta^{18}\text{O}\) of sulfate and \(\delta^{13}\text{C}\) of dissolved inorganic carbon we aim to correct the suspended and dissolved load for organic, atmospheric and anthropogenic inputs. These results will be complemented by erosion rates derived from the volume of sediment stored behind reservoirs of known age. Preliminary erosion rates, based on accumulated suspended matter from both reservoirs in the Rhenish Massif vary between 4 and 24 mm/ka over a period of 13 to 28 a.

Carbon, nitrogen, and sulfur cycling in a euxinic end-Permian ocean

K.M. MEYER\(^1\), L.R. KUMP\(^1\) AND A. RIDGWELL\(^2\)
\(^1\)Department of Geosciences, The Pennsylvania State University, USA (kmeyer@geosc.psu.edu; lkump@psu.edu)
\(^2\)School of Geographical Sciences, University of Bristol (andy@seao2.org)

Abundant isotopic, geochemical, and biomarker evidence suggests the end-Permian mass extinction coincided with widespread anoxia and possible euxinia (anoxic and sulphidic waters). Anoxia might have resulted from a coincidence of warm surface ocean temperatures, low atmospheric oxygen content, and high \(\text{O}_2\) demand in the deep ocean. Subsequent organic matter remineralization by bacterial sulphate reduction would produce euxinic conditions. Phosphate release from shallow sediments under a sulphidic water column would further enhance oceanic euxinia through positive feedbacks to primary productivity. Here we use earth system modelling to investigate the physical and biogeochemical conditions necessary for the development of intense euxinia during the end-Permian. We hypothesize that reasonable variations in oceanic nutrient content will induce deep ocean euxinia.

We use the end-Permian configuration of GENIE (www.genie.ac.uk), an energy-moisture-balance atmospheric model coupled to a 3-D, non-eddy-resolving, frictional geostrophic model to evaluate this hypothesis. The model includes marine carbon, nitrogen, and sulfur cycles and accounts for metabolisms critical for the transition to ocean euxinia. We performed model simulations over a range of oceanic phosphate concentrations to relate nutrient content to the buildup of widespread euxinia and subsequent chemocline (oxygen-sulphide interface) destabilization. Deep-water \(\text{H}_2\text{S}\) appears with a doubling of oceanic phosphate, and we observe the greatest deep-water sulphide concentrations in the Paleo-Tethys Ocean. The metabolic activities of sulfide-oxidizing phototrophs and denitrifying organisms delay, but do not prevent \(\text{H}_2\text{S}\) buildup. Additionally, \(\text{H}_2\text{S}\) in equatorial and high latitude upwelling zones is released to the atmosphere when the upwelling flux of sulphide exceeds the downward oxygen flux from the atmosphere. Under modern atmospheric oxygen levels, significant air-sea \(\text{H}_2\text{S}\) fluxes result from 6- to 10-fold increases in oceanic phosphate. This destabilization of the chemocline causes sulphide poisoning in both marine and terrestrial environments, imposing environmental stress that may promote extinction. These simulations support the hypothesis that extreme euxinia and episodic \(\text{H}_2\text{S}\) eruptions can result from modest changes in the ocean’s nutrient content. Comparing these spatially resolved predictions to the rock record will help constrain the geochemical environment in which the end-Permian mass extinction appears.
Crustal – mantle melt interactions during continental breakup at the Early Paleocene Vøring Plateau, North Atlantic igneous province

R. Meyer¹, J. Hertogen¹, R.-B. Pedersen², L. Viereck-Götté³ and M. Abratis⁴

¹Geo-Instituut, K.U.Leuven, Celestijnenlaan 200E, B-3001 Leuven, Belgium (romain.meyer@geo.kuleuven.be); ²Geological Institute, University of Bergen, Alleggaten 41, N-5007 Bergen, Norway (rolf.pedersen@geo.uib.no); ³Inst. Geowiss., Friedrich-Schiller Univ., Burgweg 11, D-07749 Jena, B.R.D. (lothar.viereck-goette@uni-jena.de)

Drilling during ODP Leg 104 Hole 642E showed that the Volcanic Rifted Margin (VRM) at the Vøring Plateau is built up of mafic Seaward Dipping Reflector Sequences (SDRS) of Transitional T-MORB character, underlain by silicic volcanic formations (“Lower Series”), LS. The latter are dominantly peraluminous dacites formed by anatexis of crustal material. The core samples not only provide a unique sequence to study the geodynamic processes leading to continental breakup, but they provide the opportunity to investigate in space and time geochemical variations before and during excess magmatism. The samples from the LS allow to identify the crustal components that were potential contaminants of tholeiitic dykes within the LS and the tholeiitic T-MORB Upper Series sequence. These are essential data to determine the intrinsic geochemical characteristics of the mantle sources of the mafic melts. Trace element data, and Sr, Nd and Pb isotopes indicate that a lower crustal component and a upper crustal component contributed to the isotopic signatures, either through melt mixing or through mechanical mixing of pyroclastics. In order to better understand mixing processes we have analyzed a number of selected samples for the element caesium with a low-blank ICP-MS procedure. The Cs signature of the LS rocks (6.13–0.12 ppm) confirms the crust anatectic contribution of these rocks, and the data of the Upper Series tholeiites (0.14–0.01 ppm) indicate that a minor amount of crustal material might have been involved during the SDRS formation. A systematic investigation of Cs in the Hole 642E core defined a decreasing influence of continental crust during the magma formation. The tholeiitic “Upper Series” of both the Vøring and the SE Greenland VRM are isotopically rather similar. In contrast, the “Lower Series” from the two areas are isotopically fundamentally different, due to a different composition of the crust at the two locations. The LS of the Vøring Plateau interacted with high ⁸⁷Sr/⁸⁶Sr lower to upper crust. At the SE Greenland margin the isotopic composition of Sr, Nd and Pb point to a crustal contaminant of granulitic to high grade amphibolite nature (relatively low ⁸⁷Sr/⁸⁶Sr and rather negative εNd). This marked asymmetry of the geochemical signature of the crust at both sides of the nascent North Atlantic should be taken into account into models of the geochemical evolution of the ‘Iceland Plume’ system or alternative models for the formation of the NAIP LIP.

Microbial diversity and SIP investigations of streamer biofilm communities in Yellowstone National Park

D. Meyer-Dombard¹, A. Dibbell¹, A.S. Bradley¹, E.L. Shock² and R.E. Summons¹

¹Dept. of Earth, Atm., and Planetary Sciences, MIT, Cambridge, MA, USA (drmd@mit.edu); ²School of Earth and Space Exploration, ASU, Tempe, AZ, USA (Everett.Shock@asu.edu)

Streamer-forming biofilm microbial communities (SBCs) are common in some alkaline-chloride geothermal systems. Examples of SBCs have been reported in a variety of terrestrial thermal habitats [1], including Yellowstone National Park (YPN). 16S rRNA surveys of SBCs in one YNP location (Octopus Spr.) revealed that those communities were largely composed of presumably autotrophic Aquificales-like Bacteria [3]. However, further investigation of in situ metabolic characteristics of those SBCs by SIP (Stable Isotope Probing) techniques have indicated potential heterotrophic activity [4].

The physicochemical parameters of growth of SBCs down a thermal gradient at “Bison Pool” were investigated, in the context of the geochemical environment. While “Bison Pool” is geochemically similar to Octopus Spring, 16S rRNA and total lipid extract analyses have revealed a significant crenarchaeal component to the “Bison Pool” SBCs. At “Bison Pool”, the SBC bacterial component increases in complexity (going from 3 to 11 genera) while the archaeal component varies little (from 3 to 2 genera) in a 14°C gradient down the outflow channel, crossing the chemotrophic-phototrophic fringe.

Octopus Spring and “Bison Pool” SBCs were used as inoculae for SIP investigations of metabolic function. Microcosm experiments using ¹³C labeled salts of acetate, formate and bicarbonate were conducted over an incubation period of 3-4 days at in situ conditions. Following incubation, cells were extracted by a modified Bligh and Dyer technique in order to isolate various metabolic pools for evaluation of overall carbon uptake and its pathway into cellular metabolism.

SBC lipids showed uptake of ¹³C-labeled acetate and uptake was preferentially seen in archaean lipids after a short incubation (several hours), especially in caldarchaeol and its cyclic counterparts. Non-isoprenoid lipids also showed selective uptake, with the lipids diagnostic of Aquificales showing little or no isotope uptake. Further detailed analyses of these samples should shed light on the uptake of inorganic carbon and its incorporation into cellular metabolism.

Chemical erosion in the Himalayas-Tibet for the past 4 million years studied by Pb and Nd isotopic stratigraphy

L. Meynadier, A.T. Gourlan, P. Louvat and C.J. Allegre

Equipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris et Université Paris-Diderot, CNRS; 4 place Jussieu, 75005 Paris, France (meynad@ipgp.jussieu.fr)

A record of the $^{143}$Nd/$^{144}$Nd ratio of Northern Indian Ocean seawater has been obtained for the past 4 Ma using a new method of differential dissolution on marine sediments. We studied ODP Sites 758 and 757 both located on the Ninetyeast Ridge. At Site 758, the $\varepsilon$Nd and $\delta^{18}$O curves fluctuate in conjunction during the glacial-interglacial periods. The largest variation occurred during the last 20 kyrs where $\varepsilon$Nd varies from -7.5 at Last Glacial Maximum to -10.5 during the Holocene, whereas the amplitude of the variation of the seawater signal is less than 1 $\varepsilon$Nd unit 2.5 Ma ago. The correlation between maxima and minima of $\varepsilon$Nd and $\delta^{18}$O is excellent (r=0.95). However, a detailed comparison of the two signals show that $\varepsilon$Nd and $\delta^{18}$O vary simultaneously during warming while $\varepsilon$Nd is delayed with respect to $\delta^{18}$O during cooling.

The southern ODP Site 757 shows little variations in Nd isotopic ratio. We thus interpret the $\varepsilon$Nd fluctuations at Site 758 as being linked to the erosion regime in the Himalayas-Tibet rather than to variations in the intensity of the deep ocean conveyor belt which flows from the South to this area. A simple quantitative model assuming that seawater Nd is a mixture of Nd that was chemically eroded in the Himalaya-Tibet with Nd coming from Indonesian island arcs indicates that chemical erosion in the Himalaya-Tibet was 2 to 4 times more intense during interglacial than during glacial periods.

We have shown by chemical tests that the same technique of partial dissolution can be also applied for lead isotopes. At Site 758, the lead isotopes ratios fluctuate following glacial interglacial alternation, but within a very small range. Indeed, $^{206}$Pb/$^{204}$Pb, $^{207}$Pb/$^{204}$Pb, $^{208}$Pb/$^{204}$Pb varies from 18.9 to 19.0, 17.73 to 17.77, 39.23 to 39.42 respectively. These variations are extremely well correlated suggesting a binary mixture. We suggest that the two component are the Trans-Himalaya-Belt and the High-Himalaya-Chain.

These results gives strong constrains on the enhancement of monsoon rainfall during Interglacials but also on the glacier occurrence in the Himalaya-Tibet highlands during glacial periods.

Many submarine basalts have assimilated hydrothermally influenced material before they erupt. High Cl and Cl/K in mid-ocean ridge basalts (MORB), submarine ocean island basalts (OIB) and submarine back-arc basin basalts (BABB) are often correlated with Mg#, and suggest that altered rock or brine is involved. It is possible to constrain the H$_2$O/Cl of the assimilated material if it is assumed that mantle derived H$_2$O/Ce ratios are fairly constant at 180 – 250 for Pacific MORB and many Pacific OIB sources, and that mantle-derived Cl/K is fairly low; ≤0.06 in MORB and OIB. (Robust values for low-Cl MORB and OIB). The maximum H$_2$O/Cl ratio in assimilated material can be determined by subtracting Cl from basalt analyses to obtain mantle Cl/K values, and subtracting H$_2$O up to the amount where H$_2$O/Cl constraints are violated. This exercise works best using samples that have very high Cl/K >0.30, such that the mantle contribution is relatively small and the uncertainty on the mantle contribution to Cl is negligible. For samples from the Galapagos Spreading Center (GSC) 86°-92°W, many glasses have <0.4Cl/K<0.6. The maximum H$_2$O/Cl content that does not violate H$_2$O/Ce constraints is H$_2$O/Cl = 1.0. If low-Cl/K samples from the nearby Galapagos Platform can be used to more tightly constrain the mantle H$_2$O/Ce, then the best fit is obtained with H$_2$O/Cl=0: e.g., halite addition. The requirement of a very dense brine or halite means that assimilation involves rocks at very high temperatures, consistent with assimilation of a narrow magma-hydrothermal transition zone.
Martian clay minerals: Context and implications for weathering of a basaltic crust

JOSEPH R. MICHALSKI
Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove, Pasadena, CA, 91109, USA
(Joseph.R.Michalski@jpl.nasa.gov)

The Mars Express OMEGA team discovered clay minerals on the Martian surface from near infrared remote sensing spectra [1-4]. In this paper, I examine some of these clay deposits using near infrared (\(\lambda \approx 0.4-3 \mu m\)) OMEGA data as well as thermal infrared (\(\lambda \approx 6-40 \mu m\)) spectra from the Mars Global Surveyor TES instrument. I also use high resolution images and thermophysical data to constrain the geologic context of these deposits.

At least two clay mineral types are detected (Al- and Mg/Fe-bearing) [1-3] and, in general, the Martian clay deposits correspond to extremely ancient rocks. The occurrence of clay minerals is usually tied to specific photogeologic units; the clay mineral distributions do not cut across multiple terrain units. Based on thermal infrared spectral observations, the clays are usually associated with other silicate minerals (plagioclase, ± mafic glass, ± pyroxene, ± olivine). To date, none of the clay mineral occurrences are associated with detectable quartz, opal-CT, zeolites, or carbonates. Thermal infrared spectra do not show the same strong evidence for clay minerals as the near infrared observations show.

The geologic scenarios that are most consistent with these observations are: 1) erosion and redistribution of a basaltic protolith where the clay minerals occur as clasts or cement in clastic rocks, or 2) diagenetic alteration of mafic ash or sediments. The geologic context of localized Martian clay mineral deposits detected to date is not consistent with origin by volcano-ice interaction, regional metamorphism, or low-temperature weathering of rock surfaces or varnish-like rock coatings. These deposits on Mars provide insight into early Solar System aqueous surface processes at a time when the surfaces of Mars and Earth may have been much more similar.

Native PAHs in hard coal particles as a possible source of increased PAH concentrations in river sediments

VESNA MICIC¹, CHRISTINE ACHTEN¹,
JAN SCHWARZBAUER² AND THILO HOFMANN¹

¹Department of Environmental Geosciences, Vienna University, Althanstr. 14, 1090 Vienna, Austria
²Institute of Geology and Geochemistry of Petroleum and Coal, RWTH Aachen University, Lochnerstr. 4-20, 52056 Aachen, Germany

Due to coal mining, transport and incomplete coal combustion, coal particles can be dispersed into soils and sediments where they can present a source of polycyclic aromatic hydrocarbons (PAHs) [1]. Once released into the environment, they play a pivotal role (amongst char coal, coke and soot) by carrying the predominant part of e.g. PAHs present in the sediment-water system. These particles together with their carcinogenic load can be taken up by organisms and the emanating risks have rarely been investigated [2]. While pyrogenic PAHs are known to be ubiquitous in environment, it is hardly recognized that native PAHs are the reason for elevated PAH concentrations in hard coals [3] being released into the environment during coal mining and transport. Although native PAHs have been in focus of previous research, [4, 5], a general overview of PAHs in hard coals from various large hard coal mining areas has not yet been reported.

The aim of this study is to elucidate (1) whether increased native PAH concentrations are present in hard coal samples from large mining areas and (2) whether PAH amounts and patterns correspond to hard coal rank.

In this study, for the analysis of PAHs in hard coal samples from some large mining areas (i.e. China, US, Australia, Indonesia, Poland, Germany, Ukraine, Kazakhstan), we applied accelerated solvent extraction using dichloromethane and fractionation according to polarity by column chromatography. Subsequently, fractions containing PAHs (~50 PAHs) were analyzed by GC-MS. First results of the study will be presented.

The source and the character of enrichment of Tholeiitic magmas developed on the spreading ridges near the Bouvet triple junction

N.A. MIGDISOVA¹, N.M. SUSCHEVSKAYA¹ AND B. BELYATSKY²

¹Vernadsky Institute of Geochemistry, Moscow, Russia (nadyas@geokhi.ru)
²VNIIOkeanologia, St. Petersburg, Russia (nadyas@geokhi.ru)

The Bouvet Triple junction Zone (Bouvet TJ) is characterized by mutual influence of three slow-spreading zones of the South Ocean – MAR, AAR and SWIR, position of which relatively each other has been changing in space and time. Within these zones there are different types of tholeiite magmas but their geochemical features are close by many parameters. By enrichment type the tholeiites belong to E-MORB developed in some segments of the MAR which are under the influence of Discovery hot-spot and at less degree of Shona plume (leRoux et al., 2002). Normalized spectrums of incoherent elements of Bouvet TJ basalts are characterized by relative maxima for Nb, Ta, La and minima for Pb and less pronounced for Th and U, and by these parameters are close to the enriched tholeiites of the southern part of the MAR. At the same time, these basalts differ from the plume magmas of Etendeka-Parana – the preceding to the opening of South Atlantic in the region 36-38° S. Normalized spectrums of Etendeka evolved basalts are characterized by U, Pb and Zr maxima and Nb and Ta minima, which evidence to crust contamination.

Similarities in geochemical and isotope data, in particular, for Sr, Nd, Pb in magmas of the Bouvet triple-junction region and Quaternary alkaline basalts of Antarctica (Hart et al., 1997) evidence to the participation in the melting process of material from enriched source, which is developed in the region of west Antarctica and stretches to the west extremity of the SWIR. The enriched component is characterized by high-radiogenic isotope ratios of Pb and Sr and low-radiogenic of neodymium ratio. All these events took place together with destruction of the old and formation of the new Bouvet TJ. As there have been some changes in relative movement of plates in the course of mantle flows migration during the oceanic rift propagations (the western part of the SWIR) and spreading ridges jumping, the melting of the low parts of the earlier formed oceanic lithosphere metamorphosed by the melts of earlier rifiting stages was occurred. During rift propagation and jumping of spreading ridge axis within all ridges of the South Atlantic areas have been forming with wide distribution of enriched tholeiites with similar geochemical characteristics. About 2-2.5 Ma ago development of the triple-junction was complicated by Bouvet hot-spot formation in pull-apart style. Such mechanism is suggested for the formation of many islands of the Antarctic peninsula (Hole et al., 1993).

The impact craters and linear magnetic anomalies.

A.V. MIKHEEVA AND A.S. ALEKSEEV

Institute of Computational Mathematics and Mathematical Geophysics SB RAS, Novosibirsk, Russia

The method description

The big literature where modern representations about methods of the geochronological studying an anomaly magnetic field of the ocean and a structure of inversion magnetic-active layer ([1] etc.) are stated has already collected. A new maps of ocean bottom age are constructed. As an example it is possible to result the Tectonic globe of RSRI “ForeignGeology”, served by a cartographical basis for electronic variant [2]. The geometrization of LMA constructions and break structures allows to draw a conclusion on influence on them of various nonlinear geodynamic effects which may be caused as deep processes in geospheres, and various external influences on the ground.

New Results

The analysis of the LMA map [2] allows to locate the clearly circular anomalies in arrangement areas of the known impact craters (see the catalogue [3]). Three of them: a: Pribalhash-Iliyskaya (D=720 km), b: S. Atlantic G.A. (D=300 km) and Popigai (D=100 km) are shown in figure 1.

Figure 1: LMA of known impact craters

Conclusions

Proceeding from these supervision, it is possible to assume, that ring structures may become predicting attribute for a task of new astroblems detection. In Figure 2 the examples of similar structures are shown.

Figure 2: LMA of Barbados and Jan Mayen Islands

⁴Technische Universität München, Germany

Little is known about the properties and reactivity of Fe oxyhydroxides formed in the presence of exopolymers of microbes and plants. We synthesized ferrihydrite (Fh) in the presence and absence of acid polysaccharides (polygalacturonic acid, PGA; alginate, xanthan) and characterized the solids with micro-spectroscopic techniques, gas adsorption, and electrophoretic light scattering. The desferrioxamine B (DFOB)-promoted dissolution of the solids was studied in batch experiments at pH 7 in the presence and absence of citrate or malate. The total ligand concentration was ≤100 µM. In all cases 2-line ferrihydrite (Fh) was the main product of the synthesis. Mössbauer spectroscopy indicated a smaller particle size and a magnetic dilution of Fh in the coprecipitates. The embedding of Fh clusters in the polysaccharide matrices was confirmed by C-1s NEXAFS images. Compared to pure Fh, the coprecipitates comprised an up to 84% lower microporosity. Pure Fh sorbed about four times less DFOB than a PGA-Fh coprecipitate, and its ligand-promoted dissolution in the presence of 50 µM DFOB was two orders of magnitude slower. Our dissolution experiments indicated that, due to Fh coagulation (pH supplementation = 7.1), only a small fraction of the Fh surface was accessible to ligands. In contrast, Fh in the coprecipitates was sterically and/or electrostatically stabilized by the polymers. We show that ‘ligand-accessible surface area’ was the key control of the dissolution reaction and that ligand/adsorbent charge or crystallinity/particle size effects were of minor importance. The solubility of biogenic Fe oxyhydroxides may thus exceed that of pure phases by several orders of magnitude at circum-neutral pH.

History of trace metal contamination in Tagus prodelta cores, Portugal

Favourable oceanographic and environmental conditions allow the formation of a fine-grained deposit (Tagus prodelta) located at the mouth of the Tagus river. This fine-grained deposit results from the sink and accumulation of terrestrial and marine derived materials. Three short sediment cores dated with 210Pb were analysed to determine historical trends in trace metal concentrations in the Tagus prodelta. The geochemical composition of this fine-grained deposit reflects the accumulation of marine biogenic materials, terrestrial and anthropogenic materials transported by the Tagus river. Historical trends indicate significant anthropogenic enrichments for Hg, Pb, Zn, Cu, Sb and Sn since the fifties. Hg presents the highest level of anthropogenic enrichment (ca. EF_mhg=20) in cores PO287-26-1B and PO287-27-1B. Core PO287-28-1B is characterised by high Ca contents that acts as a diluting factor of trace metal concentration derived from anthropogenic activities. Despite the improvement in the treatment of domestic and industrial effluents since the eighties, only slightly decreases in up-core metal trends were observed, revealing the importance of sediment re-working.
Natural Rhenium Isotope Variations

Analyses of industrial and natural Re, expressed as $\varepsilon_{187}\text{Re} = [(187\text{Re}/185\text{Re}_{\text{smpl}}/187\text{Re}/185\text{Re}_{\text{std}}) - 1] \times 10,000$ with $\varepsilon_{187}\text{Re} = 0$ provisionally defined as $187\text{Re}/185\text{Re} = 1.7025$ [1], show ‰-scale isotope variation. External reproducibility of standards is currently ~2 $\varepsilon$ units.

Re is extracted and purified from sample powders with an aggressive leach and anion chromatography. Column-induced fractionation occurs, but is unimportant due to quantitative recovery. Solutions with 20 ng Re g$^{-1}$ are analysed by MC-ICP-MS (ThermoFinnigan Neptune) after doping with natural W to exponentially correct for instrumental fractionation ($^{186}\text{W}/^{183}\text{W} = 1.98594$; [2]). $^{189}\text{Os}$ is monitored to correct $^{187}\text{Re}$ when necessary. Re-rich samples with unknown but very large $^{187}\text{Os}/^{189}\text{Os}$ are stripped of Os by sparging. Other interferences, tailing, and sample matrix effects are insignificant.

Standards prepared in house from high-purity commercial Re and HReO$_4$ are identical ($\varepsilon_{187}\text{Re} = -26$) while an Alfa Aesar Re standard has an $\varepsilon_{187}\text{Re}$ of -28.

Natural samples consist of sulphides, shales, and water samples from an acidic pit lake. Sulphides show ~1‰ variation from $\varepsilon_{187}\text{Re} = -20$ (Archaean MoS$_2$) to a modern rhenite ($\varepsilon_{187}\text{Re} = -29$). Varibly-weathered Devonian black shales span $\varepsilon_{187}\text{Re}$ from -28 to ~32. Acid pit waters from both surface and depth (-76 m) are isotopically indistinguishable ($\varepsilon_{187}\text{Re}$ of -27 and -28).

Detection of natural Re isotope variations mandates a careful study of their utility as a geochemical tool. As Re has no known biogeochemistry, comparison with Mo and Se could prove useful as Re may quantify the strictly abiotic proportion of isotope fractionation.

Fine-scale isotopic structure in OIB trends: New insights from São Jorge Island, Azores

M.-A. MILLET, R. DOUCELANCE AND P. SCHIANO

Laboratoire Magmas et Volcans (UMR 6524 CNRS), Observatoire de physique du Globe de Clermont-Ferrand, Université Blaise Pascal, 5 rue Kessler, 63036 Clermont-Ferrand cedex, France (millet@opgc.univ-bpclermont.fr; doucelance@opgc.univ-bpclermont.fr; schiano@opgc.univ-bpclermont.fr)

Sr, Nd and Pb isotopic compositions (and, at a lesser extent, Os, Hf, He) of Oceanic Island Basalts (OIB) are commonly used to constrain the nature of mantle sources. However, isotope variations measured in OIB can be related either to variable proportions of the various components present in the deep source of basalts, or to interactions between pristine melts and the environments encountered during their ascent to the surface. Therefore, extracting the part of shallow-level processes from the global geochemical signature of OIB is a key to retrieve the source information and to investigate mantle topology in greater details. Consequently, fine-scale studies of OIB, at a single island or archipelago scale, are mandatory.

Here, we present a detailed study of São Jorge Island, Azores archipelago. We report new major-, trace-element concentrations and Sr-Nd-Pb isotope ratios measured for 22 basaltic samples covering most geological formations of the island. We observe variations in agreement with previous studies of the whole archipelago; notably our samples plot on the Pico-Terceira trend that was already documented in the different isotope variation diagrams. We also reveal the existence of a fine-scale structure of isotopic data best evidenced in the $^{206}\text{Pb}^{204}\text{Pb}$ vs. $^{206}\text{Pb}^{204}\text{Pb}$ plot. Our samples indeed draw two sub-parallel trends corresponding to distinct Sr and Nd average values, defined as the unradiogenic (low $^{87}\text{Sr}^{86}\text{Sr}$, $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{206}\text{Pb}^{204}\text{Pb}$) and radiogenic (high $^{87}\text{Sr}^{86}\text{Sr}$, $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{206}\text{Pb}^{204}\text{Pb}$) trends. This isotopic grouping shows a complex relationship with the geographical location of basalts. The radiogenic trend is composed by samples all collected on the eastern part of São Jorge. Conversely, the unradiogenic trend brings together basalts coming from various locations on the island. We will discuss these observations in terms of shallow-level vs. source information in a context of plume-ridge interaction.
Palaeoproterozoic metamorphism in the Limpopo Belt: New petrological and geochronological constraints

L.J. MILLONIG\textsuperscript{1}, A. ZEH\textsuperscript{1}, A. GERDES\textsuperscript{2} and R. KLEMD\textsuperscript{1}

\textsuperscript{1}Mineralogisches Institut, Am Hubland, Universität Würzburg, D-97074 Würzburg, Germany (leo_jakob.millonig@mail.uni-wuerzburg.de, armin.zeh@mail.uni-wuerzburg.de, reiner.klemd@mail.uni-wuerzburg.de)
\textsuperscript{2}Institut für Geowissenschaften, Mineralogie, Senckenberganlage 28, D-60054 Frankfurt am Main, Germany (gerdes@em.uni-frankfurt.de)

Metasediments closely associated with the 3.28 Ga Sand River gneiss of the Central Zone of the Limpopo Belt, South Africa, were deposited after 2.615 Ga and underwent a structural- metamorphic overprint at 2.035-2.025 Ga. This is supported by CL-images in combination with \textit{in situ} LA-ICP(MC)-MS U-Pb, and new petrological results. Zircon core analyses reveal that the investigated metasediment succession consists of detritus of weathered Archean granitoids, predominately formed at ~2.61 Ga and minor at ~3.3 Ga. Zircon overgrowths yield an age of 2027 ± 6 Ma, which is interpreted to reflect the timing of the high-grade metamorphic overprint. This age is identical within error with an U-Pb monazite ages of 2036 ± 8 Ma, but distinctly younger than U-Pb monazite ages of ~2.61-2.64 Ga analysed from the same respective sample. The Neoarchean monazite grains are interpreted to be of detrital origin. This is supported by the finding of both monazite generations enclosed in syndeformative garnet. These structure-age relationships unambiguously show that the observed mineral assemblage sequence: Grt+Bt, Grt+St+Bt, Grt+St+Ky+Bt, Grt+Pt+Ksp/Liq., and Grt+Pt+Ksp/Liq.+Crd was formed during a single orogeny at ~2.03 Ga, characterized by a prograde $P$-$T$ path from 600°C/5kbar to 800°C/10 kbar, and followed by decompression and cooling to 750°C/5kbar.

Lithium isotopes in geothermal systems

R. MILLOT, PH. NÉGREL AND B. SANJUAN

BRGM, Orléans, France, (r.millot@brgm.fr, p.negrel@brgm.fr, b.sanjuan@brgm.fr)

We measured the lithium isotopic composition of water samples (geothermal wells, thermal springs, thermal submarine springs and surface waters) and rock samples from different geothermal reservoirs. The overall objective of the present work was to establish the nature, extent and mechanism of Li isotope fractionation between 100 and 250°C during water/rock interaction.

For that purpose, a new analytical procedure was developed, based on the Neptune multi-collector ICP-MS in operation at BRGM, that enabled the analysis of Li isotopic ratios in liquid (water) and solid (rock) matrices with a level of precision of ±0.5‰ (2 standard deviation) for $\delta^7$Li values on quantities of 10-50 ng of Li.

Geothermal reservoirs located in the French West Indies (Guadeloupe and Martinique islands) were studied and particular emphasis was placed on the characterization of the behavior of Li isotopes during water/rock interaction in a volcanic context at high temperature. In addition, we also determined Li, B and Sr isotope compositions on waters collected from different geothermal sites in metropolitan France in order to characterize geothermal reservoirs by coupling a multi-isotopic approach with in-depth temperature of the reservoir calculated using chemical geothermometers.

The deep waters collected from geothermal wells and thermal springs in the Guadeloupe and Martinique islands indicate that Li isotopic signatures are very homogeneous for a given site but remain however very different from one site to another, probably due to not only lithological differences (reservoir rocks) but also highly variable water/rock interaction temperatures (90-120°C, 180-200°C and 250-260°C) for the Lamentin plain, the Diamant-Mount Pelée areas and the Bouillante geothermal fields, respectively.

Experiments of seawater/basalt interaction were also carried out at different temperatures (from 25°C to 250°C) and the results of isotope exchange experiments confirm the temperature dependence of Li isotope fractionation, ranging from +19.5 to +6.8‰ ($\Delta_{\text{solution-basalt}}$) between 25°C and 250°C, in agreement with field and experimental data reported in the literature.

The variations in B and Sr isotope tracers in geothermal waters appear to be largely controlled by the dominant host lithologies. In contrast, temperature plays an important role in controlling the lithium isotope composition of the geothermal fluids. This result seems to prove that lithium isotopic systematics represents a useful tool suitable for the study of geothermal waters and suggests that the $\delta^7$Li composition of geothermal waters may be utilised not only to characterize the geothermal reservoir (lithology, depth) but also to constrain the temperature of water/rock interaction.
Contribution of bacterial biomass components to the formation of refractory soil organic matter

A. MITTNER1, R. KINDLER2 AND M. KÄSTNER1

1Department of Bioremediation, Helmholtz Centre for Environmental Research UFZ, Permoserstr. 15, 04318 Leipzig, Germany (anja.miltner@ufz.de, matthias.kaestner@ufz.de)
2Department of Soil Science, Berlin University of Technology, Salzufer 11-12, 10587 Berlin, Germany (reimo.kindler@tu-berlin.de)

In general, plant material is regarded as the main precursor of soil organic matter (SOM). Recently however, evidence has been shown that also microbial compounds contribute to the formation of refractory SOM. Although microbial biomass in soils is regarded as rapidly decomposable, about 50% of the C derived from 13C-labelled Gram-negative bacterial biomass (Escherichia coli) persisted in soil after 224 days of incubation. About a fifth of this C was channelled into the microbial food web, the remainder was stabilized in non-living SOM. Further studies of this process are needed to elucidate the consequences for the chemical composition and the stability of SOM. We therefore studied the fate of E. coli-derived fatty acids and amino acids in soil. For both compound groups we distinguished the microbial fraction from the bulk soil fraction. Total amino acids did not decline during degradation, but we found a shift from the microbial to the non-living fraction at the beginning of the incubation. During this process, neither the amino acid pattern nor the isotopic composition of the amino acids changed. This suggests that whole peptides were transformed by the microorganisms, that E. coli-derived peptides were not utilized preferentially and that peptides are potentially refractory. The 13C declined in both the total fatty acids and the microbial (PLFA) fraction by about 80%. Also here a shift from the microbial to the non-living fraction was observed, which continued until the end of the experiment. The isotopic composition of the PLFA shows the redistribution of the labelled C from E. coli to the members of the soil microbial community. The half lives of the 13C-labelled compounds, in particular those of the non-living fractions show that both amino acids and fatty acids derived from E. coli contribute to the formation of refractory SOM thus imprinting a microbial-derived chemical structure on it. The distribution between the microbial and the non-living fraction was compound-specific with the proteins tending more strongly to accumulate in the non-living fraction. Together with the stabilization of compounds which are readily degradable as monomers, this shows that both the chemical structure and the molecular environment of a compound determine its fate in the soil.

Oxidative dissolution of Cr(OH)$_3$(s) by manganese oxides under circumneutral conditions

B.R. MIN1, J.S. PARK1, G. LEE1 AND S. LEE2

1Department of Earth System Science, Yonsei University, Seoul, Korea (bora2013@yonsei.ac.kr, en_geochem@yonsei.ac.kr, ghlee@yonsei.ac.kr)
2Environmental Engineering section, Catholic University of Korea, Bucheon, Korea (Slee@catholic.ac.kr)

Chromium generally exists in the +VI and +III oxidation states under surface and subsurface conditions. Cr(VI) is highly mobile and has deleterious health effects. Cr(III), by contrast, is generally immobile in the subsurface under neutral to alkaline conditions because it precipitates as sparingly soluble Cr(III)- or mixed Cr(III)-Fe(III) hydroxides. However, when these solids may be a potential source of toxic Cr(VI) under natural conditions when they are exposed to oxidants. Among the oxidants in nature, manganese oxides are ubiquitous and known to readily oxidize dissolved Cr(III).

This study investigates a possible pathway for the release of Cr(VI) to groundwater through the oxidative dissolution of Cr(OH)$_3$(s) by manganese oxides under circumneutral conditions. In this study, dissolution of synthetic Cr(OH)$_3$(s) was conducted in the absence or presence of MnO$_2$(s) at pH~8 in 0.01 M NaNO$_3$. The concentrations of dissolved Cr(VI) was determined by diphenylcarbazide method using UV-vis spectrophotometer and those of total Cr and Mn by atomic absorption spectrometry (AAS). During the dissolution of Cr(OH)$_3$(s) for 165 h, the concentrations of dissolved Cr(VI) were all below detection limit (50 µg/L) in the absence of MnO$_2$, whereas it increased with time and reached up to ca. 500 µg/L in the presence of MnO$_2$. The results of this study indicate that a small amount of dissolved Cr(III) ([Cr(OH)$_3^{+}$] = K$_{sp}^{conc} < 10^{-6.84}$) in equilibrium with Cr(OH)$_3$(s) is readily oxidized to Cr(VI) by MnO$_2$ and that this process can accumulate dissolved Cr(VI) in usual groundwater systems.
Radiocarbon and $^{13}$C variations during the last 300 years in lacustrine sediments of Lake Biwa, central Japan

M. MINAMI$^1$, N. TANE$^2$ AND T. NAKAMURA$^1$

$^1$Center for Chronological Research, Nagoya University, Nagoya 464-8602, Japan
(minami@nendai.nagoya-u.ac.jp)
$^2$Department of Earth and Planetary Science, School of Science, Nagoya 464-8602, Japan

Lacustrine sediment cores collected from the northern and southern basins in Lake Biwa were measured for carbon content, $^{13}$C and $^{14}$C. Acid-alkali-insoluble fraction (residue) and acid-soluble fraction obtained by acid-alkali-acid treatment of the sediments were analyzed. The sedimentation rates of the northern basin sediment (KAN) and the southern basin sediment (KAS) were estimated to be ca. 0.13 cm/y and ca. 0.50 cm/y, respectively, by the $^{210}$Pb or $^{137}$Cs method. Carbon content of KAN is very high at the upper layer than 5cm depth and that of KAS has a highest peak at 19cm depth. $^{13}$C of KAN is the highest at 3cm depth layer and that of KAS is the highest at 20cm depth. The highest peaks, both corresponded to ca. 1960 A.D., might be due to nourishing in Lake Biwa.

$^{14}$C suddenly increases from 1950 A.D. to 1985 A.D. in the vertical distribution of KAN residue (Fig. 1). This high $^{14}$C is due to contribution of artificial $^{14}$C produced in atmosphere by nuclear tests after 1950 A.D. with maximum peak of 1964 A.D. $^{13}$C of KAN residue has a wide peak between about 1920 A.D. and 1980 A.D. This suggests the sediment in the southern basin could be a little disturbed. The $^{14}$C of KAN at the lower layer than 20cm, which might have no artificial $^{14}$C produced by atmospheric nuclear tests, shows ca. 4000 BP, older than the age obtained from $^{210}$Pb or $^{137}$Cs, and the true sedimentation age is difficult to be decided from $^{14}$C data of the bottom-surface sediments in this study.

Acknowledgements

We thank Dr. Oda (Center for Chronological Research, Nagoya University) and Dr. Yokota (Lake Biwa Research Institute) for arranging collection of soil samples in Lake Biwa.

Figure 1: $^{14}$C vertical distributions of Lake Biwa sediments.

Equilibrium iron isotope fractionation factors for magnetite from Mössbauer spectroscopy and inelastic nuclear resonant X-ray scattering data

S.D. MINEEV$^1$, V.B. POLYAKOV$^2$ AND Y.V. PERMYAKOV$^3$

$^1$UralPlatinum Holding Ltd. Aviamotornaya 10/2, Moscow, Russia, (mineevsu@comtv.ru)

Mössbauer spectroscopy and inelastic nuclear resonant X-ray scattering (INRXS) in synchrotron radiation experiments are two independent experimental techniques for determination of equilibrium iron isotope fractionation factors ($\beta$-factors). The iron $\beta$-factor for magnetite evaluated from our Mössbauer studies of two natural samples is presented on Fig. 1 along with the $\beta$-factor computed using the INRXS-derived partial density of states (Seto et al., 2003). The Mössbauer temperature is 494 ± 15 K for the A ($Fe^3+$) site and 429± 20 K for the B ($Fe^{2+} + Fe^{3+}$) site.

Mössbauer spectroscopy and inelastic nuclear resonant X-ray scattering (INRXS) in synchrotron radiation experiments are two independent experimental techniques for determination of equilibrium iron isotope fractionation factors ($\beta$-factors). The iron $\beta$-factor for magnetite evaluated from our Mössbauer studies of two natural samples is presented on Fig. 1 along with the $\beta$-factor computed using the INRXS-derived partial density of states (Seto et al., 2003). The Mössbauer temperature is 494 ± 15 K for the A ($Fe^3+$) site and 429± 20 K for the B ($Fe^{2+} + Fe^{3+}$) site.

Figure 1. Temperature dependence of the Fe $\beta$-factors for magnetite (different evaluations).

Seto et al. (2003) used oxidized magnetite (A and B sites ratio is 1.3:1.0) instead of stoichiometric (A/B=1:1) magnetite used in our Mössbauer study. This may explain the slight difference between INRXS- and present Mössbauer-derived $\beta$-factors (Fig. 1). New Fe $\beta$-factors for magnetite are in agreement with isotope fractionations observed in natural and laboratory conditions and obey the general correlation between the $\beta$-factor and the potential energy of the Fe-occupied site, unlike $\beta$-factors previously computed by Polyakov and Mineev (2000) using Mössbauer data by Persoons et al. (1993).
Aqueous alteration of basalts: Earth, Moon, and Mars

DOUGLAS W. MING
NASA Johnson Space Center, ARES, Mail Code KX, Houston, TX 77058, USA (douglas.w.ming@nasa.gov)

The geologic processes responsible for aqueous alteration of basaltic materials on Mars are modeled beginning with our knowledge of analog processes on Earth, i.e., characterization of elemental and mineralogical compositions of terrestrial environments where the alteration and weathering pathways related to aqueous activity are better understood. A key ingredient to successful modeling of aqueous processes on Mars is identification of phases that have formed by those processes. The purpose of this paper is to describe what is known about the elemental and mineralogical composition of terrestrial systems. Although aqueous alteration has not occurred on the Moon, it is crucial to understand the behaviors of basaltic materials exposed to aqueous environments in support of human exploration to the Moon over the next two decades.

Several methods or indices have been used to evaluate the extent of basalt alteration/weathering based upon measurements made at Mars by the Mars Exploration Rover (MER) Mössbauer and Alpha Particle X-Ray Spectrometers. The Mineralogical Alteration Index (MAI) is based upon the percentage of total Fe (Fe₂) present as Fe³⁺ in alteration products (Morris et al., 2006). A second method is the evaluation of compositional trends to determine the extent to which elements have been removed from the host rock and the likely formation of secondary phases (Nesbitt and Young, 1992; Ming et al., 2007). Most of the basalts that have been altered by aqueous processes at the two MER landing sites in Gusev crater and on Meridiani Planum have not undergone extensive leaching in an open hydrolytic system with the exception of an outcrop in the Columbia Hills. The extent of aqueous alteration however ranges from relatively unaltered to pervasively altered materials.

Several experimental studies have focused upon the aqueous alteration of lunar materials and simulants (e.g., Keller and Huang, 1971; Eick et al., 1996). Lunar basalts are void of water and highly reduced, hence, these materials are initially very reactive when exposed to water under oxidizing conditions.

Crystal Water on Mars: Insights from the Mars Exploration Rovers

D.W. MING1, B.C. CLARK2, R.V. MORRIS1 AND THE ATHENA SCIENCE TEAM

1NASA Johnson Space Center, Mail Code KX, Houston, TX 77058, USA. (douglas.w.ming@nasa.gov)
2Lockheed Martin Space Systems, POB 179, MS S-8000, Denver, CO 80201, USA

The purpose of this paper is to constrain the total water contents from crystal H₂O and OH in several materials analyzed by the Mars Exploration Rovers (MER). Crystal H₂O is part of the unit cell and cannot be removed without changing the structure. Minerals that contain only OH in their structures are anhydrous minerals containing hydroxyls, although they are formed as a product of aqueous activity and will decompose with evolution of H₂O when heated.

The crystal water and OH contents of a bulk material at the MER landing sites can be estimated from mineralogical composition, which is determined by a combination of Fe-mineralogy obtained by the Mössbauer Spectrometer and mineral abundances based upon the chemical composition determined by the Alpha Particle X-ray Spectrometer.

Jarosite, along with Ca- and Mg-sulfates, have been suggested as the sulfur-bearing phases in Meridiani Planum outcrop. Models of various hydration states of Fe-, Ca-, and Mg-sulfates and other possible secondary phases suggest that 6 to 22 wt.% of the outcrop may occur as crystal H₂O and/or OH (Clark et al., 2005). This estimate of water is consistent with measurements from the Odyssey orbiter, where 7 % H₂O-equivalent H was measured down to a depth of approximately 1 m for the region (Feldman et al., 2004).

The Peace outcrop material, which is composed of basaltic sands cemented by Mg- and Ca-sulfates, exhibited the highest water content (1.2 to 6.9 wt.% H₂O) of rocks and outcrops encountered on the northwestern flank of Husband Hill in Gusev crater (Ming et al., 2006, 2007). Paso Robles soil on Husband Hill contains Fe³⁺-, Mg-, Ca-bearing and other sulfates, Ca-phosphates, and other secondary phases (Ming et al., 2006). The water content derived from these materials ranges from 2.4 to 16.9 wt.% (Ming et al., 2007).

Unfortunately, the MER Athena instrument payload has not identified the secondary aluminosilicates in outcrops, rocks, and soils at the two landing sites. Therefore, it is likely that the total water constraints listed above are higher than suggested if hydrated secondary aluminosilicates are present.

Frequent observations of tubular to vermicular microchannels in altered basalt glass have led to increasing appreciation of a possible significant role of microbes in the low-temperature alteration of seafloor basalt. We have examined such microchannel alteration features at the nanoscale in basalt glass shards from the Ontong Java Plateau using a combination of focused ion beam milling, transmission electron microscopy and scanning transmission x-ray microscopy. Three types of material were found in ultrathin cross-sections cut through the microchannels by FIB milling: fresh basalt glass, amorphous Si-rich rims surrounding the microchannels, and clays within the microchannels. X-ray absorption spectroscopy at the C K-edge and Fe L2,3-edges showed the presence of organic carbon in association with carbonates within the microchannels and partial oxidation of iron in palagonite compared with basalt glass. Although these observations alone cannot discriminate between a biotic or abiotic origin for the microchannels, they provide new information on their mineralogical and chemical composition and thus better constrain the physical and chemical conditions prevailing during the alteration process. Finally, we will compare these results on modern samples with preliminary observations we made using the same analytical approach on altered archean (3.5 Ga old) basalts from Barberton (South Africa).

Age constraints on the Late Cretaceous alkaline magmatism on the West Iberian Margin

R. MIRANDA1, J. MATA1, V. VALADARES2, P. TERRINHA2, M. R. AZEVEDO3, M. GASPAR1, J.C. KULLBERG4 AND C. RIBEIRO5

1Dep. de Geologia, Universidade de Lisboa; (rmmiranda@fc.ul.pt)
2DGMINET;
3Dep. de Geociências, Universidade de Aveiro;
4Dep. de Ciências da Terra, Universidade Nova de Lisboa
5Dep. Geociências, Universidade de Évora

The post-Paleozoic magmatic activity of the West Iberian Margin (WIM) has been subdivided in three major magmatic cycles occurring at 190-160 Ma, 130-135 Ma, and 100-70 Ma (Ferreira and Macedo, 1979). Magmatic occurrences produced during the last cycle have been grouped along with other intrusions in the Pyrenees in the Late Cretaceous Alkaline Igneous Province of Iberia (Rock, 1982) and in the Circum-Mediterranean Anorogenic igneous province (Lustrino & Wilson, 2007). The onshore magmatic activity postdates by at least 40 Ma the end of the rifting that preceded the opening of the North Atlantic (Rasmussen et al., 1998).

In order to better constrain the sequence of events that characterized the Late Cretaceous magmatic cycle, we present several LA-ICP-MS U-Pb, Ar-Ar, K-Ar and Rb-Sr datings on several intrusions distributed along the WIM.

The new age determinations, combined with the previously published data, allow us to define two distinct pulses of magmatic activity. The first one (94-80 Ma) occurred synchronously with the rotation of Iberia and consequent opening of the bay of Biscay (123-80 Ma; , Sibuet et al., 2004) and clusters around the Lisbon area (above N38º20').

The second pulse (75-72 Ma) has a wider geographical distribution between Algarve in the southermost Portugal (N37º20') and the Lisbon area.

Trace element geochemistry and isotopic data indicate that different mantle sources supplied the two Late Cretaceous pulses, with the more recent one being characterized by more important enrichment in incompatible elements, but less radiogenic Sr and more radiogenic Nd isotopic signatures.

Experimental re-examination of the phase transition quartz-coesite – The reaction in presence of H₂O and at anhydrous conditions

P.W. Mirwald
Institute of Mineralogy and Petrography, Univ. Innsbruck, Austria (peter.mirwald@uibk.ac.at)

The quartz-coesite phase transition has been studied extensively because of its outstanding significance in petrology (cf. Hemmingway et al., 1998). Despite a nominally anhydrous composition, the two SiO₂ polymorphs may contain small amounts of H₂O (e.g. Lathe et al. 2005). Most experimental studies were conducted in presence of H₂O (e.g. Mirwald & Massonne, 1980; Bohlen and Boettcher, 1982). Contrasting results obtained by anhydrous experiments (Walter et al., 2002) gave rise to a re-examination.

The study was performed with a piston cylinder apparatus (400-1100°C, up to 3.5GPa) using pure synthetic SiO₂ as starting material. The phase transition was monitored by differential pressure analysis (DPA) and was controlled by additional quench experiments.

The „wet“ data (400-900°C) confirm previous studies in general reveal, however, a pronounced inflection at 2.7GPa/600°C. (boundary <600°C: P = 2.11 + 0.00096*T). Preliminary data of the anhydrous experiments (700-1100°C) suggest a significantly different P-T course of the transition boundary. (P/GPa = 2.7 + 0.00025*T[C]). The different P-T location of the „wet“ and „dry“ boundary indicates that H₂O incorporation in these phases has a considerable effect on their P-T stability. The observed inflection at 2.7GPa/600°C is attributed to a PVT anomaly of H₂O as similarly found for the nominally anhydrous reaction albite = jadeite + quartz (Mirwald 2005a) and for the brucite dehydration boundary (Mirwald, 2005b).

While in „wet“ experiments the sample material was wetted by breathing into the filled capsule, in dry experiments the capsules were heated to 1000°C for 5-12 hours before welding.

Interrogating a paleo-cratonic margin – The Peruvian Cordillera Oriental batholiths

A. Mišković¹, U. Schaltegger¹ and J. Košler²
¹Dept. of Mineralogy, University of Geneva, Switzerland (miskovic@terre.unige.ch)
²Dept. of Earth Sciences, University of Bergen, Norway

Batholiths of the Eastern Cordillera of Peru exhibit profound variations in chemistry and timing of emplacement from north to south. As products of long-lived, craton-peripheral, intrusive flare-ups, these plutons mark tectonic boundaries between the Western Gondwana and variable Proterozoic to Paleozoic crustal domains accreted during the final assembly and the ultimate break-up of Pangaea.

A striking geochemical relationship exists between three principal plutonic belts: 1) Mississippian to Pennsylvanian, metaluminous, hornblende and magnetite bearing, I-type granitoids are restricted to the segment north of 10°S, and display calc-alkaline evolutionary trends with elevated LILE/HFSE ratios and Nb-Ta anomalies characteristic of subduction zones; 2) Permian to Early Triassic, peraluminous, S-type, mica and ilmenite rich granitoids of the east-central Peru (10-14°S), are characterized by restricted bimodal compositional range, moderate Fe enrichments, low LILE/HFSE values which are associated with transitional, post-orogenic (within-plate) suites; 3) Late Triassic, initially Caledonian I-type monzogranitoids of the southern Cordillera de Carabaya terminate as peralkaline, SiO₂-undersaturated nepheline syenites (Allincapac Gr.) emplaced contemporaneously with eruption Mitu Gr. basanites. The Allincapac Gr. Intrusives and lavas display extreme Fe enrichments, steep REE profiles, and overall low LILE/HFSE ratios. Combined Sr-Nd-Pb-Hf isotope systematics from all three intrusive provinces however lack variation, and suggest uniformly large degrees of assimilation of the Proterozoic Amazonian basement. In addition to the systematic change in the plutonic chemistry, the U-Pb and ³⁹Ar/⁴⁰Ar chronometries reveal a general younging-southward trend from 345 to 188 Ma with the exception of the 310-275 Ma magmatic lull.

Our preliminary geodynamic model envisions, initially orthogonal, eastward subduction of the paleo-Pacific crust below the Western Amazonia during Carboniferous, which was terminated by accretion of a buoyant segment of oceanic crust. This scenario explains the sudden termination of arc-related magmatism in Pennsylvanian as well as uplift and eventual relaxation of the cratonic margin which in turn might have facilitated emplacement of the central Permo-Triassic granites. Simultaneously, a change in conversion angle to southeast during Permian induced development of transtensional, ensialic basins and subsequent back-arc extension along the inherited suture between the Gondwanan craton and the Neoproterozoic Arequipa-Antofalla terrane. The southernmost Carabaya plutons seem to reflect a phase of incipient rifting and re-accretion of the Arequipa terrane.
Sulfate Reduction and Sulfur Isotope Fractionation in Modern Evaporite Ponds

KRISTEN MITCHELL¹ AND DON E. CANFIELD²

¹Faculty of Earth Science, Utrecht University, Utrecht, The Netherlands, (k.mitchell@geo.uu.nl)
²Nordic Center for Earth Evolution (NordCEE) and Institute of Biology, University of Southern Denmark, Odense, Denmark (dec@biology.sdu.dk)

The oldest evidence for sulfate reduction is found in ~3.5 billion year old barites from North Pole, Australia (Shen et al., 2001). These rocks are thought to have first precipitated as gypsum in a marine evaporitic setting. Sulfides are fractionated compared to sulfate by 8 ‰ to 22 ‰, with a mean of 11.6 ‰. This is well within the range of fractionations observed for pure cultures of sulfate reducers, ~10-25 ‰ (Kaplan and Rittenburg, 1964).

A modern analogue to this ancient environment is found in the concentrating ponds of the Eilat Salt Company, Israel. Here, stratified populations of microbes exist in gypsum crust which house active sulfate reducers (Sørensen et al., 2004). These communities are well adapted to the high salinities found in the evaporation ponds (Sørensen et al., 2004).

Fractionation and sulfate reduction rate studies were carried out using a plug flow-through reactor (Roychoudhury et al., 1998). The crusts were separated into two layers, the top 2 cm containing the colorful, phototrophic organisms and the bottom 2 cm, with the non-phototrophic communities.

Fractionations of 25 ‰ were found in both the top (oxic) and (anoxic) bottom layers. Sulfate reduction rates in the bottom 2 cm ranged from 0.02 to 2.65 nmol cm⁻¹ hr⁻¹. The sulfate reduction rates found in the upper 2 cm are higher, ranging from ~13 to ~20 nmol cm⁻¹ hr⁻¹.

The sulfur isotope fractionation found in modern gypsum crust microbial communities is of the same magnitude as found in Archean barites, lending support to the hypothesis that the sulfides here were produced by microbial activity.

Mobility of REE, Sr, Zr and other rare elements during late stage processes in peralkaline rocks: A mineralogical perspective

R. MITCHELL

¹(rmitchel@lakeheadu.ca)

Both over and undersaturated peralkaline syenites are notable for their enrichment in rare elements and complex mineralogy. In contrast to common plutonic aluminous granites and syenites, peralkaline syenites are typified by extended crystallization intervals (~1000-450°C) with a continuum from late-stage magmatic crystallization to alkaline hydrothermal residua. Interaction of the latter with previously-formed minerals can result in distinctive auto-metasomatic processes that result in the mobilization of many elements which are commonly considered as incompatible and/or immobile. Peralkaline complexes are characterized by distinctive styles of low temperature alteration and replacement depending upon whether the hydrothermal residua have either formed discrete pegmatites (e.g. Lovozero) or reacted in-situ (e.g Pilansberg), with previously-formed mineral assemblages. In some instances, (e.g. Strange Lake) externally-derived fluids have had a significant influence on the style of alteration. Elements which can be redistributed during metasomatic transformations involving alkaline-Cl-F-bearing low temperature fluids include the rare earths, Zr, Hf, Nb, Ta, and Sr. This mobility has consequences for ore deposits associated with alkaline rocks, whole rock geochemical studies and for geochronology based on the Lu-Hf, Sm-Nd and Rb-Sr systems. Examples illustrating the mineralogy of metasomatic micasitic, agpaitic and hyperagpaitic replacements are presented for eudialyte and other minerals from Ilimaussaq, Pilansberg, Pocos de Caldas, Gordon Butte, and Pajarito Mountain together with experimental data on the solubility of Nb and Ta in Ca-O-H-F fluids.
Analyses of drilled and surface samples of Ries, Sierra Madera and Takamatsu craters

Y. MIURA
Inst. Earth Planet. Sci., Graduate School, Sci. & Eng., Yamaguchi University, Yoshida 1677-1, Yamaguchi, 753-8512, Japan (yasmiura@yamaguchi-u.ac.jp)

Example Co, Ni and Ir contents of drilled samples

Iron-group elements (Fe, Ni, Co) and platinum-group element (Ir) are measured on drilled samples of Ries (1,000m in depth) and Takamatsu (930m and 960m in depth), compared with surface breccias of Sierra Madera (Texas, USA) as shown in Fig.1.

Discussion

Meteoritic craters show considerable amounts of iron-and platinum-group elements from meteoroids.

Fig.1. Co, Ni and Ir contents of Ries, Takamatsu and Sierra Madera craters.

Significance of chloritite bodies found from the dike-gabbro transision of the Oman ophiolite

SUMIO MIYASHITA1, YOSHIKO ADACHI2, NATSUKI NEO1 AND SHINJI TANAKA1

1Graduate School of Sci. and Tech., Niigata Univ., Niigata, 950-2181 Japan (miyashit@geo.sc.niigata-u.ac.jp, f05j007a@mail.cc.niigata-u.ac.jp, f06j001g@mail.cc.niigata-u.ac.jp)
2Center for Transdisciplinary Res., Niigata Univ., Niigata, 950-2181 Japan (adachi.ys@nifty.com)

Chloritite body with abnormal bulk compositions was first found from the south branch of Wadi Hilti area in the northern Oman ophiolite (Neo et al., 2004 JPGU meeting). Furthermore, another chloritite bodies were found from two localities, north-branch of Wadi Suhayli and north-branch of Wadi Bani-Umar. These three bodies have a similar size and extend about 100x70 m. Original textures are completely obliterated except for a remnant of the primary grain-size. The chloritites are composed of iron-rich chlorite with accessory epidote, titanite, hydrated rutile (anatase) and apatite.

It should be emphasized that these three bodies occur at the same stratigraphic position, i.e., uppermost horizon of the upper gabbro unit, corresponding to a root zone of sheeted dike complex. Sharp but gradual contacts between the black bodies and host rocks (mainly varitextured gabbro and dolerite dikes in places) confirm that the black bodies were altered products. The fact that they occur at the same stratigraphic horizon suggests strongly that the genesis of the chloritites is controlled by a stratigraphic control.

Chlorites of the chloritites are more Fe- and Al-rich than those of host rocks. Surprisingly, calcic plagioclases that are invaded by chlorites along the margin of the chloritites keep the primary composition. These lines of evidence suggest that temperature conditions during the hydrothermal alteration were higher than greenschist facies conditions. Abundant epidotes occur near the margin of the chloritites, but decrease rapidly away from the contact (inward the chloritite body).

Bulk rock compositions of the chloritites show that they underwent very intensive metasomatism during the hydrothermal alteration. That is, severe removal in SiO2, CaO and LIL elements, and large uptake in FeO characterize the chloritites. Such types of the alteration is not known from the hydrothermal system beneath ocean ridges, but we believe that the black bodies found in the Oman ophiolite may give a new aspect on the hydrothermal system.
Partial melting of oceanic crust: Anatectites in the gabbro-dike transition of Oman ophiolite

SUMIO MIYASHITA1, YOSHIKO ADACHI2 AND SHINJI TANAKA1

1Graduate School of Sci. and Tech., Niigata Univ., Niigata, 950-2181 Japan (miyashit@geo.sc.niigata-u.ac.jp)
2Center for Transdisciplinary Res., Niigata Univ., Niigata, 950-2181 Japan (adachi.ys@nifty.com)

There are two different models for the origin of oceanic plagiogranite; 1) extreme fractional crystallization of mafic melts (Spulber and Rutherford, 1982) and 2) partial melting of crustal rocks. Furthermore, two different partial melting processes are debated: hydrous melting (Koepke et al., 2004) and dehydration melting (Beard and Lofgren, 1991). It is still unclear that which mechanism is most effective. We found numerous large blocks retaining partial melting processes from the basal part of the Suhaylah plagiogranite complex in the northern Oman ophiolite.

The Suhaylah complex, about 2.5 x 2.5 km, occurs between gabbro and sheeted dike complex. The complex shows heterogeneous occurrence and is composed of leuco gabbros-diorites, quartz diorites and tonalites.

The basal part of the complex is characterized by a frequent occurrence of metamorphosed dike blocks. The size of blocks is variable and attains about 20 x 5 m. They are traceable over 1.5 km slightly oblique to the boundary between gabbro and the Suhaylah complex. The blocks are composed of two pyroxenes, and plagioclase with variable amount of quartz. Texture is heterogeneous within one specimen and blocks to blocks. Most common textures are globular aggregates consisting of opx-cpx-oxide wrapped by quartz set in a matrix of pl-opx-cpx-oxide. Quartz occurs also as single rounded crystal, globular aggregate and irregular shaped vein. Thus, these blocks may reveal a dehydration melting as similar as the Troodos ophiolite (Gillis and Coogan, 2002).

Minor elment compositions of these anatectites show two contrastive behaviors; one group is characterized by highly depleted feature and the other group by evolved MORB signatures. The former group is composed of two-pyroxene assemblage with few quartz, and regarded as restite. While the latter group contain abundant quartz and is assumed to be melt-rich part.

Temporal changes of the subduction components in volcanic products from Aso area, SW Japan.

M. MIYOSHI1, M. SHIMONO1, T. HASENAKA1, T. SANO2, T. FUKUOKA3 AND T. SHINMURA4

1Graduate School of Science and Technology, Kumamoto University, Japan; (miyoshim@es.sci.kumamoto-u.ac.jp; shimono@es.sci.kumamoto-u.ac.jp; hasenaka@sci.kumamoto-u.ac.jp)
2National Science Museum, Tokyo, Japan;
3Department of Environmental Systems, Rissho University, Japan; (tfukuoka@ris.ac.jp)
4Faculty of Economics, Kumamoto Gakuen University, Japan; (shinmura@econ.kumagaku.ac.jp)

Aso volcano is located in a critical area where Philippine Sea plates (PSP) of old age (40-115 Ma) in the south and young age (15-26 Ma) in the north and Eurasian plate meet. To investigate the temporal changes of subduction signatures, we analyzed boron (B) and other major and trace element compositions in Aso basalts and andesites which erupted since 4 Ma. Boron is a key element for evaluating the slab influence on the subjacent mantle compositions in subduction zones, because this element is enriched in altered oceanic crust and sea floor sediment.

We grouped volcanic activities of Aso area into four stages. Different geochemical types of magmas were found in all stages.

I) 4 Ma: High-magnesium andesites (HMA); II) 2-0.5 Ma: Adakitic andesites, arc-type andesites and high-alumina basalts (HAB);

III) 0.3-0.09 Ma (caldera forming stage): Arc-type andesites and HAB accompanied by large volume of dacites and rhyolites;

IV) 0.09-0 Ma (post-caldera stage): Arc-type andesites and HAB accompanied by small volume of dacites and rhyolites. The ratios of B to fluid-immobile elements are useful tracer of subduction, because they are not controlled by crustal contamination, fractional crystallization and/or partial melting processes. The ratios of B/Sm (1.0-0.4) and B/Zr (0.03-0.05) in the HMAs are lower than those of the HABs (1.3-5.0 and 0.06-0.17, respectively). B/Nb ratios in the HMAs are similar to those of the mantle values (0.05-0.5). On the other hand, B/Nb ratios (1.4-4.0) in the HABs overlap with those of basalts from cool subduction zones (Kurile and NE-Japan).

These observations suggest that the released phase has slab component beneath Aso area changed from melt derived from dehydrated slab to hydrous fluid between stage I and II. This may have resulted from the lowering of geotherm beneath Aso area caused by the change of subducted plate from young PSP to the old one. This implies that the boundary between young and old PSP moved northward crossing Aso area from 4 to 2 Ma.
Paleo-hydrochemical changes of deep groundwater in Mizunami area, Japan

T. Mizuno, A.E. Milodowski and T. Iwatsuki

1Japan Atomic Energy Agency, 1-64 Yamanouchi, Akeyocho, Mizunami, Gifu, Japan (mizuno.takashi@jaea.go.jp)

3Japan Atomic Energy Agency, 432-2, Hokushin, Horonobe-cho, Hokkaido, Japan (iwatsuki.teruki@jaea.go.jp)

Introduction

Multilayered fracture-filling calcite mineralization was studied to assess the long-term hydrochemical changes of deep groundwater in the Mizunami area, Japan. Four generations (I to IV) of calcite precipitation can be differentiated on the basis of detailed studies using optical and cathode-luminescence microscopy, SEM, laser ablation microprobe-ICP MS, stable isotope geochemistry, and fluid inclusion analysis.

Results and Discussion

Carbon and oxygen isotopic ratios suggest that the Generation I calcite is of hydrothermal origin. On the other hand, generations II, IV and III calcite were precipitated from freshwater and marine water, respectively. Fluid inclusions could only be observed in calcite generations II and III. These fluid inclusions show no obvious change in fluid salinity between generation II and III calcite mineralization. The generation II and III calcites were possibly precipitated from mixture of freshwater and marine water. The calcite crystal morphology is sensitive to the chemistry and salinity of the groundwater. Morphological change during generations II to IV coincides with the changes of groundwater origin indicated by stable isotope and fluid inclusion composition. On the other hand, REE distribution patterns within the different generations of calcite show that no differential behaviour between REEs and Ce, which is known to be redox sensitive, and the trivalent REEs. This suggests that the redox condition of groundwater have remained relatively reducing during the different generations of calcite precipitation, even though groundwater chemistry had changed.

Conclusion

Detail analysis of multilayered calcite fracture mineralization associated with groundwater flow paths provides a valuable information to evaluate long-term palaeohydrogeological changes of groundwater chemistry.

Fission-track thermochronology evidence on Wulonggou gold mineralization, eastern Kunlun Mountains, northern Qinghai-Tibet Plateau

Xuanxue Mo and Wanning Yuan

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (mxx@cugb.edu.cn ywm010@yahoo.com)

Wulonggou gold ore district is located at the eastern Kunlun Mountain, northern Qinghai-Tibet Plateau. The mineralization category belong to tectonic altered rock type. The gold mineralization is intensive and distribute mainly along construct-zone. Fission track thermochronology has been used to constrain the mineralization histories of gold ore districts in eastern Kunlun Mountains in this work.

Five zircon fission track ages for the ore and altered rock samples range from 235±4 Ma to 194±10 Ma, concording with various Rb-Sr and K-Ar isotopic ages (207.1-252.9 Ma) for the mineralization (Lu et al., 1999; Mock et al., 1999; Qian et al., 1999). Two apatite fission track ages of the ore samples are 201±7 Ma and 151±6 Ma respectively, which corrected ages are close to the zircon fission track ages and isotopic ages. Therefore, the FT age could presents the time of mineralization thermal events. Another two apatite samples collected both from selvage and faulted lens with 50±3 Ma and 45±4 Ma FT ages recorded late tectonic activities.

Mineralization thermal histories are modeled and the samples produced remarkably similar thermal paths. Polymineralization could be identified. The major mineralization period was around 240–150Ma. It is the polymineralization that not only prolongs the mineralization period, but also enhances mineralization degree. The mineralization temperature didn't exceed about 300°C after about 240 Ma according to the zircon fission track data. The mineralization thermal events were mainly relevant to the subduction along South-Kunlun sutrue and the intrasubduction along Middle-Kunlun zone at that time.

In situ measurements vs. lattice strain model calculations: Distribution of REE between Grt and Cpx in garnet peridotites from Vitim (Siberia)

B. MOCEK1,2, E. HELLEBRAND1,3 AND D. IONOV1,4

1Max Planck-Institut für Chemie, Abteilung Geochemie, Mainz, Germany
2present address: Institut für Geowissenschaften, Universität Potsdam, Germany (bmocek@geo.uni-potsdam.de)
3present address: Dept. of Geology & Geophysics, University of Hawaii, Honolulu USA (ericwgh@hawaii.edu)
4present address: Dept. de Geologie-Petrologie-Geochimie, Université Jean Monnet, Saint-Étienne, France (dmitri.ionov@univ-st-etienne.fr)

We present newly determined REE-distribution coefficients between clinopyroxene (cpx) and garnet (grt), which can be used to model and understand geochemical processes such as crystallisation, differentiation and melting.

From the literature it is known that discrepancies exist between calculated REE-distribution coefficients from natural samples (whole-grain separates) and those collected from experimental run products. To address these discrepancies we measured cpx and grt of grt-peridotites xenoliths from the Vitim volcanic field in Siberia. The samples were selected because they are well studied, formed over a restricted P-T range (1050-1200°C, 2.1-2.5 GPa) and do not show evidence of metasomatism and other secondary processes. The minerals were analysed in-situ, within thin sections, by electron microprobe and secondary ion mass spectrometer (SIMS). Only samples with unzoned minerals were used for the determination of REE-distribution coefficients, which were calculated from mineral core compositions.

The cpx-grt distribution coefficients vary between 240 and 360 for La and between 0.03 and 0.07 for Yb, which is consistent with experimental data from Burgess and Harte (2004) at temperatures between 900°C and 1000°C. Compared to mineral separate data for REE from Vitim xenoliths (Ionov et al. 1993) the newly determined Kds are in good agreement, but show less scatter for the HREE between different samples. This may be explained by the ability to avoid micro-inclusions by in situ SIMS analyses.

In the original lattice strain model the physical characteristics of the cation site in grt and cpx are used to predict distribution coefficients for various trace elements in equilibrium with a melt. In our case there is no melt, and our calculations are therefore based on one measured distribution coefficient to predict the others (Yb is used here). The predicted Kd pattern agrees well for the HREE (Er to Tm) with the measured, but is less steep (hinges on Yb). The maximum differences are a factor of about 2 (La to Er). We will explore the model parameters that may contribute to this remaining discrepancy.

Age and variability of dissolved organic carbon in the St. Lawrence River

M. MOINGT1,2, C. HILLAIRE-MARCEL2, L. DEVER1, Y. GELINAS3 AND F. BARBECOT1

3Chemistry and Biochemistry Department, Concordia University, 7141 Sherbrooke St. West, Montréal (Qc), Canada, H4B-1R6.

Riverine export of dissolved organic carbon (DOC) to the global ocean represents about 0.25 x 1015gC/yr. Various studies have shown that this DOC mainly derives from terrestrial organic matter (OM). It is generally considered to be refractory and transported conservatively to the ocean. However, recent work has shown that many rivers transport a high 14C content DOC. Knowledge of the age (residence time) of both labile/refractory components of DOC and of its variability is essential for a robust assessment of the role of riverine DOC in the global carbon cycle. Here we report chemical and isotopic composition of DOC from the St. Lawrence River, with a focus on 14C ages of labile vs. total DOC fractions, and on the spatial, seasonal to interannual variability of DOC export. Alkaline CuO oxidation was used to study a refractory DOC component and to identify sources and degradation stages of terrestrial organic matter. Our results indicate some variability in total DOC from year to year, but more notably, temporal and spatial variability in 14C-activities of the refractory DOC component, which represent approximately 6 to 30% of total DOC and yielded 14C-activities ranging between 75 and 96% of modern carbon (pMC). From these values, 14C-activities of labile compound were estimated and ranged between 100 and 111pMC. Labile DOC compounds are thus very young or have a short residence time in this system. This residence time is much shorter than the one estimated for water flowing through the Great Lakes/St. Lawrence River system, thus suggesting prominent terrestrial sources for this reactive organic carbon. Although accounting for lower overall DOC fluxes, refractory material display ages that suggest aging for a significant time in soils of the watershed.
Layered granitoids; Migmatites and/or granitoids mixing zone?

P. Moita¹, J. Santos² and M.F. Pereira³

³Departamento de Geociências, Universidade de Évora, Centro de Geofísica de Évora, Apartado 94, 7002-554 Évora, Portugal (mpereira@uevora.pt)

In the SW sector of the Ossa-Morena Zone (Iberian Variscides), a structurally complex and lithologically heterogeneous outcrop (Pereira & Silva, 2002) along the Almansor River was studied. This outcrop was previously considered to represent migmatization. Other works (e.g. Moita et al., 2005) in nearby areas have shown that syntectonic plutonism and migmatization have been important in the period from 330 to 320 Ma.

In this study, three main lithotypes were identified which together define a strongly layered pattern: diatexites (Dtx), weakly foliated granitoids (WFG) and leucogranitoids (LG). The Dtx are peraluminous monzogranites to quartzofeldspathic rocks with \( (\text{87Sr}/\text{86Sr}) \) from -9.32 to -8.92; the WFG are metaluminous to weakly peraluminous trondhjemitic rocks with \( (\text{87Sr}/\text{86Sr}) \) from -3.79 to -6.09. The isotopic signature and multi-element patterns of Dtx are not only internally coherent but also similar to Neoproterozoic metasedimentary rocks suggesting that they represent anatectic magmas. The WFG and LG exhibit more complex multi-element (Moita et al., 2006) and isotopic signatures which were interpreted as the result of strong magmatic differentiation from mafic magmas accompanied by interaction with crustal melts.

Therefore, the studied outcrop, rather than testifying in loco migmatization seems to correspond to complex mingling/mixing(?) of magmas, evolved through different sources and processes (crustal anatexis and magmatic differentiation), within a shear zone.

Graphite + apatite in >3.83 Ga ferruginous quartz-pyroxene (supracrustal) rocks from Akilia, southern West Greenland

Stephen J. Mojzsis¹, Dominic Papineau¹,², Jon D. Adam¹ and T. Mark Harrison³

¹Geological Sciences, University of Colorado, UCB 399, Boulder, Colorado 80309-0399 USA (mojzsis@colorado.edu)

³Earth & Space Sciences, IGPP, University of California, Los Angeles, California 90095-1567 USA (tmh@argon.ess.ucla.edu)

Graphite associated with apatite (Fig. 1) is present in magnetite-bearing banded quartz-pyroxene units from an early Archean supracrustal succession preserved on Akilia (island), West Greenland [1]. This observation stands in contrast with some recent reports that graphite was absent in apatite crystals from these same units [2]. Sample (G91-26; ref. 1) comes from rocks of sedimentary protolith with \(^{13}C\)-enriched carbon (\( \delta^{13}C < -30\% \)) in intimate association with apatite and previously presented as evidence for life on Earth before ca. 3.83 Ga [3]. Here, we report further examples of graphite+apatite in pre-3.78 rocks of sedimentary protolith from other Akilia association enclaves on Innersuatuq island (West Greenland; ref. 4) and metasediments of the pre-3.75 Ga Nuvvuagittuq Supracrustal Belt (northern Québec, Canada; ref. 5).

Since the original description, geochemical evidence has accumulated that significantly bolsters the initial interpretation that the Akilia rocks were originally chemical sediments deposited before 3.83 Ga, and that they provide information on surface processes and biological activity on the early Earth [6].

Glacial-interglacial variations in the $^{87}\text{Sr}/^{86}\text{Sr}$ composition of seawater

F. Mokadem, K.W. Burton, I.J. Parkinson, B.L.A. Charlier and E. Hathorne

1Dept. of Earth Sciences, The Open University, Walton Hall, MK7 6AA, UK (f.mokadem@open.ac.uk; k.w.burton@open.ac.uk; i.j.parkinson@open.ac.uk; b.l.a.charlier@open.ac.uk)
2LMTG, Universite de Toulouse, 31400, 14 Av. E. Belin, Toulouse, F-31400, France
3DFG-Research Center Ocean Margins, University of Bremen, Loenber Strasse, D-28359, Bremen, Germany (e.hathorne@marum.de)

Many natural radiogenic isotopes in seawater show variations on glacial-interglacial timescales that can be related to either local or global changes in continental weathering and/or changes in Ocean circulation. On such timescales the long residence time of Sr necessitates very large changes in the continental flux to the Oceans to cause a measurable shift in the $^{87}\text{Sr}/^{86}\text{Sr}$ value of seawater (Richter & Turekian, 1993). Early studies reported fluctuations in marine $^{87}\text{Sr}/^{86}\text{Sr}$ over glacial-interglacial cycles (Dia et al., 1991; Clemens et al., 1993) but later work indicated that at the ±13 ppm level there was no evidence for any change (Henderson et al., 1994) However, changes of 6-9 ppm could not be ruled out, which, though small, correspond to a ~30% change in the riverine Sr flux.

Since that time a new generation of TIMS instruments, has enabled a 5-10 fold improvement in the precision of absolute isotope ratio measurement. This study presents very-high precision $^{87}\text{Sr}/^{86}\text{Sr}$ measurements for planktonic foraminifera from ODP site 758 in the Indian Ocean, that complement existing $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{187}\text{Os}/^{188}\text{Os}$ isotope data for the same samples. Repeat measurements of NBS 987 demonstrate a long term reproducability of ±3.4 ppm 2 s.d (n = 30). Size restricted samples of the species G. conglobatus and N. dutertrei were subject to oxidative-reductive cleaning and Sr separated using Echlon Sr-spec resin. Preliminary results indicate the presence of 3-9 ppm cycles over glacial-interglacial timescales, but unlike Nd and Os these cycles are not in phase with the oxygen isotope curve (as predicted by Richter & Turekian, 1993). The simplest interpretation is that these variations reflect changes in continental input accompanying climate cycles, corresponding to a ~10-30% change in the riverine Sr flux.

The origin of Tertiary intraplate volcanism in the Siebengebirge volcanic field, Germany

M. Moll, C. Münker and Holger Paulick

1Universität Bonn, Germany (melanie_moll@gmx.de)
2Universität Münster, Germany

The Miocene (~25 Ma old) Siebengebirge volcanic field, belonging to the Central European Volcanic Province (CEVP), is located at the SE end of the Northern Rhine Embayment near Bonn, Germany. For its relatively small size of ca. 900 km$^2$, mafic magma compositions are unusually diverse, ranging from basanites to alkali basalts. Differentiated rocks comprise both silica saturated (latitic to trachytic) and undersaturated compositions (phonotephritic to tephrilithic), which only occur in a small area in the central part. In contrast to other volcanic provinces in Germany, nearly all magmas appear to be subvolcanic.

In order to unravel mantle sources of the magmas, trace element and isotope compositions were determined for representative mafic and felsic samples. In mafic samples (MgO > 7 wt.%), εHf range from +6.5 to +8.0, εNd from +3.1 to +4.4, $^{87}\text{Sr}/^{86}\text{Sr}$ from 0.7034-0.7038, and Pb isotope compositions from 19.46-19.69 (207Pb/204Pb), 15.63-15.66 (206Pb/204Pb) and 39.34-39.62 (208Pb/204Pb). Together with the Hocheifel volcanic field, the mafic Siebengebirge samples display the highest Pb isotope compositions amongst all other volcanic provinces in Germany (i.e., Hessian Depression, Westerwald, West Eifel, East Eifel, Vogelsberg).

Trace element patterns show a strong enrichment of LREE compared to the HREE, indicating enriched sources in the spinel and garnet peridotite transition zone. Isotopically, the primitive samples cover a range between a “HIMU-like” endmember composition, compositions reflecting the influence of subducted sediments (“EM-2 like”) and depleted endmembers. High Zr/Hf ratios and positive Nb anomalies confirm the presence of HIMU-like domains, originating from recycled oceanic crust.

Alkali basaltic compositions reflect higher melting degrees and lower average melting depths than basanitic compositions, indicating a variable lithosphere thickness. Negative K-anomalies in primitive mantle normalized trace element diagrams reveal the influence of a volatile- and K-rich phase, most likely amphibole in the lithospheric mantle. Notably, the K anomalies are neither correlated with trace element or Pb isotope variations, suggesting a minor role of lithospheric components. Hence, the enriched signatures rather originate from locally enriched domains in the convecting asthenospheric mantle.

The silica saturated group of differentiated rocks can be shown to originate from alkali basaltic parental magmas whereas the undersaturated group crystallized from basanitic parental magmas. High $^{87}\text{Sr}/^{86}\text{Sr}$ (up to 0.7062), low εNd and εHf (as low as -2.3 and +0.4, respectively) indicate significant upper crustal contamination for both groups.
REE distribution between zircon and orthopyroxene in granulites as a link between petrology and geochronology

ANDREAS MÖLLER1, ERIC HELLEBRAND2, RENATO MORAES3 AND BEATE MOCEK1

1Institut f. Geowissenschaften, Univ. Potsdam, D-14776 Potsdam-Golm, Germany, (amoeller@geo.uni-potsdam.de)
2Max Planck-Institut für Chemie, Abteilung Geochemie, Mainz, Germany, present address: Geology and Geophysics Dept., University of Hawaii, Honolulu, USA, (ericwgh@hawaii.edu)
3Instituto de Geociências, Universidade de São Paulo, São Paulo, Brazil, (moraes@igc.usp.br)

Zircon has been the most versatile tool for high temperature geochronology for many decades. New trace element tools are now developed to use it also as thermometer and link it to pressure and temperature evolution of metamorphic rocks. The main focus in studies on the distribution of rare earth elements (REE) has been on garnet and zircon; with an ongoing debate about which distribution patterns constitute equilibrium under different metamorphic conditions in granulites, eclogites and migmatites. There is little data available for REE exchange with other minerals in high grade metamorphic assemblages.

We present in-situ ion microprobe data on coexisting zircon-orthopyroxene (opx) pairs from garnet-free high temperature leucosomes (tonalitic composition) as well as both garnet-absent and garnet-bearing granulites of granitic composition. The samples are from the high-temperature low-pressure granulites of Rogaland (SW Norway) and the UHT medium pressure granulites from the Brasilia fold belt. All investigated rocks without garnet yield similar patterns for orthopyroxene, with low abundances of L-MREE (La to Eu) between 0.1 to 1x chondritic values, small negative Eu anomalies and steeply increasing M-HREE to ca. 50x chondrite for Yb. Zircon in the orthopyroxene-bearing leucosome and garnet-absent granulites have steep REE patterns, including a steep rise in HREE (at variable absolute values) with Yb/Gd of 10-20. The relatively flat HREE zircon-orthopyroxene distribution patterns (10-30 for Gd to Lu) are quite similar to patterns obtained from UHT leucosomes and granulites for zircon-garnet pairs (own studies and other authors). It can be concluded that when present in equilibrium with zircon in high temperature rocks, orthopyroxene is a sink for MREE and HREE not to be overlooked. The impact on HREE abundances in zircon is thus diminished and the HREE pattern of zircon in equilibrium is steep.

As a result, we caution against overinterpretation of REE patterns from detrital zircon, i.e invoking granulate conditions for source rocks based only on flat or decreasing HREE patterns.

PGE distributions in Mesoarchean chromitites and mafic-ultramafic rocks in the Singhbhum Craton (India): Evidence for presence of a subchondritic source mantle domain

SISIR K. MONDAL

Department of Geological Sciences, Jadavpur University, Calcutta-700032, India (sisir.mondal@gmail.com).

In the Singhbhum Craton of India the layered ultramafic bodies with chromite deposits occur within the Archean greenstone sequences of Iron Ore Group mainly in the Nuasahi, Sukinda and Jojohatu areas. In many places these ultramafic bodies are closely associated with gabbroic intrusions. The massive chromitites of seams from the Nuasahi area are enriched in total platinum group element (PGE) concentrations (∑PGE=142 to 549 ppb) compared to host peridotitic (∑PGE=7 to 26 ppb) and adjacent gabbroic rocks (∑PGE=3 to 116 ppb). The PGE compositions for peridotitic rocks are near chondritic with strong Ir-depletion with a general positive slope (Pd/Ir = 3 to 10). The PGE compositions of chromitites are superchondritic with strong Pt depletion coupled with Ru enrichments. Gabbroic rocks have strong subchondritic IPGE compositions and show distinct PPGE fractionated trend with strong positive slope. The geochemical distributions of the PGEs in chromitites and silicate lithounits bear directly on the two problems (1) why PGEs fractionate and (2) why are they enriched in chromitites. The strong depletion of Ir and relative enrichments of PPGE in ultramafic suite along with high PGE concentrations in chromitites are genetically related to crystallization from a boninitic parental magma in a suprasubduction zone setting in Archean. However, it is difficult to explain the strong fractionation between IPGEs (Os/Ir and Ru/Ir) in the peridotitic rocks by the existing models. The strong subchondritic Ir pattern is perhaps related to the presence of a subchondritic source mantle domain beneath the Singhbhum Craton. The notion of the presence of a subchondritic source domain within the upper mantle beneath the Singhbhum Craton is also supported by the recent Os isotopic studies of these rocks.
The stability of calcite and aragonite
in sediments overlying zones of
basement fluid upwelling in the
eastern flank of the Juan de Fuca ridge

CHRISTOPHE MONNIN1, C. GEOFFREY WHEAT2 AND
MICHAEL M. MOTT3

1Laboratoire Mécanismes et Transferts en Géologie,
CNRS/Université Paul Sabatier, 16 Avenue Edouard Belin, 31400 Toulouse, France.
(monnin@lmtg.obs-mip.fr)
2Global Undersea Research Unit, University of Alaska, P.O. Box 475, Moss Landing, CA 95039, USA
3Department of Oceanography, University of Hawaii at Manoa, 1000 Pope Road, Honolulu, HW 96822 USA

Heat flow measurements and sediment porewater composition data collected on the Eastern flank of the Juan de Fuca ridge during numerous cruises have evidenced the extend and the features of the low temperature fluid circulation in ridge flanks, with the aim of quantifying the contribution of this circulation to heat and mass fluxes between the ocean and the oceanic crust. One of the questions is to know how basement fluid may react with the sediment, with the consequent modification of the composition of basement fluids discharging to the seafloor.

The Retroflux expedition (September 2000) has mapped fluid discharge zones associated with basaltic outcrops and seamounts using heat flow measurements and coring. Ninety three cores (up to 7 meters in length) were collected during this expedition. Porewaters were analyzed on board for chlorinity, Ca, Mg, pH, alkalinity, and nutrients and on shore for trace elements. In upwelling areas, porewaters display a rapid Mg depletion and Ca enrichment with depth consistent with a fluid in basement that has reacted with basalt at low temperatures. These upwelling fluids have an alkalinity that is lower than that of seawater. In contrast, porewaters from cores collected outside zones of fluid discharge have alkalinitities that increase with depth resulting from the oxidation of organic matter and the reduction of sulfate during diagenesis. Thus a variety of alkalinity depth profiles exists reflecting the competition between alkalinity production from diagenetic reactions and the transport of an alkalinity-depleted basement fluid. pH variations reflect sediment heterogeneities (local chemical reactions?) that persist even in zones of rapid fluid upwelling. Thermodynamic calculations show that equilibrium with aragonite is achieved for cores without diagenesis or flow, at in situ T and P, which excludes any sampling bias. They also reveal a variety of cases for equilibrium and/or supersaturation with respect to either aragonite or calcite, depending on the increase in alkalinity, the rate of fluid upwelling and the degree of alteration of discharging basement fluids with respect to normal seawater.

Melt segregation and melt – mantle interaction in a supra-subduction zone context: An example from the Khoy ophiolite, NW Iran

I.MONSEF AND M.RAHGOSHAY

Shahid Beheshti University, Earth Sciences Faculty, Evin, Tehran, Iran (iman_monsef@yahoo.com)

Introduction

Petrographic and geochemical studies of residual mantle exposures in supra-subduction zone environment provide important information on partial melting, melt segregation and melt – mantle interaction processes in the oceanic mantle lithosphere. Ultramafic tectonites comprise dominantly lherzolites and cpx-harzburgites in Khoy ophiolites.

Discussion of results

These peridotites can be distinguished into three groups:
1- Peridotite type-(I) samples contain Al – rich spinels (Cr# of 0.16 – 0.26, Mg# of 0.75 – 0.68 and TiO2 = 0.01 - 0.12 Wt %) with generally smooth LREE – depleted and fairly flat MREE – HREE profiles. 2 - Peridotite type-(II) samples contain Cr – rich spinels (Cr# of 0.31 – 0.66, Mg# of 0.66 – 0.89 and TiO2 = 0.00 to 0.06 Wt %) with LREE – depleted and positive slopes MREE – HREE profiles. 3 - Particular peridotite samples contain Cr – rich spinels (Cr# of 0.45 – 0.88, Mg# of 0.63 – 0.86 and TiO2 = 0.13 to 1.03 Wt %) with U – shaped REE patterns indicative of interaction between LREE – depleted mantle peridotites and LREE – enriched extracted melt.

Conclusions

The results illustrate that the peridotite type-(I) samples resemble fertile abyssal peridotites, which has probably originated as the residue from less than 15% partial melting and MORB magma extraction in a slow – spreading back – arc basin centre. Peridotite type-(II) samples represent depleted abyssal or supra – subduction zone peridotites, which has experienced more than 15% partial melting from segregation of IAT or transitional IAT-MORB magmas. Peridotite type-(II) samples were subsequently modified to particular peridotite samples by interacting with divers types of arc magmas in a supra-subduction zone setting.

Magma chamber processes and geochemical aspects of megaporphyritic basic-intermediate lava in West Alborz Iran

R. MONSEF 1AND M.H. EMAMI2

1Islamic Azad University, Estahban Branch, Iran
2Research Institute of Earth Science, Geological Survey of Iran

The studied area is in the northwest of Khalkhal (Azerbaijan, NW of Iran) and related to Alborz – Azerbaijan structural zone. The oldest stratigraphic units belong to pre-Cretaceous deposits and the youngest units are quaternary alluvial deposits. The Eocene volcanic rocks are composed of olivine basalt, trachy basalt, trachy andesite and megaporphyritic basic-intermediate lavas. The latter have few centimeters phenocrysts of plagioclase and are extended in a large area from NW to SE of Iran volcanic belt (Urumieh-Dokhtar magmatic belt). They are a good indication for Upper Eocene volcanic activity in Iran. Geochemical and isotopic data for megaphyritic lavas show that the basaltic rocks have transitional trend with sodic character and the intermediate terms belong to calc-alkaline series with sodic or potassic affinities due to different rates of crustal contamination and fractional crystallization (AFC process). The basaltic lavas are not relatively rich in plagioclase phenocrysts and have been ascended rapidly to the surface but the rich megaporphyritic intermediate lavas are the result of basic magma storing in upper crust chambers, suffering fractional crystallization and crustal contamination. These megaporphyritic lavas are also interested for Cu,Pb,Zn mineralization.

Rhombohedral calcite precipitation from CO2-H2O-Ca(OH)2 slurry under supercritical and gas CO2 media

G. MONTES-HERNANDEZ1*, F. RENARD1, L. CHARLET1 AND J. PIRONON2

1LGIT, Maison de Géosciences, BP 53 X, 38420 Grenoble Cedex 9
2UMR-G2R 7566 UHP-CNRS-INPL-CREGU, BP 239, 54506 Vandoeuvre les-Nancy, France
*Corresponding author: German Montes-Hernandez;
(German.MONTES-HERNANDEZ@obs.ujf-grenoble.fr;
german_montes@hotmail.com)

The formation of solid calcium carbonate (CaCO3) from aqueous solutions or slurries containing calcium and carbon dioxide (CO2) is a complex process of considerable importance in the ecological, geochemical and biological areas. Moreover, the demand for powdered CaCO3 is recently very important in various fields of industry. The aim of this study was then to synthesize fine particles of calcite with controlled morphology by using an original method.

The morphology of precipitated particles was identified by transmission electron microscopy (TEM/EDS) and scanning electron microscopy (SEM/EDS). In addition, the x-ray diffraction was performed to investigate on the carbonation efficiency and purity of solid product.

The carbonation of dispersed calcium hydroxide (Ca(OH)2 + CO2 → CaCO3 + H2O) in presence of supercritical or gas CO2 allowed the precipitation of sub-micrometric isolated particles (<1µm) and micrometric agglomerates (~5µm) of calcite rhombohedral-crystals. For this study, the global Ca(OH)2-CaCO3 conversion is not significantly affected by PT conditions after 24h of reaction. However, the x-ray spectra for solid products suggest a better purity for supercritical CO2 system. The use of high pressure of CO2 could be desirable for increasing the production rate of CaCO3, carbonation efficiency and purity, approximately 47.94 kg/m3h, 95% and 96.3%, respectively for this study. The dissipated heat for this exothermic reaction was estimated by calorimetry concept, -31.42 kJ/mol for supercritical CO2 system and -41.9 kJ/mol for gas CO2 system.

Keywords: Supercritical CO2; Calcite precipitation; Rhombohedral-crystals; Calcium Hydroxide; Carbonation.
The effect of LMW organic ligands on Plutonium and Uranium solubility under hyperalkaline conditions

V. MONTOYA¹, M. GRIVE¹, X. GAONA¹, L. DURO¹ and E GIFFAUT²

¹Enviros Spain S.L, Valldoreix, Spain
(vmontoy@enviros.biz)
²ANDRA, 1/7 rue Jean Monnet - 92298 Chatenay Malabry cedex - France

The chemical degradation of organic materials present in low/medium activity nuclear waste leads to the formation of LMW organic ligands that may contribute to the mobilisation of radionuclides. Among the expected ligands, isosaccharinic acid (ISA), acetate, phthalate and adipate have been identified as the most relevant compounds resulting from the degradation of polyurethane, cellulose and plastics materials. This work aims at assessing the effect of these organic ligands on the possible mobilization of Uranium and Plutonium under the hyperalkaline conditions defined by a cementitious environment.

The first step has consisted of the preparation of a complete and consistent database including complexes of U and Pu with ISA, acetate, phthalate and adipate. The sensitivity study has focused on the solubility of U and Pu under alkaline conditions and has taken into account the following parameters: a) a concentration range of organic compounds; b) a concentration range of calcium and c) a redox conditions range (from reducing to oxidant conditions).

Under the studied conditions, acetate, phthalate and adipate show almost no effect on U and Pu solubility, given both, the low affinity of these ligands toward U and Pu and the high affinity of Ca present in the system towards the studied ligands. Indeed, the presence of Ca in the system reduces the amount of available free organic ligand to radionuclide complexation showing a minor influence of organics ligands on Plutonium and Uranium solubility. Nevertheless, ISA has been shown to significantly increase the solubility of U and Pu, even when Ca is present in the system.

Using reactive transport models and chronosequence data to elucidate differences between laboratory and field mineral dissolution rates

J. MOORE¹, P.C. LICHTNER², A.F. WHITE³ and S.L. BRANTLEY¹

¹Center for Environmental Kinetics Analysis, Department of Geosciences, Pennsylvania State University, University Park, PA 16802 USA (joelmoore@psu.edu; branley@essc.psu.edu)
²Los Alamos National Laboratory, Los Alamos, NM 87545, USA (lichtner@lanl.gov)
³U.S. Geological Survey, Menlo Park, CA 94025, USA (afwhite@usgs.gov)

Silicate mineral weathering rates in soils have implications for processes including ecosystem nutrient cycling, soil formation, and groundwater quality. The orders of magnitude difference between laboratory and field dissolution rates results from factors including hydrology, proximity to chemical equilibrium, inhibition of aqueous species (e.g., aluminum), and reactive surface area. An ideal approach to quantifying the effects of such factors on differences between laboratory and field rates is to use a reactive transport code to model dissolution.

The Merced chronosequence is an ideal system for applying the reactive transport model FLOTRAN because of the large dataset collected for soils ranging in age from 40 to 3000 ka. Measured values were used for the mineral volume, porewater chemistry, flow rates, and BET surface area (SA). If the measured values were used with laboratory values for the rate constants and pH-dependence, model dissolution proceeded too quickly. The only way to achieve model results that matched the field data was to reduce the product of the rate constant and reactive SA. Laboratory rate constants were assumed to be intrinsic rates (whereas field rates can be thought of as “apparent” rates). Thus reducing the reactive SA of the parent material by 3 orders of magnitude compared to the BET SA gave results that matched field data well. Alternatively, a good model fit was achieved with a non-TST (non-linear) rate law by decreasing the reactive SA by 2 orders of magnitude. Model results did not match field data well when increased clay solubility, decreased clay precipitation, or inhibition of plagioclase dissolution by aqueous species were used as primary fitting parameters.

Mineral dissolution, including plagioclase dissolution, across the Merced chronosequence was successfully modeled by reducing the parent material reactive SA. Chronosequence data provided constraints that increased the uniqueness of model fits. For example, greater clay solubility reduced plagioclase dissolution in younger chronosequence soils, but resulted in too little K-feldspar dissolution in the oldest soil. These model results point to the usefulness of reactive transport models for understanding field weathering and corroborate other studies that point to the importance of developing techniques to measure reactive SA.
Estimating submarine groundwater discharge in the range $10^1$ to $10^8$ km$^2$ using Ra Isotopes

WILLARD S. MOORE
Dept. Geological Sciences, Univ. South Carolina, Columbia, SC, USA (moore@geol.sc.edu)

The flux of submarine groundwater discharge (SGD) provides an important pathway for enriching coastal waters in nutrients, carbon, and metals. Here SGD is defined as all flow of subsurface water from the continental margin to the ocean, regardless of composition or driving force. Regional quantification of SGD is difficult because direct measurement over large temporal and spatial scales is not possible by conventional means. Measurements of naturally-occurring radionuclide tracers at the aquifer-marine interface and in the coastal ocean provide a method to produce integrated flux estimates of discharge not possible by other means. In this talk I will explore the use of four radium isotopes to quantify SGD at scales ranging from small tidal creeks to the entire Atlantic Ocean. Radium is especially useful in this regard because it has high concentrations in SGD relative to coastal waters, low reactivity in the ocean, and four isotopes with half lives ranging from 3.7 days to 1600 years.

At small and intermediate scales, the technique requires a measure of the Ra inventory in the surface water and its concentration in SGD, evaluation of other sources of Ra, and a measure of the residence time of the water body. With this information, the inventory of Ra in the water is converted to the SGD Ra flux. This Ra flux must be replaced by new inputs of Ra from SGD. Thus, Ra concentrations in SGD convert the Ra flux to the SGD flux.

On a large scale, the decay of the $^{228}$Ra inventory in the upper 1000 m of the Atlantic must be balanced by a flux from the continental margins. By evaluating other sources of $^{228}$Ra and concentrations in SGD, a total flux of SGD to the Atlantic is obtained. This flux is in the range 0.5 to 1.0 of the river flux to the Atlantic. Because SGD is generally higher than river water in nutrients, metals, and carbon, the SGD fluxes of these materials probably exceed their riverine fluxes to the Atlantic.

The evidences of magma mixing and mingling in the Aran area (central Iran zone)

M. MORADIAN$^1$, M. KHEIRKHAN$^2$ AND M.H. EMAMI$^3$
Research Institute of Geological Survey of Iran (mm_raha2004@yahoo.com, m_kheir2003@yahoo.com)

This area is located in Eurmia-Dokhtar zone. The Eocene volcanism in this area is related to the orogeny activities in middle Alp. The tectonic activities in central Iran indicate most movement in this time. There are some deep marine sedimentary within volcanic-sedimentary rocks (i.e. ash and pumice tuff). There are some magma mixing evidences in this area which contain existence three different glasses (acidic, basic and hybrid glasses) in the matrix of hyaloclastic breccias and some plagioclases and pyroxenes with sieve texture, absorption and corrosion in their rims. Existence of basic micro pillows in acidic matrix and amphiboles with opaque rims. There are some mingling evidences in this area which are result of entrance of hot basic magma into co-magmatic and differentiated acidic magma in the magma chamber like two basic glasses with different composition and reverse, oscillatory zonation in the minerals.
Hf-in-zircon perspective on crustal growth and recycling in the Arabian-Nubian Shield

NAVOT MORAG1*, DOV AVIGAD1, KEREN KOLODNER1, ELENA BELOUSOVA2, TREvor IRELAND3 AND YEHUDIT HARLAVAN4

1Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel
2GEMOC, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia
3Planetary Science Institute, The Australian National University, ACT 2611, Australia
4The Geological Survey of Israel, Jerusalem 95501, Israel

The Arabian-Nubian Shield (ANS) is a collage of Neoproterozoic (850-750 Ma) island arcs that were accreted together and then squeezed again towards 640 Ma in relation to Gondwana assembly. Arcs accretion was followed by a widespread, late-post kinematic, calc-alkaline igneous activity that culminated at ~ 630-600 Ma, and by subordinate alkaline magmatism. Isotopic evidence, mostly Sr and Nd, indicate that the ANS was formed as juvenile crust during the Neoproterozoic. The northern tip of the ANS is exposed in southern Israel (Elat area) where it displays ca. 200 m.y of crustal evolution via igneous activity and dynamo-thermal metamorphism. We analyzed zircon U-Pb and Lu-Hf isotope data from 5 representative rock units of the Elat association whose age spans the entire crustal history in the region. All calculated Epsilon Hf values are positive, and define a linear array when plotted versus age. Intersect of this line with the DM evolution line suggests crustal extraction at ca. 1000 Ma. This demonstrates that although the ANS as a whole is rightly considered juvenile, most of its Neoproterozoic evolution is characterized by crustal recycling and or differentiation processes. Detrital zircons from the Elat schist representing the oldest island arc material show a considerable spread over more than 8 Epsilon units, from the DM evolution line down towards CHUR values. This spread highlights the possible contribution from an additional source, beside the DM, to the island arc magmas. This additional source could either be an enriched mantle or a slightly older, ca. 1100-1200 Ma, juvenile crust.

Terrestrial plandes formation: Our Solar System and extra-solar Worlds

ALESSANDRO MORBIDELLI

Observatoire de la Côte d’Azur, B.P. 4229, 06304 Nice Cedex 4, France. (morby@obs-nice.fr)

According to our current understanding, terrestrial planets form in two steps. First, a disk of planetesimals gives origin to the rapid formation of a system of numerous planetary embryos, of masses comparable to that of the Moon or of Mars. Then, the embryos start to collide with each other, as their orbital eccentricities are excited by mutual perturbations and by the giant planets. According to N-body simulations for our Solar System, this leads to the formation of a few (3-4) terrestrial planets in the 0.5-2 AU region, and a substantially depleted asteroid belt. The problems with these simulations is that the resulting planets are typically on orbits that are too eccentric and inclined with respect to the real orbits, and the formation time exceeds 100 My.

A possible solution of the problem consists in accounting for the interaction between the growing planets and the disk of planetesimals. By a process called dynamical friction, the planetesimals damp the eccentricities and inclinations of the terrestrial planets. The most modern simulations accounting for this process have allowed to achieve, for the first time, terrestrial planets on orbits consistent with the real ones and formation timescales of order of 30-40 My, consistent with Hf/W chronology. However, these spectacular results have been achieved assuming that the giant planets at the time were already on their current orbits. Unfortunately, there is a growing consensus that Jupiter and Saturn had to have quasi-circular, less separated orbits. With this set-up, the terrestrial planets still appear to form a bit too slowly and on orbits slightly too excited. It is possible that the future generation of simulations, accounting for a larger number of planetesimals and for their regeneration during collisions among the embryos, will allow to obtain ‘good’ terrestrial planets even in the framework of circular giant planets.

All current simulations show that the accretion of terrestrial planets is heterogeneous; material is incorporated in a stochastic way from a large variety of heliocentric distances, including from the asteroid belt. Thus, water could have been accreted during the formation process from the regions where hydrated meteorites come from.

The process of terrestrial planets formation has also been explored in the context of different giant planets systems, inspired by extra-solar planets discoveries. In general, more eccentric or massive giant planets lead to the formation of a smaller number of more massive terrestrial planets. Eccentric planets also inhibit the delivery of water from the asteroid belt equivalent. More recently, it has been shown that the radial migration of a giant planet toward the central star does not abort terrestrial planets formation.
Geochemical model and temporal distribution of Ni laterites in Urals

L. MORDBERG
Centre of Isotopic Research, VSEGEI, St Petersburg, Russia
(leonid_mordberg@vsegei.ru)

Nickel lateritic deposits of Urals have been forming during late Triassic – Early Jurassic and Early to Late Cretaceous. Remobilisation and redistribution of Ni is related to Tertiary processes. Blanket-like, linear and combined types of deposits have traditionally been distinguishing by Russian geologists. Presented is a model showing that all listed types represent a result of the same geochemical process.

Generalization of published materials and author’s experience point to the dual nature of Ni concentration during lateritic weathering. Within laterite and saprolite, Ni concentrates in situ due to removal of alkaline and alkaline earth elements as well as Si. Ni accommodates in oxides and hydroxides (goethite, haematite, maghemite, magnetite) within laterite zone and in layered silicates (smectites) within saprolite zone. Infiltration of Ni partly dissolved by weathering and its following precipitation leads to formation of rich quartz-garnierite ore in the zones of faults and deep karst cavities along the contacts of serpentinites and carbonate rocks. Such mineralization can be traced to the depth 400 – 500m. It seems that two described mechanisms cannot exist without each other: on the one hand, lateritic profile cannot develop without developing intensive drainage system which provides downward solution movement and leaching primary minerals; on the other hand, zones of faults and contacts with carbonate rocks play the role of such systems also being geochemical barriers for Ni precipitation.

Thus, the existence of poor residual (lateritic) or poor infiltrative (linear) deposits seems to be doubtful. These types were distinguished due to weak tectonics study of ultrabasic massifs and impossibility of proper erosion level estimations.

Preliminary Ni isotope study (δ60Ni and δ62Ni, MC-ICP-MS Neptune, Centre of Isotopic Research, VSEGEI) shows, that with respect to Ni isotope composition of parent serpentinites, samples of quartz-garnierite infiltration ore show more heavy composition, while in-situ laterite samples have more light composition. This indirectly confirms the opinion about dual nature of Ni behavior during lateritic weathering of ultrabasic rocks.

Noble gas concentrations and isotopic ratios in single chondrules using laser ablation: Constraints on the origin of noble gases in chondrites

MANUEL MOREIRA
Institut de Physique du Globe de Paris, 4 place Jussieu, 75005 Paris, France. (moreira@ipgp.jussieu.fr)

The question of the origin of the noble gases on Earth remains unclear. Solar wind irradiation with mass fractionation due to sputtering on parent bodies is one scenario, dissolution of a dense primordial atmosphere in a molten earth is another one. Neon and argon isotopes measured in mantle-derived rocks suggest that the irradiation scenario is strong. In order to understand how parent bodies acquired their noble gases, we have developed an ablation system coupled to a noble gas mass spectrometer allowing measurement of noble gases in situ. The ablation system is an Excimer laser (193nm), giving ablation spots of ~60µm in diameter and ~50µm in depth. It is coupled to our glassy mass spectrometer ARESIBO II.

NWA3128 is a LL3.8 ordinary chondrite that shows chondrules up to 1mm in size. A sample of 0.1mg was first heated using a 10W continuous Wave Ytterbium fiber laser in order to get bulk helium and neon compositions. 4He and 20Ne concentrations were 7 * 10^-3 and 3 * 10^-4 ccSTP/g respectively. 4He/3He ratio is 2870 (SW=2500), 20Ne/22Ne=11.44 and 21Ne/22Ne=0.0780, suggesting a solar wind implantation in this sample.

We then have performed profiles in different chondrules from NWA3128 using our ablation system. Our results clearly show that the solar gases are at the surface of the chondrules. The concentrations obtained in the rims are more than ten times higher than the interior the chondrule. Moreover, isotopic ratios are solar-like in the rim (e.g. 20Ne/22Ne=11.59±0.07) whereas the interior presents a more important cosmogenic contribution (20Ne/22Ne=8.6 and 21Ne/22Ne=0.15).

Our results show that the chondrules were formed in an environment with a strong solar wind that was implanted at the surface of chondrules before the formation of the chondrite. An important proportion of noble gases that are present in the earth’s mantle may derive from the solar wind implantation in chondrules, close to the young Sun. These chondrules will then mix to a matrix to form the different chondrite classes. Noble gases are then a mixture of these solar gases, fractionated during implantation, and gases from the matrix. Thermal metamorphism will homogenize these components to give the planetary signature.
Os isotope and PGE evidence for major disruption and addition to the lithospheric mantle: A study of peridotites from the Premier Mine, Kaapvaal craton, SA

M.L.A MOREL1, D.G. PEARSON2, A. LUGUET2 AND G.R. DAVIES1

1FALW, Vrije Universiteit, Amsterdam, NL
2Dep. of Earth Sciences, Durham University, UK

Determining the processes responsible for modification of sub continental lithospheric mantle (SCLM) is key to understanding early crust formation and stabilisation. The Kaapvaal SCLM, as a residue from partial melting, is characterised by depletion in basaltic melt components, but contains high silica and incompatible trace element contents indicative of a complex melt-fluid enrichment history (Griffin et al., 2003).

Tomographic studies have establish that Kaapvaal SCLM forms a thick buoyant lithospheric root except for a region in Central Kaapvaal where a marked seismic anomaly coincides with the region of a major magmatic activity that formed the Bushveld Province at 2.05Ga.

This study aims to establish the effect of this major magmatic event on the SCLM through a study of mantle xenoliths from the Premier kimberlite pipe that occurs in the centre of the seismic anomaly. The specific goal is to determine if new SCLM was formed at 2.05 Ga or if there was a major modification of existing SCLM. A combined petrology, major and trace element and Hf-Os isotope study will be reported. Peridotites range from highly depleted spinel and garnet harzburgites to garnet lherzolites. The Premier suite is characterised by two distinct PGE patterns. Group 1 is characterised by fractionated I-PGE to P-PGE patterns typical of residua from high % partial melting (PdN/IrN<0.4) while Group 2 has 0.3<PdN/IrN<1.6. Os model ages of Group 1, are generally Archaean whereas Group 2 clusters at ca. 2.0 Ga. A model will be presented to explain the observed depth vs. age of melt depletion relationships which will constrain amount of new vs. modified SCLM beneath Premier.

2-D diffusion modelling – extracting timescales and crystal histories from BSE images

D.J. MORGAN1 AND V. MARTIN2

1School of Earth and Environment, University of Leeds, Leeds, LS2 9JT UK. d.j.morgan@leeds.ac.uk
2Department Earth Sciences, University of Durham, Durham, DH1 3LE UK. victoria.martin@durham.ac.uk

Modelling of diffusion profiles within phenocrysts from igneous systems has become more common in recent years. Initial modelling was conducted from linear traverses across crystals measured quantitatively by electron microprobe. Use of Back-Scattered Electron (BSE) imaging allows us to improve the spatial resolution to that of a focused electron beam, at less than a micrometre per pixel, and also to work with two-dimensional images rather than simple traverse lines. When calibrated against electron microprobe analysis, such images can, for certain elements in certain minerals, be used as high-resolution compositional maps.

Combination of imaging with other techniques such as Electron Back-Scatter Diffraction (EBSD) and U-stage measurements allows us to account for many of the geometric uncertainties that exist in diffusion, with crystal orientation (and hence diffusional anisotropy), and boundary orientation being measurable. This presentation introduces a simple finite-difference model (FINDIF) that can incorporate diffusional anisotropy, compositional dependence of both diffusion coefficients and trace element activity coefficients, and elemental partitioning between different crystal phases and liquids (modelled as infinite buffers). Initial states can be read in from TIFF files created with standard image manipulation software, allowing the direct modelling of BSE images that are frequently captured in this format. Multiple grains of multiple minerals can be considered simultaneously, allowing the modelling of polymineralic aggregates.

The program can model the degree of fit between modelled values and an input value within specific pre-defined regions of interest, allowing separate treatment of different regions of interest within the same field of view.

The results indicate that diffusion processes in phenocrysts are actually rather complex even within single crystals and are intimately tied into the dynamic processes of growth, cracking and dissolution to which a crystal is subject during magmatic residence.
**In-situ** arsenic speciation in Earth surface environments: Importance of iron oxides

Contamination of aquifers by one of the most toxic forms of arsenic, As(III), is an important health concern in many parts of the world \(^{[1]}\). Recent studies have revealed that intimate relations exist between As and Fe cycling in Earth surface environments: microbial reduction of As(V) and Fe(III) is thought to be responsible for large-scale contamination of aquifers by As(III) in Southeast Asia \(^{[2,3,4]}\); in contrast, microbial oxidation of As(III) and Fe(II) leads to efficient water decontamination, especially in acidic environments \(^{[5]}\). Further modelling of As transformations partly suffer, however, from the scarcity of data addressing molecular-level speciation in field samples.

In this context, we have compared in situ speciation of As in natural and impacted soils, by combining XANES and EXAFS spectroscopy with selective chemical extractions. Our results indicate that As mainly occurs as surface complexes on iron oxides \(^{[6]}\). The relative importance of phyllosilicates as arsenic sorbents is generally difficult to evaluate in soils. It may, however be responsible for an increase of As(III) mobility \(^{[7]}\), especially in iron-depleted anaerobic media.

Recent investigations of acid mine drainage \(^{[5]}\) and geothermal springs \(^{[8]}\) revealed similar coupling between arsenic and iron chemistry in these acidic environments. In both contexts, microbial oxidation of Fe(II) and As(III) leads to the formation of amorphous As(V)-Fe(III) hydroxysulfate compounds with similar local environments of As(V) and Fe(III). Importantly, the solubility of these compounds decreases with increasing Fe/As ratio. Frequently associated with biological substances, such compounds could be considered as potential markers of microbial activity in acidic environments.

\(^{3}\)Department of Geology, Niigata University, Niigata, Japan

**Introduction**

An oceanic core complex located at 25°S (25°S OCC) of the Central Indian Ridge (CIR) was explored by SHINKAI 6500 of the Japan Marine Technology Center. Serpentinitized peridotites and gabbros were collected with metamorphosed/ altered basalts from the OCC. Highly deformed rocks of variable origins including peridotite and gabbros were also collected on the top surface of the OCC. These characteristics support that the OCC is a tectonically exposed deep-seated rock on the sea floor. Plagiogranite was recovered from the 25°S OCC. Quartz-bearing granitic small veins crosscut a gabbro. Origin of plagiogranite is still in debate (Koepke et al., 2007). We report petrology and chemical compositions of plagiogranites in the CIR.

**Results and discussions**

The plagiogranite in this study consists of fine grains of quartz and sodic plagioclase with small amount of amphibole, epidote including allanite, apatite and zircon. Geochemical characteristics of the plagiogranite are extremely high in SiO\(_2\) content (80 wt. %) and low TiO\(_2\), FeO\(_{total}\) and P\(_2\)O\(_5\) contents. Chondrite-normalized REE pattern of the plagiogranite is characterized by high REE abundances with conspicuous negative Eu anomaly, indicative of very high degree of fractional crystallization. In addition, convex (M-type) tetrachloride effect is clearly recognized in the sample, implying unusually volatile-rich (e.g., H\(_2\)O, CO\(_2\), Li, B, F, and/or Cl) parent magma of the plagiogranite (Nakamura et al., 2007). These characteristics suggested that plagiogranite was formed by either interaction with an external fluid originated from seawater or hydrous partial melting of pre-existing rocks in the initiation of amagmatic opening related to intermediate-spreading ridge.

Formation of amorphous forsterite particles by levitating Mg$_2$SiO$_4$ melt droplets

Y. MORIUCHI, K. NAGASHIMA AND K. TSUKAMOTO

Graduate School of Science, Tohoku University, Sendai 980-8578, Japan (moriuchi@ganko.tohoku.ac.jp)

To simulate the evolution of amorphous Mg$_2$SiO$_4$ (forsterite) to the forsterite crystals, we need amorphous particles in the experiment as the starting materials. Although amorphous forsterite has been synthesized from vapor phase [1], these particles are too small ($\phi < 1 \mu m$) to be investigated by optical method. Therefore, we have applied a gas jet levitator method to solve this problem. A gas jet levitator method is useful to avoid heterogeneous nucleation during cooling process and thus melt droplets were very stable at large supercooling (> 1000 K) [2].

The starting materials were synthesized forsterite spherules (~ 2 mm), which was set at the top of the nozzle (1 mm in diameter) of the gas jet levitator and then levitated by introducing Ar gas. The spherule was melted by CO$_2$ laser (100 W) irradiation. The melt temperature was measured with a pyrometer. The crystallization and vitrification process from the supercooled melt were observed with a CCD camera.

The experimental results show that amorphous formation of forsterite took place at ~ 1000 K with a larger cooling rate than 300K/s (fig. 1), which was much smaller cooling rate as obtained by Tangeman et al. (2001), 700 K/s [3]. While, enstatite melts with higher SiO$_2$ content formed only amorphous material at any conditions.

The value of 300 K/s is not led only by heat radiation but by additional gas flow during cooling. If forsterite melt droplets were cooled only by radiation in space, melt droplets with less 10 μm in diameter, could become amorphous particles rather than crystalline particles. Presence of amorphous forsterite particles around AGB stars might be due to this reason.

Fig. 1 Cooling curves during formation of (a) amorphous forsterite and (b) forsterite crystal in levitation. (c) The sample was set on a graphite rod.

Reaction kinetics of shallow water marine carbonates: Successes and failures in bringing laboratory experiments and the ocean together

JOHN W. MORSE

Department of Oceanography, Texas A&M University, College Station, TX 77843 (morse@ocean.tamu.edu)

A wide range of geochemical observations have been made of the composition and behavior of marine carbonates in shallow water carbonate-rich sediments generally found in tropical to sub-tropical waters typified by environments such as atolls and lagoons, carbonate banks and platforms, and coral reefs. The carbonates found in these environments are often a complex mixture of aragonite, high and low magnesian calcites, and, rarely, (proto) dolomite. They may have both biotic and abiotic origins, and can undergo both formation and dissolution during early diagenesis. Because they will play a significant role in the response of the ocean to its “acidification” due to rising atmospheric pCO$_2$, there has been renewed interest in understanding the reaction kinetics of their formation and dissolution.

A major question that has often been hotly debated and continues to be a major source of concern is how well laboratory measurements of factors influencing their precipitation and dissolution kinetics, and pseudo-solubility behavior are representative of their behavior in the “real world”. These concerns center around several basic factors. Perhaps foremost amongst these are the clear and potential differences between natural biogenic material and abiotic carbonate minerals. Numerous studies of the behavior of magnesian calcites, which typically comprise about 24% of shallow water marine carbonates, stand as all too clear examples of the limitations and failures that can be encountered. However, in situations where abiotic marine carbonate formation occurs, such as aragonite needles in “whitings” on the Great Bahama Bank, experimental and observed reaction rates can be brought into close agreement, but, even in these types of situations surprises can be found-e.g. the “kinetic” solubility is about twice that of aragonite.

After over half a century of trying to understand the behavior of natural marine carbonates in marine sediments from laboratory kinetic experiments there is clearly still much to learned.
Oxygen isotopes of diatom silica and their utility for palaeothermometry

ROBERT MOSCHEN¹, ANDREAS LÜCKE¹, JÖRN PARPLIES¹,² AND GERHARD H. SCHLESER¹

¹Institute of Chemistry and Dynamics of the Geosphere V: Sedimentary Systems, Research Centre Juelich, D-52425 Juelich, Germany (r.moschen@fz-juelich.de, a.luecke@fz-juelich.de, j.parplies@fz-juelich.de, g.schleser@fz-juelich.de)
²Department of Geography, Universität zu Köln (University of Cologne), D-50923 Cologne, Germany

The use of the oxygen isotope composition of diatom silica ($\delta^{18}O_{\text{diatom}}$) as a palaeothermometer has found increasing attention. Two main reasons have hindered an even broader application: Firstly, substantial analytical problems with the preparation of diatom frustules, particularly from fresh diatom silica and, secondly, considerable uncertainty with respect to the temperature dependence of the oxygen isotope fractionation during silica formation. We have developed a novel technique for the determination of $\delta^{18}O_{\text{diatom}}$ which is based on inductive heating and high temperature carbon reduction (iHTR) of the silica. With the new iHTR method quantitative silica disintegration with low sample amount and high accuracy and precision is achieved in one continuous routine in a high-vacuum device. Calibration studies with marine and freshwater diatoms had provided contradictory results with published temperature coefficients varying from zero to –0.5‰/°C. Therefore, we have accomplished a calibration study using fresh diatoms grown during an annual cycle in Lake Holzmaar, a small freshwater lake (Germany). Based on identical results for three different diatom size fractions we propose a value of –0.2‰/°C as the most realistic temperature coefficient of oxygen isotope fractionation between diatom silica and lake water. However, at the sediment surface and within the surface sediment, an effect of silicon dissolution / biogenic silica maturation takes place that causes an $^{18}$O enrichment of the diatom silica and introduces a possible bias with respect to palaeothermometry.

Investigating empirical equations of determining concentration time of flood in Karaj river basin

B. MOTAMEDVAZIRI¹ AND, M. AGHAII²

¹Islamic Azad University , Science & Research Branch, Faculty of Agriculture & Natural Resources, Tehran, Iran, (bmvaziri@yahoo.com)
²Curative Services Office, Sanandaj, Iran, (Email: pegi_mv@yahoo.com)

Time parameters are used mostly in hydrologic and hydraulic models. The most often used time parameter in hydrology is concentration time.

Concentration Time is the time required for a particle of water to travel from the hydrologically most distant point in the watershed to outlet or designing point. Concentration time is used for designing spillway, estimating flood volume, preparing flood hydrograph and many other hydrologic analysis.

Many methods (empirical equations) are available for estimating concentration time. the aim of this research is selecting the best method(s) for estimating concentration time in the studied basin. To achieve the said aim, a field method based on measurement of travel time by salt solution is used. In order to select the best method(s) for estimating concentration time in the basin, the difference between values obtained by using these methods and the field method are determined.

Results of this research show that In steep area, SCS Lag method is the best for estimating concentration time. In this area Ventura, Gianduti, Passini, and Carter methods provide a fairly good estimate of concentration time.

In flat area, Chow, Kirpich, Basoo, and California methods provide a fairly good estimate.
Sulphur solubility in andesitic to basaltic melts: An example of Hekla volcano

S. MOUNE, F. HOLTZ AND R.E. BOTCHARNIKOV
Institute für Mineralogie, Calvinistrasse 11, 30167 Hannover, Germany

The magmatic gas phase plays a major role at active volcanoes and the interest in studying degassing processes has been continuously increasing in modern volcanology. However, the mechanisms of volatile release and partitioning between melt and fluid phase during eruptions of andesitic to basaltic volcanoes are not yet well-understood. In fact, mainly to model the distribution of complex volatiles between volcanic gases and natural silicate melts, especially for mafic systems, are limited to a few studies.

In this work, particular attention is given to the Hekla volcanic complex (one of the most active volcanoes in Iceland), which is well characterised, both for the petrology and degassing behaviour (Sigmarsson et al., 1992, Moune et al., 2006, Moune et al., 2007). The distribution of sulphur between silicate melts and coexisting gas phase has been determined experimentally at 300 MPa, 1050°C and FMQ oxygen buffer in the systems containing H-O-S-bearing fluids. Experimental products and natural phases is used to interpret and during magma ascent. The comparison between the gas phase compositions during magmatic differentiation these experimental results show the evolution of the melt and basaltic melts of Hekla coexisting with pyrrhotite. Moreover, experimental results confirm a saturation of 2500 ppm S in the variations in sulphur during volcanic eruptions as well as eruptive mechanisms.

Further Helium isotopic evidence for a lower mantle contribution to the Cape Verde plume

C. MOURÃO1, J. MATA1, M. MOREIRA2, R. DOUCELANCE3 AND J. MADEIRA1,4
1CeGUL & Dep. Geologia, Universidade de Lisboa, Portugal (ccmourao@fc.ul.pt; jmata@fc.ul.pt)
2IPGP, France (moreira@ipgp.jussieu.fr)
3Laboratoire Magmas et Volcans - OPGC, France (doucelance@opgc.univ-bpclermont.fr)
4LATTEX & IDL (jmadeira@fc.ul.pt)

The origin of Cape Verde Islands has been intensely debated, and controversy still exists concerning the influence or not of a deep mantle plume beneath the archipelago. In order to better constrain the ultimate origin of the Cape Verde magmatism we will present and discuss He isotopic data, which has been considered one of the most powerful geochemical tools presently available to identify the contribution of the lower mantle to magmatism.

For Brava, one of the youngest Cape Verde islands, He isotopic signatures were performed on olivines, extracted from mafic silicate rocks, and on calcites and apatites occurring in sôvitic carbonatites. While apatites are strongly radiogenic, owing to their high U and Th contents, calcites and olivines are usually characterized by 4He/3He values lower than the typical value of 90,000±10,000 reported for MORB, presenting values as low as 60,711 (11.9Ra) and 53,663 (13.4Ra), respectively. Low 4He/3He was obtained for silicate rocks of S. Nicolau (45,928; 15.73Ra) and S. Vicente (58,887; 12.27Ra) (Doucelance et al., 2003). R/Ra values as low as 46,414 (15.5Ra) were also obtained for S. Vicente carbonatites. Cape Verde islands define two alignments (Northern and Southern islands), presenting distinct elemental and isotopic signatures (e.g. Doucelance et al., 2003). Our helium isotopic data for Brava are clearly distinct from those reported for other Southern Islands where the lower 4He/3He values are MORB-type. These results show that for both Northern and Southern islands, silicate and carbonatitic magmas preserve signs of the contribution from a relatively undegassed/primitive reservoir, as compared with the upper mantle sampled by MORB. We consider this a compelling evidence for a lower mantle origin of the Cape Verde plume, thus supporting the tomographic data imaging the plume down to significantly below the 670 km discontinuity (Montelli et al., 2006).

This is a contribution of the FEDER/FCT project PLINT (POCTI/CTA/45802/2002).
Pressure induced phase transition in hydrous Sr-anorthite

M. MROSKO, K. HARTMANN AND M. KOCH-MÜLLER
GeoForschungsZentrum Potsdam, Department Chemistry of the Earth, Potsdam, Germany (marianmrosko@gmx.de)

A recent survey of hydrous species and concentrations in igneous feldspars (Johnson and Rossman, 2004) shows that feldspars may contain structural OH (0-512 ppm H2O) and structural H2O (0 – 1350 ppm). However, little is known about the defect locations of the trace hydrous species, their concentrations as a function of pressure and temperature and their effect on the physical properties. In this contribution we report on OH in Sr-anorthite including in-situ FTIR experiments as a function of pressure in a diamond anvil cell (DAC) in regions of OH stretching and lattice vibrations to evaluate the effect of OH on pressure induced phase transitions.

Two syntheses were performed at 20 kbar and 700 °C in a piston cylinder apparatus. The monoclinic products (space group I2/c) consist of 100 - 300 μm large clear single crystals which were investigated by FTIR, X-ray diffraction and electron microprobe. Polarised single crystal infrared spectra in the OH stretching region showed a broad but weak band centered around 3400 cm−1 plus three sharp and intense bands: band (1) at 3628 cm−1, band (2) at 3598 cm−1 and band (3) at 3500 cm−1. We interpret the broad band to result from OH stretching vibrations of structural water and/or molecular water in inclusions. From the pleochroic behaviour we assigned band (1) to vibrations of a O3-H dipole and bands (2) and (3) to O6-H dipoles most probably bonded both to O8 oxygens but occurring in different chemical environments (Al, Si). The water content of the synthetic Sr-anorthite is with 1100 ppm twice the maximum value observed for natural anorthite.

The DAC experiments in the OH stretching region show a clear change in the behaviour of band (1) between 8 and 9 GPa which was fully reversible upon pressure release. We interpret this as an indication for a phase transition in that region. For pure monoclinic Sr-anorthite McGuinn and Redfern (1994) described only one phase transition at 3.2 GPa, i.e. from monoclinic to triclinic (I1-). For a feldspar with composition Ca0.25Sr0.6Al2Si2O8 Nestola et al. (2004) observed an additional transition at 7.3 GPa from monoclinic I 2/c to a not further specified monoclinic symmetry. Most probably the observed transition in this study corresponds to the transition described by Nestola et. al. (2004). As observed for hydrous ringwoodite (Chamorro Perez et al., 2006) the presence of structural bonded OH and/or H2O may trigger the transition and/or displace phase boundaries as compared to the dry system.

The δ18O of the Ocean at 3.8 Ga

K. MUEHLENBACHS1, H. FURNES2, M. DE WIT3, M. ROISING4 AND H. STAUDIGEL5

1Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta T6G 2E3, Canada (karlis.muehlenbachs@ualberta.ca)
2Centre for Geobiology & Department of Earth Science, University of Bergen, 5007 Bergen, Norway

4Geological Museum, University of Copenhagen, 1350, København K, Denmark
5Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA 92093-0225 USA

The recently discovered hydrothermally altered sheeted dike complex at Isua, Greenland provides insights into the 3.8 Ga ocean and may resolve the long standing controversy regarding the δ18O of ancient oceans and sediments. It has been argued that the very low δ18O Archean cherts (12 to 24‰ SMOW) may have precipitated from a hot Archean ocean, a conclusion incompatible with some models of atmosphere and seawater compositions. Critics of a hot ocean have invoked moderate surface temperatures but a very low δ18O ocean (-13‰). The δ18O of the ocean is held at its present value by a balance of low and high temperature water rock interactions primarily linked to plate tectonic processes. Thus as long as there is extensive hydrothermal alteration of the seafloor by seawater the δ18O of the oceans will be near 0‰. A -13‰ ocean would impose a very large 18O-depletion on any hydrothermally altered rock. The Isua dikes range in δ18O from 5.7 to 6.9‰ giving no evidence of low, but rather a slightly enriched 18O seawater at 3.8 Ga. The data from Isua as well as previous studies on pillow lavas from Pilbara and Barberton show that a very low δ18O ocean is untenable and that modern style seafloor spreading, including hydrothermal systems, may have been operating in the Archean.

The δ18O of the pillows and dikes indicate that the earliest ocean crust had already reacted chemically with seawater. This has great implications to the composition of the oceans themselves because seawater/seafloor rock reactions are known to massively affect if not control the chemical make up of seawater. The composition of seawater (as well as the inferred hydrothermal systems) may also play a role in the evolution of life.

Ar, Kr, and Xe composition of the Earth’s mantle: Implications for the formation of the atmosphere

S. Mukhopadhyay

Dept. of Earth and Planetary Sciences, Harvard University, Cambridge, MA 02138, USA; (sujoy@eps.harvard.edu)

Establishing whether the Earth’s mantle has solar or planetary heavy noble gases is crucial for planet accretion models and understanding how volatiles were incorporated into the solid Earth. Furthermore, isotopes of Ar, Kr, and Xe that are not produced by radioactive decay, can provide a critical test for models that suggest the Earth’s atmosphere was derived from mantle degassing. Here, I report new high-precision Ar, Kr, and Xe in gas-rich basalt glasses from the Atlantic and Pacific Ocean basins that indicate the atmosphere was not primarily derived from outgassing of the mantle.

The noble gases were extracted from fresh basalt glass by step crushing and measured using the Nu multicollector noble gas mass spectrometer at Harvard. Significant improvements in the measurements of heavy noble gases have been made in the Harvard laboratory that allow detection of small isotopic anomalies, of order few per mil, in Ar, Kr, and Xe.

Compared to atmospheric ratios of $^{124,126,128}\text{Xe}^{130}\text{Xe}$, a clear excess in these ratios is observed in basalt glasses from both the Atlantic and Pacific basins. The maximum excess in $^{128}\text{Xe}^{130}\text{Xe}$ was 18‰ and correlated with excess $^{129}\text{Xe}$ and $^{136}\text{Xe}$. The $^{124,126,128}\text{Xe}^{130}\text{Xe}$ ratios are consistent with mixtures of either air-solar or air-chondritic (Q) xenon. Solar Ar and Kr are significantly different in isotopic composition compared to their chondritic counterparts. Hence, isotopes of Ar and Kr could potentially fingerprint the excess xenon to be either solar or chondritic. The excess in non-radiogenic xenon isotopes is accompanied by air-like non-radiogenic Ar and Kr isotopes. The $^{38}\text{Ar}^{36}\text{Ar}$ composition of the atmosphere is indistinguishable from chondritic, and while atmospheric Kr is isotopically heavier than chondritic, it is closer to chondritic than solar composition. It is possible that mantle Ar and Kr in the basalts were overprinted by air-contamination. While this possibility cannot be disproved, based on the excess non-radiogenic xenon isotopes and the high-precision measurements, I argue that Ar, K, Xe composition of the Earth’s mantle is closer to chondritic than solar.

A chondritic composition for heavy noble gases in the Earth’s mantle implies that degassing of the mantle followed by mass fractionation through hydrodynamic escape cannot generate the atmospheric Ne, Ar, Kr, and Xe isotopic compositions. Delivery of volatiles via late accreting planetesimals may better explain the origin of the terrestrial atmosphere. If the bulk of the present atmosphere was not derived from the mantle degassing, the excess $^{129}\text{Xe}$ in MORBs, compared to the atmosphere, cannot be used to calculate a degassing age for the mantle. Rather the excess $^{129}\text{Xe}$ simply indicates that the mantle and the atmosphere have evolved with different I/Xe ratios.

Hydrogen isotope variations in hydrated volcanic glass as tracers of late Cenozoic precipitation patterns in the western United States

A. Mulch1,2, A.M. Sarna-Wojcicki3, M.E. Perkins4, and C.P. Chamberlain2

1Institut für Geologie, Leibniz Universität Hannover, Germany; (mulch@geowi.uni-hannover.de)
2Geological and Environmental Sciences, Stanford University, USA; (chamb@pangea.stanford.edu)
3U.S. Geol. Survey, Menlo Park, USA; (asarna@usgs.gov)
4Geology & Geophysics, University of Utah, USA; (perkins@earth.utah.edu)

Volcanic ash deposits characterize large portions of the Miocene-to-recent sedimentary successions in the western United States. Within thousands of years after deposition at the Earth’s surface, volcanic glass in these ashes incorporates relatively large amounts of water (3-5 wt.%). This hydration process provides a hydrogen isotope record that directly reflects paleoclimate and precipitation regimes. Once correctly correlated, widely distributed ashes may then serve as excellent paleoclimatic and paleoaltimetry proxies as a) deposition and hydration are almost instantaneous on geologic timescales and can be dated with high temporal resolution and b) the chemical composition of the proxy is constant over large areas (100-100,000 km2) thus eliminating compositional uncertainties related to proxy formation. Here we present, hydrogen isotope data from volcanic glasses across the Basin and Range Province and relate the long-term changes in isotopic composition to changing surface topography and precipitation patterns. Glasses from individual ash layers found in the Central Valley (CA) strongly contrast those in the Northern and Central Basin and Range. Moreover, systematic variations in the dD of volcanic glass at various locations in the Basin and Range Province document the long-term interplay between regional changes in surface elevation, developing topography, and changing precipitation patterns.
Infrared spectroscopic identification of aqueous uranium(VI) species

K. MÜLLER, H. FOERSTENDORF AND G. BERNHARD
Forschungszentrum Dresden-Rossendorf, Institut für Radiochemie, Postfach 510119, 01314 Dresden, Germany

Migration of uranium(VI), the most stable form of uranium in environmental waters, is largely controlled by its geochemical reactions, both in solution and at the mineral-water interface. Current knowledge about U(VI) speciation is mainly based on thermodynamic calculations using data obtained by non-structural experiments, i.e. potentiometric titration [1]. A spectroscopic verification of the speciation of aqueous U(VI) is still insufficient. For the identification of different molecular species previous studies applied primarily EXAFS and Raman spectroscopy at very high uranyl concentrations (>100 mM) unexpectedly in an environmental context [2-4].

In this study we used Attenuated Total Reflectance Fourier-transform Infrared (ATR-FTIR) spectroscopy, that allows the direct measurement of liquid samples. Our aim was to obtain additional vibrational spectroscopic information on the U(VI) species and especially to verify the U(VI) speciation throughout a wide pH range (pH 2-10) at a micromolar concentration level. The obtained spectral information was compared to previously reported thermodynamic data [1].

ATR-FTIR spectra were recorded at UO$_2^{2+}$ concentrations ranging from 5 to 0.005 mM at pH 4. The spectroscopic results indicate distinctly that dimer and trimer hydroxo complexes become dominant upon lowering the uranyl concentration at pH 4. The obtained spectral information was compared to previously reported thermodynamic data [1].

At the micromolar concentration level the calculations predict the dominance of the uncomplexed uranyl ion until pH 5 and the formation of uranyl hydroxo complexes at neutral pH. Uranyl complexes with atmospheric carbonate in alkaline solutions are proposed above pH 6.5. However, the obtained ATR-FTIR spectra of low concentrated 0.02 mM uranyl solutions already show the coexistence of free and hydroxo complexed uranyl at pH 2.5. The appearance of carbonate complexes in solution becomes noticeable at the spectra of solutions at pH 7. Since the results are partially contradictory to previous predictions of U(VI) speciation a critical review of the present knowledge of uranium migration in the environment is required.

Crystal size distributions (CSD) of periclase are presented for two profiles near the Cima Uzza summit, located in the southern Adamello massif (Italy). The data base was combined with geochemical and petrologic information to deduce the controls that acted on the periclase forming reaction.

Contact metamorphic dolomite marbles are exposed as xenoliths surrounded by mafic intrusive rocks. Periclase was retrograded to brucite. Periclase growth is the consequence of limited high temperature fluid infiltration. Stable isotope data show depletion for $^{13}$C and $^{18}$O in a narrow region (~40cm) near the igneous contact, whereas the periclase forming reaction front extends up to 4m into the host rock. A similar median grain sizes for periclase crystals was found over the entire profiles, but a larger proportion of bigger grains with increasing distance from the contact was observed. Textural analyses are combined with geochemistry data in a qualitative model that describes the dynamic nucleation and crystallization of periclase in this infiltration driven system. We attribute variations in grain sizes to changing reaction affinities along a dispersed infiltration front. This study highlights the need to invoke disequilibrium processes for metamorphic mineral growth and expands the use of CSD’s to systems of mineral formation driven by fluid-infiltration.

Deformation experiments on natural omphacite: A TEM study

W.F. MÜLLER1, N. WALTE2, N. MIYAJIMA2, D.J. FROST2 and R. KLEMD3

1Geomatериалwissenschaft, TU Darmstadt, D-64287 Darmstadt; (wmueller@geo.tu-darmstadt.de)
2Bayerisches Geoinstitut, Univ. Bayreuth, D-95440 Bayreuth; (Nico.Walte@Uni-Bayreuth.de)
3Mineralogisches Inst., Univ. Würzburg, D-97074 Würzburg; (reiner.klemd@mail.uni-wuerzburg.de)

The rheological behaviour of eclogite is dominated by the deformational properties of omphacite which therefore are most important for the geodynamic processes of subduction and exhumation of oceanic and continental crust. The deformation mechanisms activated are obviously not the same in eclogites from different geological areas as shown by several transmission electron microscopy (TEM) studies. In order to attribute the specific microstructures of omphacite to the deformation conditions of the eclogite in its geological environment, deformation experiments on natural omphacite under conditions of high pressure metamorphism have been started. The source material was fibroblastic omphacite with the space group P2/n from Tianshan (Gao and Klemd, 2001). TEM showed that it contained small-angle grain boundaries formed by crystal growth and the common 1/2[110] antiphase domains. The experiments were conducted using a Deformation-DIA (D-DIA) high-pressure apparatus at a strain rate of 10^{-5} s^{-1}, a confining pressure of 2 GPa, and temperatures between 800 °C and 500 °C.

The omphacite deformed at 800 °C had still the space group P2/n, was well-ordered and showed in addition to the defects in the omphacite as-grown) deformation twin lamellae on (100) with widths which varied between a few nm and about 0.5 µm. Deformation twin lamellae on (100) have been repeatedly observed in omphacites from eclogites of various occurrences but not in all (Godard and Van Roermund 1995; Müller et al. 2004). Defects parallel to (100) which apparently consist of numerous dislocations lined up parallel to (100) were seen in one area of the specimen. They are interpreted as precursors of twin lamellae; these microstructures have not been reported before. In addition, planar faults parallel to (110) and (1-10) stretched between dislocations have been observed. They may be similar or identical to crystallographic shear planes parallel to (110) which were found for the first time in the ultra-high pressure metamorphic rocks of Lago di Cignana (Müller and Compagnoni 2007, unpublished). Chain multiplicity faults parallel to (010), however, which are so frequent in omphacite from the Lower Schist Cover of the Tauern Window (Müller et al. 2004), have not been observed so far in the experimentally deformed omphacite.

Impact of future Greenland deglaciation on global weathering fluxes and atmospheric CO2

G. MUNHOVEN1, V. BROVKIN2, A. GANOPOLSKI2 and D. ARCHER1

1LPAP—Institut d’Astrophysique et de Géophysique, Université de Liège, Liège, Belgium (Guy.Munhoven@ulg.ac.be)
2Potsdam Institute for Climate Impact Research, Potsdam, Germany (Victor.Brovin@pik-potsdam.de, Andrey.Ganopolski@pik-potsdam.de)
3Department of the Geophysical Sciences, University of Chicago, Chicago, U.S.A. (d-archer@uchicago.edu)

About 1.76x10^6 km² of Greenland are currently covered by ice. It is expected that this large ice mass will melt away over the next 3000 years if anthropogenic CO2 emissions continue to rise (Alley et al., 2006). As a result, the bedrock currently covered by ice will lie free and become subject to chemical weathering. The resulting weathering fluxes will contribute to increase both the consumption rate of atmospheric CO2 and the production rate of riverine HCO3⁻. Increasing these two fluxes will tend to decrease the atmospheric CO2 partial pressure, as a result of the modified ocean-atmosphere carbon cycle. Chemical weathering may thus possibly act as a negative feedback in the Greenhouse World. Other changes (e.g., vegetation cover and additional climate change) concomitant with the melting of the Greenland ice-sheet may either amplify or dampen, if not reverse the weathering effect.

Here we use the intermediate complexity Earth System model CLIMBER-2 to quantify and analyse the weathering flux changes that result from the projected melting of the Greenland ice sheet and the implications for atmospheric CO2. The biogeochemical module of CLIMBER-2 has been extended to account for the consumption of atmospheric CO2 and the production of riverine HCO3⁻ by continental weathering processes, as a function of geographically distributed runoff (interactively provided by the CLIMBER-2 climate module) and lithology (derived from Amiotte Suchet et al., 2003). We find that the increased weathering processes alone would lead to a sustained 0.2 ppm/kyr decrease in atmospheric pCO2. The climate change resulting from the deglaciation of Greenland reduces the magnitude of this trend to 0.1 ppm/kyr. Only in the case where the effect of freshly comminuted bedrock is taken into account (Clark et al., 2006) does the weathering feedback help to reduce atmospheric pCO2 by about 10 ppm in 5000 years.

The geochemical behaviour of W, Nb-Ta, and Zr-Hf during mid ocean ridge melting

CARSTEN MÜNKER1,2, HOLGER PAULICK1 AND STEPHAN KÖNIG1,2,*

1Universität Bonn, Germany (muenker@uni-bonn.de)
2Universität Münster, Germany

Tungsten is traditionally regarded as one of the most incompatible trace elements during mantle melting, similar to Th. However, previously reported W/Th data indicate that the Earth’s mantle has a lower W/Th (0.19) compared to the Earth’s crust (0.26), suggesting that W is more incompatible than Th. In order to assess the behaviour of W relative to Th and other HFSE during mantle melting, we analysed a suite of MORB glasses from the 7°30’S and 11°30’S section of the Mid Atlantic ridge (MAR South) for their W-Nb-Ta-Zr-Hf compositions, employing isotope dilution and MC-ICPMS. Trace element compositions of the MAR South rocks nearly cover the whole range of MORB (e.g., Zr/Nb from 9-115).

Whereas contents of highly incompatible elements in the MAR South samples vary by more than an order of magnitude (9-220 ppb W, 30-1300 ppb Th), Nb/Ta and W/Th only show little variation (14.0–16.9 and 0.16-0.21, respectively). In marked contrast, Zr/Hf ratios vary from 28-39 and are positively correlated with contents of moderately incompatible trace elements. Nb/Ta ratios decrease slightly with Zr/Nb but are decoupled from Zr/Hf, similar as found in a previous high precision study on MORB samples [2]. These findings appear to be inconsistent with results from experimental studies, predicting that for mantle melting ΔNb<ΔTa and ΔZr<ΔHf (e.g., [3]).

The contrasting behavior of W-Th-Nb-Ta with respect to Zr and Hf is explained by the different bulk partition coefficients for each element group, dominated by cpx. Zirconium and Hf are much more compatible during mantle melting (e.g., [3]), leading to a much stronger fractionation of Zr/Hf in melts, even at relatively large melting degrees. Conversely, modelled W/Th and Nb/Ta ratios approach those of the mantle sources already at melting degrees of ca. 5%, thus providing a good estimate of the average W/Th and Nb/Ta in the mantle source regions. As these source regions of the MAR South magmas are variably depleted, the partition coefficients for Th and W must be similar to within ca 10%. Alternatively, both elements might rather be hosted at grain boundaries [4] and not in the pyroxene crystal lattice. The new estimate for W/Th in the depleted upper mantle (0.18±0.3, 2σ) indicates that W/Th is not significantly fractionated during dry peridotite melting, tentatively suggesting that the fractionated W/Th in the continental crust reflects a different behaviour of the two elements during subduction zone processes.

Magmatic paragonite: Vapour saturation of hydrous arc magmas at high pressure?

O. MÜNTENER1, M.W. SCHMIDT2, P. ULMER2 AND O. JAGOUTZ2

1Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland (othmar.muenter@unil.ch)
2Institute for Mineralogy and Petrography, ETH Zürich, Switzerland
3Institute of Geological Sciences, University of Bern, Switzerland

Exposed deep roots of island arcs (e.g. Kohistan arc, Pakistan; Talkeetna; Alaska) are key for understanding continental crust growth mechanisms. Igneous lower arc crust, however, is faced with high-temperature conditions prevailing for a long time, and thus apparent granulite facies ‘metamorphic’ textures often mask the igneous crystallization history of intermediate to high-pressure arc plutonic rocks. Trace element modeling cannot really discriminate between dehydration melting and high-pressure igneous crystallization when both result in the removal of a small liquid fraction at similar conditions and mineralogy. Besides thermal considerations, one of the keys is that dehydration melting leaves mostly anhydrous residues, while high-P igneous crystallization concentrates H2O in residual liquids, until (eventually) saturation and exsolution of volatiles occurs. We explore phase relations and textures in lower arc crustal rocks from the Jijal sequence of the Kohistan paleo-island arc (NE Pakistan), to constrain the dehydration melting vs igneous hypothesis.

We studied a sequence of ultramafic and mafic rocks which shows locally cyclic cumulate units (websterites, dunites, garnet clinopyroxenites), pyroxene-bearing garnet hornblendites, garnet gabbros, dissected by patches of paragonite-epidote-garnet gabbros and by garnet-bearing felsic veins. Petrography, phase relations, and thermometry are inconsistent with a dehydration melting hypothesis of the Jijal complex, because of (i) the presence of pg-epi-gar gabbros, with a very uneven distribution in the field indicating late stage localized H2O-rich melt pods, (ii) wormlike intergrowths of epi+qtz and hbl+qtz, a typical cotectic crystallization feature, (iii) the overall composition of cumulus minerals, garnet in particular, (iv) oxide, gar-hbl and gar-cpx thermometry approaching/exceeding temperatures of 1000°C. Whole rock major and trace element data demonstrate that garnet gabbros and epi-pg-gar gabbros have identical compositions indicating that the Jijal complex fractionated from low-K, hydrous, calcalkaline magma(s). However, the pg-epi-gar gabbros have lower SiO2, Na2O, Sr, and Ba, indicating loss of these elements by fluid exsolution upon final crystallization. Thus paragonite and epidote in gabbros are not indicative of retrogression but texturally and mineralogically testify local H2O saturation of hydrous arc magmas at high pressures.
Gradual rise of atmospheric oxygen between 2.5 and 2.0 Ga revealed by Fe oxidation kinetics

TAKASHI MURAKAMI1, BULUSU SREENIVAS2, SUBRATA DAS SHARMA2 AND HIROKAZU SUGIMORI1

1Department of Earth and Planetary Science, the University of Tokyo, Tokyo 113-0033, Japan (murakami@eps.s.u-tokyo.ac.jp; sugi@eps.s.u-tokyo.ac.jp)
2National Geophysical Research Institute, Hyderabad 500007, India (bsreenivas@ngri.res.in; dassharma@ngri.res.in)

The evolution of atmospheric oxygen during the Precambrian is a key to understand the co-evolution of life and environment. A change in the redox state of the atmosphere during the Paleoproterozoic has been recognized from geologic records being termed as the Great Oxidation Event. The disappearance of mass independent fractionation in sulfur isotopes confirms that oxygen increase from $\lesssim 10^{-6}$ atm to $\gtrsim 10^{-3}$ atm took place between 2.45 and 2.0 Ga indicating the timing of $P_{O_2}$ transition rather than its quantitative pattern. Despite this advancement, the precise nature of quantitative evolution of atmospheric oxygen during the Paleoproterozoic has remained elusive.

The fractions of redox sensitive elements such as Fe and Mn retained in weathering profiles should reflect the concentrations of atmospheric oxygen at the time of weathering. We calculated retention fractions of Fe and Mn (ratios of the concentrations in a paleosol relative to the parent rock on isovolumetric basis), $F_{Fe}$ and $M_{Mn}$, corrected for compaction factors using available literature data. The $F_{Fe}$ and $M_{Mn}$ increased gradually with age during the Paleoproterozoic ($M_{Mn}$ showing less steep slope than $F_{Fe}$) suggesting an almost continuous increase in the oxidation of $Fe^{2+}$ and $Mn^{2+}$ in paleosols between 2.5 and 2.0 Ga.

We, then, applied Fe oxidation kinetics (-$d[Fe^{2+}]/dt = k[Fe^{2+}][OH]^{-2}(PO_{4})^4$; $x$ is the variable) to the data set of Fe$^{2+}$ and Fe$^{3+}$ concentrations in paleosols to quantitatively model the atmospheric oxygen increase. The above equation was finally converted to:

$$\psi/\psi_A = (PO_{4})^{4-x}/(PO_{4})^4$$

where $\psi$ is the ratio of $[flowing-out Fe^{2+}]/[dissolved Fe^{2+}]$ and the parameters with subscript A are values for reference paleosol A. We also considered formation time of weathering and variation of $P_{CO_2}$ with time in our calculations. Our results suggest that the atmospheric oxygen increased linearly in the logarithmic scale from $\sim 10^{-7}$ atm at 2.5 Ga to $\sim 10^{-3}$ atm at 2.0 Ga, which is in contrast to the drastic rise at $\sim 2.3$ Ga. The gradual rise of oxygen is consistent with isotopic records of carbon and sulphur.

Influence of microbial activities on the behavior of iodine in soil

Y. MURAMATSU1 AND S. AMACHI2

1Dept. of Chemistry, Gakushuin University, Japan
(yasuyuki.muramatsu@gakushuin.ac.jp)
2Dept. of Applied Bioscience, Chiba University, Japan

Studies of iodine in soil are important because of the following two reasons. From the nutritional viewpoint, iodine is an essential element for human because of its role in thyroid gland. Therefore, it is necessary to know the levels and behavior of this element in the soil-vegetation system. From the radiological viewpoint, $^{129}$I (half-life: 16 million years) is released from nuclear industries into the environment. Because of its long half-life, it is important to understand the fate of iodine in the soil environment. In this study we have carried out laboratory experiments on the sorption, desorption and volatilization phenomena of iodine in soil with a special reference to the role of microorganisms. We also analyzed iodine concentrations in various soils collected in Japan.

Very high iodine concentrations (on average: ca. 40 ppm) were found in Andosols, the most common soil type in Japanese upland fields, although its parent materials such as volcanic ash contain very low iodine (ca. 0.04 ppm). This indicates that iodine evaporated from the ocean into the atmosphere was deposited on the soil surface and accumulated there. Using radiotracer experiments, we found that fresh soils had a very high sorption capacity for both iodide ($I^-$) and iodate ($IO_3^-$), whereas that of autoclaved soils was markedly small, specifically for iodide. This suggests the possibility that microorganisms or their products (e.g. enzyme) play an important role in the iodine adsorption. Desorption of iodine from soil under flooded conditions was observed, i.e. iodine associated with soil was dissolved into water due to the reducing conditions (low $E_h$) created by the effects of microbial activities. Low iodine concentrations observed in rice paddy soils can be explained by this effect.

From the soil-plant system, iodine evaporated as organic iodine. In order to investigate this mechanism, we have performed experiments by using bacteria. It was found that a wide variety of bacteria had capacities for producing methyl iodide (CH$_3$I) and they contributed to the volatilization of iodine from soils and also from seawater. Some kinds of fungi also showed a high ability in methylating iodine. We have also carried out studies on the oxidation and reduction of iodine by bacteria. Iodide-oxidizing bacteria, which oxidize iodide to molecular iodine ($I_2$), were isolated from underground brines containing very high iodide. Oxidation of iodide was found to be mediated by an oxygen-requiring enzyme. Iodate-reducing bacteria, which reduce iodate to iodide, were also found. Our results showed that microbial activities influence the chemical form of iodine, which is important to understand the fate of stable and radioactive iodine in the environment.
D/H of kerogen across the Permian/Triassic (P/Tr) boundary

B. NABBEFELD1, K. GRICE1, R. TWITCHETT2, A. SCHIMMELMANN3 AND P. SAUER3

1Curtin University of Technology, Perth, Australia
(B.Nabbefeld@exchange.curtin.edu.au; K.Grice@curtin.edu.au)
2University of Plymouth, Plymouth, UK
3Indiana University, Bloomington, USA

One of the most severe mass extinctions of Earth’s history occurred near to the Permian/Triassic (P/Tr) boundary approximately 251 million years ago. Nearly 90% of all marine species and 70% of all terrestrial life became extinct (Benton & Twitchett, 2003). Several stable isotope excursions (δ13Cbiomarkers, δ13Ckerogen, δ34Spyrite) occur near this boundary and suggest a global disruption to carbon and sulfur cycles (e.g. Grice et al., 2005).

Stable hydrogen isotope (δD) data from stratigraphic sequences of kerogen can provide information about changes in palaeoclimate if the kerogens are of comparable type and thermal maturity (e.g. Lis et al., 2006). We present new δD data of stratigraphic series of kerogens from 3 different localities across the P/Tr boundary from Western Australia, East Greenland and Spitsbergen. The insoluble nature of kerogen guarantees that this material reflects in situ geochemical conditions. A dramatic change in δD of kerogen (35 ‰) is evident in several of the sections. The significance of this change along with δD of biomarkers will be discussed in terms of source/facies, paleoclimate and the extinction event.

The kerogen preparation method included demineralisation of solvent-extracted and decarbonated rock samples, heavy liquid separation, a second solvent extraction and final equilibration of the kerogen with isotopically heavy and light water vapours ahead of the on-line TC/EA measurements (Robl & Davis, 1993; Schimmelmann et al., 1999).

A field-scale study on in situ measurement of microbial activities below the sea floor, Ikeshima, Japan

T. NAGAOKA1 AND E. NAKATA2

1Biotechnology Sector, Environmental Science Research Laboratory (nagaoka@criepi.denken.or.jp)
2Geosphere Science Sector, Civil Engineering Research Laboratory (nakata@criepi.denken.or.jp)
Central Research Institute of Electric Power Industry (CRIEPI) 1646 Abiko, 270-1194, Japan

We employed the push-pull test (Istock et al., Groundwater. 35(4), 619 (1997)) to determine the possibility of developing a measurement system for studying in situ microbial activities (organic matter degradation, iron and sulfate reducing activities, etc) that result in a change in groundwater geochemistry below the sea floor, Ikeshima, JAPAN. The test solution was prepared from ca. 3000 ml of groundwater with the addition of ca. 10 mmol/l KBr as a tracer, 10 mmol/l Na-lactate, and 10 mmol/l NaNO3. The test solution was injected at a pressure of 0.6 MPa into a borehole ca. 130 m below sea surface level on the Ikeshima island, Japan. The borehole was 2-m deep and 86 mm in diameter, and the working volume was ca. 12000 ml. After the injection, the groundwater in the borehole was mixed with the test solution and extracted at a specified time. During extraction, the pH, redox potential (ORP vs Ag/AgCl), and dissolved oxygen (DO) were measured, and the concentrations of lactate, Br-, and NO3- were determined by an ion chromatogram. Prior to the injection of the test solution, the properties of the groundwater were as follows: pH, 7.8; ORP, −98 mV; DO, 0.6 mg/l; EC, 4.92 S/m; and 25.8°C. After 24 h, the concentrations of lactate and NO3- had decreased drastically, and DO had reduced slightly from 0.6 to 0.2 mg/l. These results reveal that there is a possibility of a microbial effect on the geochemistry of groundwater and the measurement of in situ microbial activities.
In situ observation of radial pyroxene chondrule formation from levitated melts

K. Nagashima 1, Y. Moriuchi 1, K. K. Tanaka 2 and K. Tsukamoto 1

1Graduate School of Sci., Tohoku Univ., Japan (nagashima@ganko.tohoku.ac.jp)
2Institute of Low Temperature Sci., Hokkaido Univ., Japan

Chondrules were crystallized from levitated melts to study the rate of crystallization during cooling. Levitation is known to reduce the heterogeneous nucleation rate considerably and thus highly supersaturated melt become stable for a long time.

The levitation experiments were done by using a gas-jet levitator (Nagashima et al., 2006). MgSiO 3 glass spherule (diameter < 3 mm) was set at the top of nozzle of the gas jet levitator and the melt temperature was kept at a given temperature by adjusting the power of CO 2 laser power. To investigate the seeding effect, enstatite (MgSiO 3) particles, ~ 5 µm in diameter, in the gas flow were forced to be impinged to the surface of the supercooled melt droplet, the nucleation process of which was observed by a high speed CCD camera.

Although we had expected easy homogeneous nucleation from the melt droplets by this seeding, this seeding experiments failed over a wide range of supercooling. Crystallization was found to be possible only at a very large supercooling temperature regime (∆T ~ 260-860K). When the ∆T is less than 260K, neither homogeneous nucleation nor heterogeneous nucleation could be detected. If ∆T is more than 860K, crystallization was impossible because of glass formation.

Typical radial textures from levitated melts (fig. 1) was obtained at ∆T ~ 800K, in which a single nucleation center at surface of the melt was observed. The fact that natural radial textures in chondrule starts from the surface might suggest the impingement of a few cosmic dust particles during the cooling.

Figure 1: (A) In-situ observation of the levitated melt during crystallization. Radial texture was formed at ∆T ~ 800 K. (B) Polarized image of (A).

Crystal chemistry of pumpellyite: Chromium distribution between the octahedral sites

Mariko Nagashima 1, Masahide Akasaka 2, ATSUSHI KYONO 1, KUNIKI MAKINO 1 and KO IKEDA 1

1Institut für Geowissenschaften, Christian Albrechts Universität zu Kiel, Germany (mn@min.uni-kiel.de)
2Department of Geoscience, Shimane University, Japan (akasaka@riko.shimane-u.ac.jp)
3Division of Earth Evolution Sciences, University of Tsukuba, Japan
4Department of Geology, Shinshu University, Japan
5Department of Advanced Materials Science and Engineering, Yamaguchi University, Japan

The crystal structure of a chromian pumpellyite of general formula \( \text{VI}_n \text{H}_8 \text{VI}_n \text{X}_4 \text{Y}_4 \text{Z}_4 \text{O}_{42}(\text{OH})_{13.81} \) from Sarani, Ural, Russia, was refined using X-ray single-crystal data to investigate the crystal-chemical behavior of Cr in pumpellyite.

The chemical composition of the crystal is CaO 21.9, MgO 3.6, total Fe 2O 3 0.2, V 2O 3 0.2, Cr 2O 3 14.6, Al 2O 3 16.3, and SiO 2 35.4 wt. %.

Optical spectroscopic analysis showed the oxidation state of Cr to be trivalent. The crystal structure was refined using 1297 unique reflections that converged to a \( R \) factor of 2.8%. The site populations at the \( X \) and \( Y \) sites were determined by using the observed site-scattering values. Since Mg is only located at the \( X \) site, as confirmed by TOF neutron powder diffraction analysis (Nagashima and Akasaka, in press), it was assigned to the \( X \) site. The crystal chemical formula \( \text{Ca}_6(\text{Mg}_{0.73}\text{Cr}_{1.45}\text{Al}_{0.74})_{23.00}(\text{Al}_{0.55}\text{Cr}_{2.42})_{23.00}\text{Si}_{12}\text{O}_{42.19}(\text{OH})_{13.81} \) results. The Cr amount, derived from the site-scattering values (3.87 apfu), is consistent with that obtained by EPMA analysis (3.85 apfu). Although Cr 3+ is located at both the \( X \) and \( Y \) sites, the distribution coefficient \([\text{Cr}/\text{Al}]^3\) = 4.46 indicates a stronger preference of Cr for the \( X \) site than the \( Y \) site, contrary to the proposal of Ivanov et al. (1981) that Cr 3+ prefers the \( Y \) site. The volume of the \( \text{YO}_6 \) octahedra and the mean \( Y \)-O distance increase with increasing Cr 3+ substitution for Al at the \( Y \) site, which also causes an increase in the \( a \), \( b \), and \( c \) unit-cell dimensions.

However, the volume of the \( \text{YO}_6 \) octahedra and the mean \( X \)-\( O \) distance are not correlated with the site populations of cations at the \( X \) site. Distortion parameters for the \( Y \) site tend to decrease with an increasing mean \( Y \)-\( O \) distance and volume of the \( \text{YO}_6 \) octahedra. This indicates that the \( \text{YO}_6 \) octahedra become less distorted with the expansion of the octahedra through substitution of cations larger than Al.

The advantage of studying basalts from intra-transform
spreading centers is that they provide well-defined locations of
melt delivery and crustal formation. Also, magmatism in
fracture zones is not supported by long-lived magma chambers or along-axis transport of melt from other parts of the
spreading system. Thus lavas from fracture zones represent
pre-aggregated melts and their compositions provide insight
into models of melt generation and transport processes
beneath mid-ocean ridges.

Geochemistry of basalts from intra-transform spreading centers:
Implications for melt migration models

Washington, Washington, DC, USA

The Quebrada/Discovery/Gofar (QDG) transform fault
system offsets the fast-spreading East Pacific Rise (3°-5°S) by
approximately 400km and is composed of 7 active intra-
transform spreading centers ranging in length from 5 to 70km.
Forty-seven dredges of young intra-transform basalts were
collected from this area and analyzed for volatiles, major and
trace elements.

QDG basalts exhibit varying degrees of differentiation,
which correlate with the estimates of crustal thickness of each
ridge segment derived from gravity models. The incompatible
trace element ratios (e.g., Th/La) of these lavas range
significantly from ultra-depleted to extremely enriched
compositions. Furthermore, the level of enrichment correlates
well with both ratios of volatiles to similarly incompatible
refractory elements (e.g., H₂O/Ce) and indicators of depth of
melt segregation (e.g., Sm/Yb). Overall, the chemical
variation of these basalts is greater than that previously found
in fracture zones (such as Siqueiros and Garrett FZ) and is
similar to the compositional range defined by northern EPR
seamounts.

Models of mantle flow and melt delivery in the QDG
study area predict significantly different compositions and
crustal thicknesses at the various intra-transform spreading
centers. We will test the validity of the different models by
comparing the observed and predicted lava compositions.
Effects of self-consistently-calculated thermodynamic properties in thermo-chemical multiphase mantle convection in a 3D spherical shell

TAKASHI NAKAGAWA1, PAUL J. TACKLEY2, FREDERIC DESCHAMPS3 AND JAMES A.D. CONNOLLY4
1Department of Earth and Planetary Sciences, Kyushu University, Fukuoka, Japan (takashi@geo.kyushu-u.ac.jp)
2Institute of Geophysics, ETH Zürich, Switzerland (ptackley@ethz.ch)
3Institute of Geophysics, ETH Zürich, Switzerland (frederic.deschamps@erdw.ethz.ch)
4Institute of Mineralogy and Petrology, ETH Zürich, Switzerland (connolly@erdw.ethz.ch)

High pressure and temperature experiments and calculations of the properties of mantle minerals show that many different mineral phases exist as a function of pressure, temperature and composition (e.g. Irifune and Ringwood, 1987), and that these have a first-order influence on properties such as density and elastic moduli (hence seismic velocity). Numerical models of thermo-chemical mantle convection have typically used a simple approximation to treat these complex variations in material properties, such as the extended Boussinesq approximation. Some numerical models have attempted to implement multiple, composition-dependent phases into thermo-chemical mantle convection (e.g. Tackley and Xie, 2003; Nakagawa and Tackley, 2005) and to calculate seismic anomalies from mantle convection simulations based on polynomial fitting for temperature, composition and mineral phase (Nakagawa and Tackley, 2006). However, their linearised treatments are still approximations and may not adequately represent properties including effect of composition on phase transitions. In order to get closer to a realistic mineralogy, we here calculate composition-dependent mineral assemblages and their physical properties using the code PERPLEX, which minimizes free energy for a given combination of oxides as a function of temperature and pressure, and use this in a numerical model of thermo-chemical mantle convection in a three-dimensional spherical shell, to calculate three-dimensionally-varying physical properties. In this presentation we compare the results obtained with this new, self-consistently-calculated treatment, with results using the old, approximate treatment, focusing particularly on thermo-chemical-phase structures and seismic anomalies in the CMB region and the transition zone.

Development of chelate resin column preconcentration method for precise isotope analysis of Mo in seawater

Y. NAKAGAWA1, M. LUTFI FIRDAUS1, K. NORISUYE1, Y. SOHRIN1, K. IRISAWA2 AND T. HIRATA2
1Institute for Chemical Research, Kyoto University, Uji, Kyoto, 611-0011, Japan (ynakagawa@inter3.kuicr.kyoto-u.ac.jp)
2Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo, 152-8550, Japan

Mo is present nearly conservatively in the modern ocean (~10 ppb). However, Mo is depleted in reducing environments and hydrothermal systems and so on, and such fractionation should be reflected in the Mo isotope composition. In addition, because Mo is an essential element for organisms, biological activity may change the Mo isotope composition. Therefore, precise isotope analysis of Mo in seawater is expected to provide new valuable information, and to be a good tool in geochemical oceanography.

Only a few data have been reported on the isotopic composition of Mo in seawater. More than 50-fold concentration of Mo in seawater is required for isotopic measurement. An ion exchange resin method was used to purify Mo, but this method requires concentrated acid for elution, and may not be able to separate major elements of seawater completely. So, we have newly developed a chelate resin column preconcentration method.

8-hydroxyquinoline (8HQ) bonded covalently to a vinyl polymer resin, TSK-8HQ (Dierssen et al., 2001), was used in a column to concentrate Mo. The sample solution that has been adjusted to pH 2.0 by HCl was passed through the column, and then the adsorbed Mo was eluted by the back flushing of 2 M NH3. To obtain a high concentration factor, the eluate was evaporated to dryness, and Mo was then redissolved in 0.05% tetramethylammonium hydroxide. Mo isotope ratio was measured by MC-ICP-MS (Nu Plasma 500). The mass discrimination effect on Mo was internally corrected by 88Sr/86Sr to be 0.1194 using the exponential law. Individual sample uncertainties (2σ) of this element spike method are 0.03% per amu for 1 ppm Mo.

Mo in 500 mL seawater sample was collected quantitatively. The procedure blank was less than 10-3 times of Mo concentration in seawater. The residual ratio of major elements of seawater in the eluate was less than 10-2, and their matrix effects on isotope analysis of Mo were negligible.

δ88Mo in seawater collected from 697 m depth in Suruga Bay, Japan was 2.49 ± 0.10 (2σ) relative to JMC standard. We will report the vertical profiles of Mo isotope ratio from stations in the western North Pacific Ocean at the presentation.

Effects of hydrogen on limits of radiative emission from a planet with a saturated-water-vapor atmosphere

MIKI NAKAJIMA1, MASASHIRO IKOMA1, HIDENORI GENDA2 AND SHIGERU IDA1

1Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan
(mnakajima@geo.titech.ac.jp)
2Research Center for the Evolving Earth and Planets, Tokyo Institute of Technology, Tokyo, Japan

It is known that there are upper limits of radiative emission from a planet covered with sufficient water (i.e., an ocean). If incoming thermal flux exceeds the limits, extra thermal energy is used to evaporate the ocean, which means that an ocean is unable to exist under such a circumstance. These limits have close relationships with the early evolution and habitability of planets. Since the energy flux from the planet’s surface decreases with time because of cooling of the planetary interior, the limits constrain the timing of ocean formation. Moreover, because the stellar radiative flux decreases with distance from the star, this limits constrain the inner edge of the habitable zone in a planetary system.

Several studies investigated these limits (Komabayashi 1967; Ingersoll 1969; Abe and Matsui 1988; Kasting et al. 1988; Nakajima et al. 1992). However, no study has evaluated the effects of hydrogen on these limits. According to recent studies of the accumulation of the Earth’s atmosphere, the initial Earth is likely to have been rich in hydrogen (e.g., Ikoma and Genda 2006). Furthermore, in extrasolar planetary systems, there might exist hydrogen-rich terrestrial planets.

In this research, we have investigated the effects of hydrogen (e.g., changes in mean molecular weight and opacity) and gravity on the limits by simulating the structure of the atmosphere in the radiative-convective equilibrium. Then we discuss the early evolution of the Earth and the location of the habitable zone in extrasolar planetary system.

Chemical composition and behavior of atmospheric aerosols in the mountainous and plain regions of Toyama, Central Japan

T. NAKAMURA, T. YAMAZAKI AND K. KAWASAKI
Toyama Prefectural Environmental Science Research Center, Toyama, Japan (tokuhiro.nakamura@pref.toyama.lg.jp)

Introduction
East Asia is one of the most troubled regions in terms of atmospheric environment due to its huge population and industrial development. The emission of anthropogenic substances in East Asia has been on the rise due to the use of fossil fuels, industrialization and due to the lack of waste control practices. In particular, it is predicted that NOx emission will increase approximately 5-fold from 1990 to 2020 (Akimoto, 2003). The excessive N loading may have several adverse effects on both ecosystem health and water quality.

The western North Pacific receives a large influx of mineral dust and pollutants from East Asia through atmospheric long-range transport. The Japan Sea is a marginal sea of the western Pacific Ocean and located in a transit zone for the continental air masses traveling to the open North Pacific. The coastal area of Japan Sea is an important area to study the transport mechanisms and modifications to chemical properties of aerosols.

Method
Chemical composition of aerosols and suspendes particle matter (SPM) measurements were conducted at Mt. Tateyama (2450 m a.s.l.) and Imizu (10 m a.s.l.) in Toyama, central Japan, simultaneously from 18 May to 8 June 2006.

The sampling period was about 24 hours and the sampled air volume was from 27.7 to 39.1 m³.

Results
During the observation period, anthropogenic plume were observed. One of these episodes were almost equal nss-SO4²⁻ levels to the urban atmosphere, even in Tateyama.

The mean concentrations of nss-SO4²⁻ and NO3⁻ in Tateyama were 5.37 and 0.59 µg m⁻³, respectively. The concentration of nss-SO4²⁻ was relatively lower than that of Imizu 8.68 µg m⁻³. However, the concentration of NO3⁻ was much lower than that of Imizu (2.93 µg m⁻³). The NO3⁻/nss-SO4²⁻ ratio in Tateyama (0.11) was lower than that of in Imizu (0.34). This is probably because NO3⁻ combined with nss-Ca²⁺ removed from the atmosphere faster than that of nss-SO4²⁻. New particulate nss-SO4²⁻ is expected to form by gas to particle conversation with time.

These pollutants will influence air quality and radiative forcing. To understand the effect of nitrogen deposition to the ecosystems, both wet and dry including gaseous matter measurements are required.

The mineralogy of Comet Wild-2 nucleus samples – What we think we know and what we do not know

KEIKO NAKAMURA-MESSENGER1,2, MICHAEL ZOLENSKY1 AND THE STARDUST MINERALOGY/PETROLOGY SUBTEAM

1NASA Johnson Space Center, Houston, TX 77058 USA
2ESCG/ Jacobs Engineering, Houston, TX 77058 USA

The sample return capsule of the Stardust spacecraft was successfully recovered in northern Utah on January 15, 2006, and its cargo of coma grains from Comet Wild-2 captured in aerogel tiles has now been the subject of intense investigation by approximately 200 scientists scattered across five continents. We have now performed mineralogical and petrographic analyses of particles derived directly from the Jupiter-family Comet Wild-2.

Numerous particles were collected by impact into low density aerogel. Dozens to thousands of fragments of the impacting particles are distributed along 100 m-1cm-length tracks. So far 52 of these tracks have been harvested, and samples of 26 tracks have been studied in enough detail to give first order views of their mineralogy [1]. The recovered Wild-2 samples are mixtures of crystalline and amorphous materials. However, it is unclear how much of the amorphous material was produced from the aerogel during the particle capture. Crystalline materials are abundant in Comet Wild-2 and many are "coarse-grained" (1-10 \( \mu \)m) relative to the submicrometer scales characteristic of anhydrous IDPs and interstellar dust. Of the best studied 26 tracks, eight are dominated by olivine, seven by low-Ca pyroxene, three by similar amounts of olivine and pyroxene, and the remaining eight are dominated by other minerals, mainly Fe-Ni sulfides. Our emerging model is that many of the impacting particles were very fine-grained, loosely-bound aggregates with a bulk chondritic composition. Most also contain large individual crystals (most commonly) of olivine, pyroxene and Fe-Ni sulfides, similar to chondritic IDPs. Olivine and Low-Ca Pyroxene is present in most Wild-2 particles, with grain sizes ranging from sub-\( \mu \)m to over 10 \( \mu \)m. Wild-2 olivine has an extremely wide compositional range, from Fo1.2-100, with a pronounced peak at Fo99. The wide Mg-Fe compositional range of Wild-2 olivine is similar to both anhydrous chondritic IDPs, and also to matrix minerals of the chondrites Murchison (CM2), and Orgueil (C11), which have experienced extensive, from En45.100, with a significant frequency peak centered at En85.

Rb-Sr single bed isochron dating with evidence of isotope equilibrium

T. NAKAO1 AND T. TANAKA AND S. KOJIMA2

1Dept. Earth and Environmental Sci, Nagoya Univ, Nagoya 464-8601 JAPAN (nakao@gcl.eps.nagoya-u.ac.jp)
2Dept. Civil Engineering, Gifu Univ, Gifu 501-1193 JAPAN

Introduction

Sedimentary rocks consist of various components, isotope ratios of which are considered to indicate different ages. If isotopic age determinations of the sedimentary rocks can be carried out, the isotopes had to equilibrate, after sources of them had deposited. It is difficult to verify the isotope equilibrium. Shibata and Mizutani (1982) reported Rb-Sr isochron age of 211 ± 4.7 Ma with initial \( {^{87}}\text{Sr}/\text{Sr}^{86} \) ratio of 0.71325 ± 0.00020 for the Triassic chert, which is younger than the fossil age. They regarded the Rb-Sr age as a diagenesis age. They collected the samples ranging 10 m in thickness. The strata of this thickness is hard to regard to be formed by a single sedimentary event. They didn’t discuss equilibrium of Sr isotopes.

In this study, we used a single layer of the Triassic bedded chert in the Mino belt, central Japan to determine a Rb-Sr isochron age. Conodont fossils, one of the components of the chert, were also separated in order to measure the \( {^{87}}\text{Sr}/\text{Sr}^{86} \) ratio.

Analytical method

The sample was cut parallel to the bedding plain into twelve slices, each of which was used as a whole rock sample. Concentration of Rb and Sr of the slices were determined by a thermal ionization quadrupole mass spectrometer, Finnigan MAT Thermoquad THQ. Sr isotope ratio was measured with a VG Sector 54-30 thermal ionization mass spectrometer at Nagoya University. In case of conodonts, a Ta emitter solution (Brick, 1986) was used to load Sr onto single Re filament with 2M-H3PO4.

Result and Discussion

Rb-Sr isochron age of the chert was 219 ± 22 Ma with the initial \( {^{87}}\text{Sr}/\text{Sr}^{86} \) ratio of 0.7125 ± 0.0020. The Rb-Sr age is indistinguishable from the depositional age (Norian: Sugiyama, 1997) indicated by the radiolarian fossils.

Conodonts in the chert consist mainly of apatite. Apatite contains extremely low content of Rb but rich in Sr. This indicates that the \( {^{87}}\text{Sr}/\text{Sr}^{86} \) ratio of conodonts would not have evolved since the conodonts were deposited. Since conodonts are part of marine organisms, the \( {^{87}}\text{Sr}/\text{Sr}^{86} \) ratio must be same as that of seawater at the time of deposition. The \( {^{87}}\text{Sr}/\text{Sr}^{86} \) ratio of the Triassic conodonts, however, is 0.712211 ± 0.00020 \((^{87}\text{Rb}/^{86}\text{Sr}=0.10) \) and higher than that of Triassic seawater (=0.708), while it is indistinguishable from the initial Sr ratio (=0.7125 ± 0.0020) of the chert. This indicates that the chert layer including conodont fossils are equilibrated in term of Sr isotopes after its deposition. Because the Rb-Sr age is consistent with the radiolarian age, the Sr isotopes were equilibrated just after the sources of chert had deposited.
Noble gases and nitrogen in the Isheyevo CH/CB chondrite
D. NAKASHIMA1,2, S. P. SCHWENZER1 AND U. OTT1
1Max-Planck-Institut für Chemie, Mainz, Germany
(ott@mpch-mainz.mpg.de)
2University of Tokyo, Tokyo, Japan
(naka@eqchem.s.u-tokyo.ac.jp)

Metal-rich CH and CB carbonaceous chondrites are known to show characteristic noble gas signatures and nitrogen isotopic compositions [e.g., 1-2]. Noble gases in CHs and CBs are characterized by Ar-rich gases and low \(^{136}\text{Xe}/^{132}\text{Xe} \) ratios (solar wind-Xe like) [1]. In addition, these chondrites have the isotopically heaviest N in chondrites (\(\delta^{15}\text{N} \sim +1000\%\); [2]). In this study, we analyzed noble gases and nitrogen in magnetic fraction (MF) and non-magnetic fraction (NMF) from Isheyevo, which is an unique meteorite consisting of CH-like and CB-like lithologies [3].

Isotopic ratios of He and Ne show that light noble gases in both fractions are dominated by solar and cosmogenic noble gases. Trapped \(^{4}\text{He}/^{20}\text{Ne} \) ratios are about 400 for MF and 170 for NMF, indicative of high retentivity of solar noble gases in MF. Trapped \(^{20}\text{Ne}/^{36}\text{Ar} \) ratio of MF (~5) is lower than that of NMF (28). This can not be explained by preferential loss of solar \(^{20}\text{Ne} \), because of higher retentivity of solar noble gases in MF. It is likely that the low \(^{20}\text{Ne}/^{36}\text{Ar} \) ratio is due to enrichment of \(^{36}\text{Ar} \), i.e., Ar-rich noble gases, which are considered to be fractionated solar wind noble gases [e.g., 4]. In the case of Isheyevo, Ar-rich gases appear to be concentrated in metallic phases (MF).

Xe isotopic ratios in NMF are almost identical to Xe-Q, whereas Xe in MF seems to be the mixture of Q-Xe and solar wind-Xe (SW-Xe). This indicates that SW-Xe is contained in MF. Since MF contains both solar and Ar-rich gases, it is not clear whether SW-Xe is associated with solar or Ar-rich gases. Nitrogen in MF (\(\delta^{15}\text{N} \sim +1230\%\)) is isotopically heavier than that in NMF (+310%). Nitrogen in NMF may be diluted with isotopically “normal” nitrogen (0±50%); [5]).

Acknowledgement
We thank M. A. Ivanova for providing magnetic and non-magnetic fractions of the Isheyevo meteorite.

Physicochemical speciation of trace metals during the mesoscale iron enrichment (SEEDS II) in the western North Pacific
S. NAKATSUKA1*, Y. SOHRIN1, K. NORISUYE1, K. OKAMURA1, S. TAKEDA4 AND J. NISHIOKA4
1Institute for Chemical Research, Kyoto University, Kyoto, Japan (nakatuka@inter3.kuicr.kyoto-u.ac.jp)
2Center for Advanced Core Research, Kochi University, Kochi, Japan
3Graduate School of Agricultural and Life Sciences, The University of Tokyo, Tokyo, Japan
4Institute of Low temperature Science, Hokkaido University, Hokkaido, Japan

The mesoscale iron-enrichment experiment SEEDS II was conducted near the edge of the subarctic Western North Pacific gyre, where SEEDS I had been carried out [1, 2]. We investigated dissolved and particulate Co, Ni, Cu, Zn, Cd and Pb in seawater from both field observation for 26 days and shipboard incubation with a natural phytoplankton assemblage for 10 days. Discrete seawater samples were filtered through 0.2 µm filter and acidified to pH 2.2 for the determination of the dissolved species by ICP-MS. The filter was used to measure the particulate species by FI-ICP-MS.

Before the iron enrichment, the average concentrations for dissolved Co, Ni, Cu, Zn, Cd and Pb in the surface mixed layer (0-20 m) were 70 pM, 4.9 nM, 2.1 nM, 1.6 nM, 0.48 nM and 52 pM, respectively, and those for the particulate species were 1.7 pM, 0.052 nM, 0.094 nM, 0.46 nM, 0.037 nM and 5.2 pM, respectively. After the enrichment, there was a threefold increase in chlorophyll \(\alpha \) (~3 µg/L) by day 12. However, there was no detectable difference in the dissolved and particulate trace metals between inside and outside the patch. In the shipboard incubation, addition of 1 nM Fe caused a 30-fold increase in chlorophyll \(\alpha \) (~9 µg/L) dominated by Pseudo-nitzschia sp. and increases in the particulate trace metal fraction up to 3-45%. These results suggest that Fe was a limiting factor for the growth of phytoplankton. In addition, enhanced-grazing by mesozooplankton presumably limited the growth of phytoplankton and the transformation of trace metal speciation during the mesoscale Fe enrichment.

The Sept Iles mafic layered intrusion: An example of ferrobasaltic differentiation

O. Namur1, B. Charlier1, M.D. Higgins2 and J. Vander Auwera1

1Department of Geology, University of Liège, Belgium
2Earth Sciences, University of Chicoutimi, Canada

The Sept Iles Mafic Intrusion (SIMI) (Quebec, Canada), part of the Sept Iles Intrusive Suite (SIIS), is a 6 km-thick layered troctolite-gabbro intrusion with a funnel shape of 80 km in diameter. The SIIS has been dated at 564 ± 4 Ma [1] and supposedly results from the activity of a mantle plume related to the formation of the St-Laurent rift system. Flood basalts may have erupted before its emplacement [2]. A detailed petrologic study of the SIMI has been undertaken with the aim of better constraining the differentiation of ferrobasaltic liquids [3]. We present here the first results of this study which focus on the possible composition of the SIMI parent magma and on the main structure of this magma chamber.

The exposed part of the SIIS is surrounded by a Border zone of variable thickness made of massive and locally fine grained gabbros. These fine-grained gabbros have high FeOt (up to 15 wt. %) and TiO2 (3 wt. %) contents, moderate P2O5 content (0.35 wt. %) and no Eu anomaly (Eu/Eu* = 0.95). They are typical ferrobasalts very similar to the estimated parent magmas of the Skærgaard [4] and Newark Island intrusions [5]. The composition of liquidus phases obtained with the MELTS algorithm (plagioclase An67, olivine Fo75) perfectly matches the most primitive compositions of plagioclase (An68) and olivine (Fo75) observed in the SIMI. Moreover, the sequence of crystallization experimentally obtained by [5, 6] on samples which are very similar to the ferrobasalts from Sept Iles is in agreement with the sequence of crystallization of the SIMI (plagioclase and olivine, + Ca-rich clinopyroxene, + magnetite and ilmenite - olivine, + apatite). The fine-grained gabbros from the Border Intrusion are thus plausible compositions for the parent magma of the SIMI.

From base to top, the plagioclase composition evolves continuously from An68 to An30, then displays a significant reversal to An30 followed by a new decrease down to An25. The magnetite Cr content displays a parallel evolution. This reversal is interpreted as a new magma influx which is marked by an intraplutonic quench horizon. Other small reversals are observed throughout the Series.

7Geowissenschaftliches Zentrum, Georg August-Universität Göttingen, Germany (akronz@gwdg.de)

The possibility to determine U-Pb ages from micron-sized areas within single zircon crystals using the SHRIMP technique has opened up new possibilities for detailed studies of the history of crustal rocks and constraining their ages. This technique, however, depends on the availability of well-characterized, natural reference materials (Kennedy, 2000). We propose a gem-quality zircon (Univ. Mainz sample no. M257) as a future SHRIMP U-Pb zircon standard.

Zircon M257 is a pale brown, clear stone with a weight of 25.7 ct [for comparison, SHRIMP standard CZ3 (Pidgeon, 1997), which has been used for more than ten years, had a weight of only 4.5 ct]. M257 is remarkably homogeneous; no internal zoning at all was found using CL imaging, transmitted light microscopy and Raman line-scanning. Its comparably high actinide concentrations (U, 810 ppm; Th, 224 ppm) will account for high U and Pb count rates. Preliminary TIMS analyses (done in Giessen, Santa Barbara and Oslo) indicate a concordant U-Pb age of ~562 Ma. Unit cell dimensions (a0, 6.626 Å; c0, 6.030 Å) and Raman parameters {e.g., FWHM[ν3(SiO3)], 11.8 cm−1} correlate very well with the calculated time-integrated alpha dose of 1.66 × 1018 α/g (compare Nasdala et al., 2004). This and the (U+Th)/He age (419 ± 9 Ma), which is consistent with previous helium ages for zircon from Sri Lanka, allow us to exclude any heat-treatment. Further characterization of the isotopic composition of sample M257 is in progress.

Deficient electron microprobe totals: Discussion of potential causes

L. NASDALA1, T. VÁCZI1, A. KRONZ2, R. WIRTH3, C. PÉREZ-SOBA AGUILAR4 AND A. WILLNER5

1Institut für Mineralogie und Kristallographie, Universität Wien, Austria (lutz.nasdala@univie.ac.at; tamas.vaczi@univie.ac.at)

Radiation-damaged minerals, including zircon, coffinite, thorite and monazite, are occasionally found to yield electron microprobe results whose totals (oxide sums) are deficient, i.e. appreciably below 100 wt%. Causes of the apparently too low totals are controversial; most authors have assigned the phenomenon to enhanced contents of hydrous species, other non-analyzed elements, textural peculiarities such as voids, or instability and degradation under the electron beam. It has also been observed that micro-areas yielding low totals are typically recognized from very low BSE intensities (Kempe et al., 2000), which is in apparent contradiction to their usually high degree of radiation damage and the positive correlation between radiation damage and BSE intensity (Nasdala et al., 2006).

We have studied low-totals zircon from three localities. Deficient totals and accompanying very low BSE intensities are only detected in areas affected by secondary alteration whereas primary zircon never shows these phenomena. The alteration has often, but not always, led to enhanced actinide content, which is why low-totals areas are mostly radiation-damaged. Low-totals areas were found to contain up to 5 wt% hydrous species, which explains both the deficient analysis sums and the low BSE intensity (due to decrease of the average atomic number). In the TEM, low-totals areas show a sponge-like texture with numerous sub-micron sized voids, as it was suggested by Pointer et al. (1988). We explain the formation of this texture and the water uptake by secondary, fluid-driven alteration of previously radiation-damaged and thus volume-expanded zircon.

2GEMOC Laboratory, Macquarie University, Australia
3KM Diamond Exploration Ltd. Vancouver, Canada

Kimberlites, carbonatites, alkaline and ultramafic lamprophyres and other alkaline ultrabasic rocks have been recently discovered within the Batain Nappes in the eastern Oman Mountains. The Kimberlite area comprises several allochthonous bodies. Most of these are carbonatite and carbonate kimberlite which contains mantle derived (altered peridotitic) xenoliths and xenocrysts. The kimberlite occurs either as breccia pipes and/or as long dykes ~ 6 km long. The kimberlites contain abundant macrocrysts of mica (phlogopite and/or biotite), chromite, chrome diopside, pelletal lapilli and autolithic clasts in a calcite + serpentine matrix. The kimberlites are dominantly composed of ‘hapabbyssal and diatreme facies’ volcaniclastic rocks. These include pyroclastic lapilli-, carbonate-dominated tuffs, and volcaniclastic kimberlite, all of which intruding late Jurassic to Lower Cretaceous marine sedimentary rocks (cherts and shales) of the Wahra Formation, within the Allochthonous Batain Melange. Major and trace elements and isotopic composition indicate that the Omani kimberlites in this study form a compositionally cohesive group of rocks more akin geochemically to the Koidu type kimberlites of West Africa than the Group I kimberlites from South Africa. The kimberlite contained zircon, G9 garnet and chromite grains with typical kimberlitic morphologies and chemical properties similar to diamond inclusion chromite. However, there were no micro-diamonds observed.

Fifteen pinkish (‘kimberlitic’) zircon grains, 0.5 to 1.5 mm in size, were picked from the kimberlite tuff and were analyzed at GEMOC. Trace-element patterns are typical of kimberlitic to carbonatitic zircons. Their mean age of 137.5 ± 1 Ma (95 % confidence,MSWD = 0.49) is consistent with intrusion into Lower Cretaceous rocks. Their $^{176}$Hf/$^{177}$Hf (0.28286±1, $\varepsilon_{Hf}$ = 6.2) is typical of kimberlitic zircons of this age, and may represent the subcontinental lithospheric mantle.
Is the isotope composition of Reunion plume really homogeneous?

F. NAURET, M. ARIGOT, P. LOUVAT AND M. MOREIRA
Equipe de Geochimie-Cosmochimie. Institut de Physique du Glode de Paris. Tour 14, 3 Etage. (nauret@ipgp.jussieu.fr nauret)

Réunion Island, Indian Ocean, is the present signature on the Earth surface of the Réunion hotspot. The island is composed by two volcanoes: the inactive Piton des Neiges and the active Piton de la Fournaise. The isotope compositions of Réunion lavas are usually described as homogeneous. This homogeneity is remarkable compared to other hotspot volcanism. However, a fine study of the Réunion database reveals that the large majority of the available data comes from analyzed lavas produced by Piton de la Fournaise. Furthermore, the few available Pb isotope data have been published before 1972. Consequently, the apparent homogeneity of Reunion lavas is potentially due to analytical or sample bias.

With the intention of testing this homogeneity, we have recently sampled the Piton des Neiges. The sample collection (n=47) covers temporally and geographically this volcano.

Taking advantage of recent analytical development, Pb isotope compositions were measured using a MC-ICP-MS (Neptune) and mass fractionation is corrected using a Tl spike. The Pb isotope composition range from \(206\text{Pb}/\text{204Pb}: 18.79-18.90\), \(207\text{Pb}/\text{204Pb}: 15.56-15.60\) and \(208\text{Pb}/\text{204Pb}: 38.79-39.04\). These ranges overlap those given for the Piton de la Fournaise \(\text{206Pb}/\text{204Pb}: 18.55-18.91\), \(\text{207Pb}/\text{204Pb}: 15.58-15.65\) and \(\text{208Pb}/\text{204Pb}: 38.74-39.01\) from 71 samples). Based on these preliminary results, we suggest that lavas from both volcanoes plot on same lines in Pb isotope spaces. However, it seems that Piton des Neiges lavas might extend Pb isotopes ranges given for Reunion plume.

Pb isotopes and trace element concentration analyses currently in progress will help further constrain the geochemical composition of the Piton des Neiges, the chemical structure of the Réunion hotspot and the influence of the Reunion hotspot on the regional magmatism.

Influence of porosity on basalt weathering rates from the clast to watershed scale

A. NAVARRE-SITCHLER\(^1\), C. STEEFEL\(^2\), E. HAUSRATH\(^1\) AND S. BRANTLEY\(^3\)

\(^1\)Department of Geosciences, The Pennsylvania State University, (anavarre@geosc.psu.edu)
\(^2\)Lawrence Berkeley National Laboratory, Berkeley CA
\(^3\)Earth and Environmental Systems Institute and Center for Environmental Kinetics Analysis, The Pennsylvania State University

Production of saprolite from bedrock is an important source of both mineral detritus and dissolved ions. The rates at which saprolite is produced have far reaching impacts on important processes such as global flux of dissolved material to oceans, nutrient cycling in soils, sedimentation that ultimately leads to oil and gas generation, and the fate of atmospheric CO\(_2\) over geologic time scales. Despite their importance, saprolite production rates cannot currently be predicted. In low porosity rocks, like basalt, rates of saprolite production are dependent upon the ability of water to infiltrate the parent rock. Fracturing of these rocks by either physical or chemical mechanisms is one way of increasing available water. However, not all rocks fracture during weathering and in these systems porosity can be enhanced through the dissolution of primary phases.

We are currently using weathering rinds developed on unfractured basalt clasts as a natural system where we can study processes and rates of saprolite formation over long time periods (35-250 ka). Across a weathering interface approximately 2 mm wide parent basalt weathering to form saprolite that is completely depleted in Ca, Na, Si and Mg. Associated with the weathering is an increase in porosity from 3-50%. Theoretical calculations of diffusion limited weathering predict that the weathering rind will grow as a function of the square-root of time \((t^{0.5})\). However, these calculations are for constant porosity systems and many studies of weathering rinds indicate a \(t^{0.8}\) dependence. By including dissolution enhanced porosity in reactive transport models of the basalt clasts, we are able to predict both the geometry of the weathering interface and time dependence of rind formation.

Given similar lithology and climate, the knowledge we have gained by studying saprolite production on basalt clasts should provide insight into weathering of basalt watersheds. However, making comparisons between watershed denudation rates and weathering rind advance rates is complicated due to the difference in methods used to measure surface area. We compare weathering advance rates (\(\text{mm yr}^{-1}\)) calculated from laboratory, clast, soil profile and watershed studies using fractal theory in an attempt to reconcile basalt weathering rates across scales.
**The impact of subducting sediment on the HFSE budget of arc-related igneous rocks, Banda arc, Indonesia**

O. NEBEL¹, M.L.A. MOREL¹, P.Z. VROON¹, G.R. DAVIES² and M.J. VAN BERGEN²

¹Department of Petrology, Vrije Universiteit Amsterdam, The Netherlands
²Department of Petrology, Universiteit Utrecht, The Netherlands

Subduction processes and associated arc volcanism play a key role in determining the chemical composition of continental crust. The contribution of subducting sediment to arc magmatism is still poorly constrained but potentially accounts to a significant extend for the HFSE budget of arc-related igneous rocks. The Banda arc in Indonesia has a unique geologic setting that allows HFSE behaviour in a subduction zone to be studied. The amount of subducting sediment being dumped into the subduction regime increases from NE-SW from 0.1 to 5 wt.% [1]. Samples collected along the arc front, well defined for their Nd-Pb-Sr-O isotopes and trace elements [2,3], are analyzed for their Hf isotopes and HFS element concentrations. Hafnium isotope data, ranging from $-3.4 \epsilon_{\text{Hf}}$ to $+13.0 \epsilon_{\text{Hf}}$, and negative-correlated Hf-O isotope co-variations support the increase in sedimentary influx. The Hf isotope data are systematically decoupled from Nd isotopes, most likely due to partially enhanced fluid-melt mobility of LREE. Zr/Hf exhibit no variation with Th/Yb, which points to no significant decoupling of Zr from Hf with elevated amounts of subducting sediment. In contrast, Nb/Yb is significantly elevated with Th/Yb, pointing to enhanced Nb concentrations with increasing sediment subduction. High precision Nb/Ta data will be used to monitor variations in HFSE caused by sediment subduction and potential residual mineral phases.

²Universität Bonn, Germany
³Vrije Universiteit Amsterdam, The Netherlands
⁴Universität Frankfurt/Main, Germany
⁵Curtin University, Perth, Australia

Witnesses of the infant crust on Earth are rare because no rocks that formed in the first 500 Myrs are preserved and the only remnants of Hadean material are zircon crystals that survived reworking of their host rocks. In order to unravel the evolution of the Earth’s oldest crust, Archean and Hadean detrital zircons from the Mt. Narryer Gneiss Complex were investigated for their U-Pb and Lu-Hf isotope systematics. The U-Pb systematics of six zircons from the Meeberrie Gneiss define an upper concordia intercept age of 3300 Ma and two lower intercepts at ~ 500 Ma and 700 Ma, which we interpret as the formation ages of the gneiss protolith and later thermal overprints, respectively. Corresponding $\epsilon_{\text{Hf}}$ range from -8.6 to -11.2. Eight zircons from a metasediment from Mt. Narryer show ages from 3.2 to 4.2 Ga with corresponding $\epsilon_{\text{Hf}}$ of +3.4 to -2.9. The age distribution and corresponding initial Hf isotopes indicate similar source regions for the Mt. Narryer metasediments and Meeberrie Gneiss. Older (>3.8 old) grains from Jack Hills and the Mt. Narryer metasediments origin from sources that already formed in the Hadean. The combination of these new data with published zircon data, indicate that crustal growth during the first 500 Myrs occurred more or less continuously by formation of small crustal domains.
Trace element partitioning in the granulite facies

F. NEHRING¹, S. FOLEY¹ AND P. HÖLTTÄ²

¹Institute of Geosciences, Johannes Gutenberg-University Mainz (nehring@uni-mainz.de)
²Geological Survey of Finland, Espoo

Granulites from Central Finland experienced pT-conditions of 800-950°C at 9-11 kbar during a major collisional event in the late Archean. Anatectic was induced by dehydration melting of amphibole leading to the formation of cpx, opx, garnet and tonalitic melts. We constrained granulite facies trace element distribution by in situ LA-ICP-MS studies of the principal mineral phases. Our analyses indicate that equilibrium was attained between most phases. Garnets grew in microdomains and only equilibrated with their immediate surrounding. Hence, garnet exerts limited control on the bulk partition coefficient. Accessory phases are important hosts of REE (apatite), HFSE (ilmenite) and transition elements (ilmenite, magnetite).

Using predictive models, comparisons with published data and relationships between minerals and observed melt compositions, we formulate $D_{\text{mineral/melt}}$ values that are applicable for trace element modelling under lower crustal conditions; these are broadly similar to magmatic values for intermediate melt compositions. Uniform $D_{\text{mineral/cpx}}$ for the REE were integrated into the set of $D$-values so that

$$D_{\text{mineral/melt}} = 3 \times D_{\text{amph/cpx}}$$

We provide the first self-consistent set of $D$-values for Sc, V, Cr and Ni between cpx, amph, grt, opx, bt and ilm:

<table>
<thead>
<tr>
<th></th>
<th>$D_{\text{mineral/cpx}}$</th>
<th>$D_{\text{mineral/melt}}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>cpx</td>
<td>1</td>
<td>11</td>
</tr>
<tr>
<td>grt</td>
<td>0.8-1.2</td>
<td>11-12</td>
</tr>
<tr>
<td>amph</td>
<td>0.15-0.25</td>
<td>1.0-3.0</td>
</tr>
<tr>
<td>opx</td>
<td>0.15-0.25</td>
<td>1.0-3.0</td>
</tr>
<tr>
<td>bt</td>
<td>0.15-0.25</td>
<td>1.0-3.0</td>
</tr>
<tr>
<td>ilm</td>
<td>0.15-0.25</td>
<td>1.0-3.0</td>
</tr>
</tbody>
</table>

Ilmenite was found to strongly influence the distribution of Nb and Ta and has partition coefficients an order of magnitude higher than amphibole. Thus, ilmenite has to be considered in future discussions about the role of melting of amphibole-bearing source rocks as the driving mechanism for Archean crust generation.

Geochemistry of I-type granodiorite and tin-bearing S-type granites from Gouveia area, central Portugal

A.M.R. NEIVA

Department of Earth Sciences, University of Coimbra, 3000-272 Coimbra, Portugal (neiva@dct.uc.pt)

The Gouveia area is located in the Iberian Massif, which is a large segment of the European Variscan Belt. Granitic rocks intruded a Cambrian schist-metagraywacke complex and predate the area. SHRIMP U-Pb zircon age for a peraluminous biotite I-type granodiorite is 481.8±5.9 Ma. So, it was emplaced during the Early Ordovician. The granodiorite has ($^{87}\text{Sr}/^{86}\text{Sr})_{\text{ Initial}}=0.7036$, $\varepsilon_{\text{Nd}}(482)=2.5$ and $\delta^{18}\text{O}=8.84\%$, which indicate that it contains a mantle component.

Seven peraluminous two-mica S-type granites are Variscan, as SHRIMP U-Th-Pb monazite ages range from 288 to 304 Ma and record granite emplacement. They have average Sn contents of 16-40 ppm. Most granites define individual fractionation trends, have REE patterns that intersect each other and distinct initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios ranging from 0.7086 to 0.7129 and $\delta^{18}\text{O}$ values of 10.34-13.34 %o and represent different pulses of granite magma. Their zircon core ages range from ~300 to 2100 Ma suggesting that these granites were derived by partial melting of sediments having a range of sources. Granites contain zircon cores similar in age to the granite.

One of these granites and another granite define a sequence shown by fractionation trends for major and trace elements of granites and their micas, subparallel REE patterns of granites and a common whole-rock Rb-Sr isochron. Least square analysis of major elements and modelling of trace elements indicate that the younger granite is derived from the older granite by fractional crystallization of quartz, plagioclase, biotite and ilmenite. Initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio and $\delta^{18}\text{O}$ values increase from the older to the younger granite suggesting that fractional crystallization was accompanied by assimilation of metasedimentary materials. Fractional crystallization was the mechanism responsible for the increase in Sn content in individual granites, sequence and their micas, but it is crucial that the granite melt contains at least 8 ppm Sn. Muscovite retains a higher granite tin content than biotite does.

Cooling $^{39}\text{Ar}/^{40}\text{Ar}$ plateau ages of micas through the Ar closure temperature range from 285 to 293 Ma. There is no significant difference between these ages if errors are taken into account. When the four youngest S-type granites were emplaced at 288-290 Ma, I-type granodiorite emplaced at 482 Ma and the three oldest S-type granites emplaced at 301-304 Ma were affected by the Saalian Variscan movements and their mica $^{39}\text{Ar}/^{40}\text{Ar}$ ages record recrystallization or Ar loss. Trace elements of biotite from the I-type granodiorite were affected, while trace elements of micas from the three oldest S-type granites define individual fractionation trends.
Improved U-(Th)-Pb dating of monazite by ion microprobe: Correcting for an isobaric interference of PrP04 on 204Pb

DAVID R. NELSON1 AND ANDREAS MÖLLER2

1Department of Applied Physics, Curtin University, Bentley 6102, Australia (d.nelson@info.curtin.edu.au)
2Institut f. Geowissenschaften, Univ. Potsdam, D-14776 Potsdam-Golm, Germany (amoeller@geo.uni-potsdam.de)

High U and Th abundances, resistivity to diffusion and resilience to weathering make monazite one of the most important minerals for U-Th-Pb dating. Chemical characteristics (e.g. Y content, REE pattern) can be used as indicators of monazite growth reactions, and allow correlation of age data with metamorphic, magmatic or hydrothermal processes.

It has been noted that ion microprobe analysis of Th-rich monazite can yield discordant Pb-U and Pb-Th dates (e.g. Stern & Berman 2000; Zhu & O'Nions 1998), or may show excess scatter on the 207Pb/206Pb dates. Both effects compromise the analytical accuracy and the geological interpretation. These effects may be attributable to matrix effects, i.e. subtle crystallographic differences may result in different ablation and Pb/U characteristics of unknowns and the monazite inter-element fractionation standard used during SIMS analysis. In comparison to zircon, commonly occurring monazite cover a much wider range of chemical compositions.

To evaluate the effects, we have systematically studied a suite of monazite reference materials with a range of chemical compositions, from the brabantite (CaTh(PO 4)2) as well as the huttonite (ThSiO 4) solid solution series, and with varying Yttrium content. Independently determined age data exist for all these materials from TIMS measurements.

We propose that the observed excess scatter on the 207Pb/206Pb ratios results from an isobaric interference of PrP04 on 204Pb that has so far been ignored in ion microprobe data reduction and correction procedures. Using a correction based on the La/Ce counts, routinely measured in monazite analytical session on SHRIMP, and extrapolating to Pr, a correction can be applied before further corrections for Th-related “excess 204Pb are applied. Our correction routine has been built into the recent version of CONCH, a visual Basic program for processing of ion-microprobe analytical data developed by Nelson (2006).

Acknowledgements

Heterogeneity of MORB composition along the eastern part of the Southwest Indian Ridge

NATSUKI NEO AND SUMIO MIYASHITA

Graduate School of Science & Technology, Niigata University, Niigata, 950-2181 Japan (f05j007a@mail.cc.niigata-u.ac.jp; miyashita@geo.sc.niigata-u.ac.jp)

Regional variations of basalt compositions from the eastern part of the Southwest Indian Ridge (SWIR) were shown by Natland (1991), Meyzen et al. (2003) and Robinson et al. (1996). However, the definitions for the regional variation along the SWIR are different from each other in above studies. We have analyzed major and minor element compositions (including REE) of basalts obtained from 55E to 70E along the SWIR. In this study, We discuss for the regional variation based on our result and PETDB.

We defined from 55E to Rodriguez Triple Junction (RTJ) into 4 areas; Area I: 68E to RTJ (70E), Area II: 60E to 68E, Area III: 57E to Melville F. Z. (60E), Area IV: 55E to Atlantis II F. Z. (57E). The basaltic rocks from Areas I&IV, II and III show different trends, indicating that they were not derived by simple fractional crystallization, but also by a different degree of partial melting.

The basalts of Areas I &IV show a N-MORB-like REE pattern, while those of II show enriched pattern in LREE. However, the compositions of Area III basalts are intermediate--both in REE pattern and Na$_2$O contents.

We conclude that enriched source in terms of LREE and Na$_2$O exists under Area II. Whereas Area I & IV are underlain by N-MORB-like source. The intermediate composition in Area III may be explained by mixing between enrich source and N-MORB source. It is noted that the enriched source of Area II is completely distinct from E-MORB signature.

Boron influence on biochemical reactions in natural zeolites

A. NEUBECK, M. IVARSSON AND N.G. HOLM

Department of Geology and Geochemistry, Stockholm University, 106 91 Stockholm, Sweden, (anna.neubeck@geo.su.se, magnus.ivarsson@geo.su.se, nils.holm@geo.su.se)

The special zeolitic characteristics such as cation exchange, molecular sieve capacity, open crystal framework and reversible dehydration make them interesting in many aspects. They may be used as absorbents for pollutants in the agricultural and environmental industry, fertilizers and in the treatment of nuclear wastewaters. Another use is to investigate their role as catalysts or adsorbents of organic compounds in their crystal channels, which provide a protected microenvironment for chemical reactions. Adsorbance of labile biomolecules onto the zeolite crystal tunnel walls may stabilize and therefore trigger their readiness to further react, possibly in polymerization reactions.

It has also recently been shown that borate minerals stabilize ribose, a highly thermo-labile pentose, by forming complexes. Even synthesis of pentoses is possible in the presence of borate. Thus, boron containing minerals may have been important in the development of larger biomolecules on the early Earth.

In our project, we are going to do gaseous and aqueous adsorption tests on natural zeolites, with and without boron in their crystal structure. In some of our material, boron has substituted for beryllium and possibly silica in the zeolitic crystal framework. The combination of the microenvironment given from the zeolite and the stabilizing properties of boron may be ideal for some organic reactions. Until now, most adsorption tests have been made on synthetic zeolites for industrial usage. Natural zeolites will provide a better analogue to actual earthly systems than synthetic ones.

Mo isotopes in modern euxinic environments: Water column and sediment data

N. Neubert1, T.F. Nägler1 and M.E. Böttcher2

1Institute of Geological Sciences, Isotope Geology Group, University of Bern, Switzerland (neubert@geo.unibe.ch, naegler@geo.unibe.ch)
2Leibniz Institut for Baltic Sea Research, Warnemünde, Germany (michael.boettcher@io-warnemuende.de)

The present study investigates the pathways of molybdenum (Mo) scavenging under euxinic conditions following the fractionation of stable Mo isotopes in three modern settings: The Black Sea, the largest permanently euxinic basin, and two anoxic troughs of the Baltic Sea. Water column profiles, as well as surface sediment samples, were recovered from different water depths and analyzed for the concentration and isotopic composition of Mo, besides other geochemical parameters.

Mo is a redox-sensitive trace metal which is soluble as the molybdate oxyanion in oxic seawater with a residence time of about 800 ka. The isotope signature of Mo is a relatively new proxy used to reconstruct the paleo-redox conditions of the Earth’s atmosphere and the oceanic system. The Mo isotope composition in seawater is homogeneous, as shown by [1]. Scavenging of Mo under euxinic conditions is related to the amount of free H2S. Near total removal of Mo from the water column is reached at a H2Saq concentration of 11±3 µM [2]. In the Black Sea this corresponds to a water depth of about 400 m. Sediment samples of the Black Sea from more than 400 m water depth show seawater isotopic composition, agreeing completely with the assumption of bulk Mo removal. However, shallower sediments deposited under lower H2S concentrations show significant Mo isotope fractionation.

Brackish Baltic Sea surface sediment samples are taken from two separate basins, the Gotland Deep and the Landsort Deep which have maximum water depths of 248 m and 459 m, respectively. The Baltic Sea oceanographic conditions, including temporary bottom water oxygenation due to sporadic North Sea water inflows, are more complex than in the Black Sea. The dissolved sulfide concentrations in the water column are less than 50 µM and the salinity is less than 22 PSU. In the anoxic part, Mo isotope signatures are shifted towards heavier values indicating in-situ fractionation upon scavenging under euxinic conditions. The surface sediments are the sink for reduced Mo and show Mo fractionation similar to the oxic to slightly euxinic sediments of the Black Sea. Intra-basinal differences and downcore variations can be explained by changes in the bottom water redox conditions due to episodes with different inflow intensities and reflect varying concentrations of dissolved sulfide in the water column.

Extremely refractory oceanic lithospheric mantle and its implications for geochemical mass balance

E.-R. Neumann1, N.S.C. Simon1, C. Bonadiman2, M. Coltorti3, G. Delpech3 and M. Grégoire4

1Physics of Geological Processes, University of Oslo, P.O.Box 1048 Blindern, N-0316 Oslo, Norway
2Earth Science Department, University of Ferrara, Via Saragat, 1 44100 Ferrara, Italy
3UMR CNRS 8148 IDES, “Interactions et Dynamique des Environnements de Surface”, Faculté des Sciences, Université Orsay-Paris Sud, Bât.504, 91405 ORSAY Cedex
4Observatoire Midi-Pyrénées, UMR 5562-DTP, OMP, Université Toulouse III, Avenue E. Belin, 31400 Toulouse, France

In several ocean islands (e.g. the Canary Islands, Kerguelen, Cape Verde and Savai‘i) the mantle xenoliths population is dominated by extremely refractory spinel harzburgites. These harzburgites (OI1) show no petrographic evidence of metasomatism, and carry no primary clinopyroxene. However, minor metasomatism may be reflected in the incompatible trace elements and radiogenic isotopes. The major element and modal compositions of the OI1 harzburgites correspond to residual mantle formed from a primordial source after 25-30% partial melting, leaving a clinopyroxene- and garnet-free residue. These peridotites are, on average, significantly more refractory than MOR peridotites. Estimated P-T conditions (850-1200°C and 0.7-1.3 GPa) indicate that the OI1 peridotites last equilibrated within the abyssal mantle lithosphere. Their textures and high solidus temperatures imply that their strongly refractory nature cannot be the result of processes (“additional” partial melting or melt – wall-rock reactions) associated with the present plumes. Although interaction with plume melts has caused minor enrichment in radiogenic isotopic ratios and the most strongly incompatible elements, their original (pre-ocean-island) compositions are preserved in the most abundant major elements and in the modal relationships. Highly refractory OI1 spinel-harzburgites have higher solubility than more fertile, clinopyroxene-bearing peridotites, and are likely to be resistant to further partial melting. We interpret the OI1 peridotites as fragments of recycled, “sterile” asthenospheric material that have been trapped in the abyssal mantle lithosphere. These peridotites imply that the convecting mantle includes material that is significantly more refractory than MOR peridotites. The OI1 peridotites are buoyant relative to less refractory, denser mantle material and may preferentially accumulate at the top of the convecting mantle, where they freeze to the base of newly formed abyssal lithosphere.
Distribution and redox status of Arsenic in framboidal pyrite from estuarine sediments

1Institut für Mineralogie und Geochemie, Universität Karlsruhe, 76131 Karlsruhe, Germany
2Institut für Synchrotronstrahlung, Forschungszentrum Karlsruhe, 76028 Karlsruhe, Germany

Synchrotron μXRF measurements of 106 μm-sized pyrite framboids from anoxic sediments of the Achterwasser lagoon, a part of the estuarine system of the river Oder, SW Baltic Sea, show highly variable As concentrations ranging from 6 to 1140 μg/g within the uppermost 50 cm of the sediment column. Even within a single depth layer, the As concentration of different framboids vary greatly with no clear depth trend visible. Median values calculated from μXRF data for each depth layer are similar to the chemical extraction data (28 to 143 μg As per g pyrite), suggesting that the applied extraction procedure yields realistic average As concentrations in pyrite from bulk sediment. Pyrite can account for 9 to 55% (average 22%) of the total As budget of the sediments indicating that authigenic pyrite plays an important role in the geochemical cycling of As in coastal sediments.

High-resolution μXRF mapping of single pyrite grains shows that As is distributed inhomogeneously within larger framboids, and more regularly in the smaller pyrite grains. This may be due to changing pore water composition during pyrite growth, with larger and older framboids being subjected to more frequent changes in the pore water composition as compared to the smaller and younger framboids from the same depth layer.

XANES spectra indicate that a considerably part of As is present in higher valence state (+III+/V) in samples from near the sediment/water interface. This can be explained by frequently occurring resuspension of the surficial sediments to the oxic water column due to wave action and subsequent re-deposition. This process might be responsible for adsorption of As(V) oxyanions onto pyrite. Reduced As(-I) species become more important in the deeper samples, reflecting decreasing redox potential and increased time since deposition. This suggests that adsorbed As(V) and As(III) species will be reduced by the sulfidic pore waters prior incorporation during pyrite growth.

Degassing of oceanic H2S and its delivery to terrestrial ecosystems during the Permo-Triassic extinction

R.J. Newton, P.B. Wignall, S.H. Bottrell and I. Metcalfe

1School of Earth and Environment, University of Leeds, UK, LS2 9JT (r.newton@see.leeds.ac.uk)
2Asia Centre, University of New England, Armidale NSW 2351, Australia

Evidence is growing that drastic changes in the oceanic sulfur cycle were intimately linked with the greatest extinction of the Phanerozoic at the Permo-Triassic boundary. Isotopic changes in proxies for seawater-sulfate suggest the transformation of a significant portion of the marine sulfate reservoir to dissolved sulfide by bacterial sulfate reduction during the late Permian (Newton et al., 2004). Rapid return to 34S depleted sulfite at the extinction level can be explained by ocean overturn and re-oxidation of this sulfide, providing a kill mechanism in the form of H2S poisoning. Modelling using end-Permian boundary conditions permits the escape of this sulfide from the surface of the ocean (Kump et al., 2005), so ocean overturn and sulfide release could therefore link the marine and terrestrial extinctions which are closely spaced in time. Here we present new results from lacustrine sediments from north-west China, and re-interpret existing results from South Africa (Maruoka et al., 2003). Sulfate concentrations in freshwater lake systems are low when compared to supplies of reactive Fe and organic matter. Hence, sulfate is often quantitatively reduced and preserved as pyrite in lake sediments, recording the isotopic composition of the original sulfate.

Isotope data from both localities record relatively stable backgrounds (δ34S between -4 to +5‰, China, and 0 to +5‰, South Africa), within the normal range for weathered sulfate from large geologically diverse catchments. Close to the P-Tr boundary these stable records are interrupted by rapid negative shifts to around -12%δ34SVPDB (both locations).

These excursions could not be caused by inputs of volcanogenic sulfur (δ34S -5 to +5‰), and provide the first direct evidence of transfers of oceanic derived H2S to terrestrial ecosystems. The exact role of H2S in the terrestrial extinction is unclear. Possible mechanisms include direct poisoning, acidification, or as part of an ozone depletion scenario, leading to radiation exposure (Lamarque et al., 2007).

Isotopic evidence for Uranium retardation in zeolitic rocks at Yucca Mountain, Nevada

LEONID A. NEYMARK

U.S. Geological Survey, DFC Box 25046, MS 963, Denver, CO 80225 (neymark@usgs.gov)

Retardation of radionuclides by sorption in the nonwelded tuffs below the proposed high-level nuclear waste repository in the unsaturated zone at Yucca Mountain, Nevada, is a positive attribute of the natural barrier. Alteration of volcanic glass in these tuffs produced thick, widespread zones of zeolite- and clay-rich rocks with high sorptive capacities. The alteration of glass to zeolites, however, was accompanied by reduction in the matrix porosity and permeability causing most flow to occur through fractures, which may have decreased the overall effectiveness of radionuclide retardation in the zeolitic rock matrix.

Chemical and uranium-series isotopic compositions were measured in samples of unfractured and rubble rock from core, surfaces of natural fractures in the core, and in rock leachates and pore water extracted from these core samples. Uranium concentrations in sodium acetate leachates indicate that the mobile $^{238}$U is 0.3 to 1.7 percent of total $^{238}$U in rock samples and allow estimates of the time-integrated in situ U distribution coefficient $K_d$ ($K_d=C_{\text{solid}}/C_{\text{water}}$, where C is concentration). Use of median U concentrations in pore water that the mobile $^{238}$U is 0.3 to 1.7 percent of total $^{238}$U in rock matrix.

Samples of rock from unfractured core, rubble core, and fracture surfaces have similar $^{234}$U/$^{238}$U activity ratios (AR) ranging from 0.92 to 1.16, indicating both enrichments and depletions in the daughter $^{234}$U relative to the parent $^{238}$U. In contrast to the rock, all pore water and rock leachate samples have elevated $^{234}$U/$^{238}$U AR ranging from 1.1 to 5.2. The chemical and isotopic data indicate that the matrix in zeolite- and clay-rich rocks is capable of exchanging uranium with $^{234}$U-enriched percolating water and that retardation of radionuclides can occur in altered rocks below the proposed repository.

Weathering of Ca- and P-bearing minerals by fungi in a northern hardwood forest

C.A. NEZAT¹, J.D. BLUM² AND D.R. ZAK³

¹Department of Geological Sciences, University of Michigan, Ann Arbor, Michigan, USA (cnezat@umich.edu)
²Department of Geological Sciences, University of Michigan, Ann Arbor, Michigan, USA (jdblum@umich.edu)
³School of Natural Resources & Environment, University of Michigan, Ann Arbor, Michigan, USA (drzak@umich.edu)

In many ecosystems, mineral weathering is the initial source of calcium and phosphorus, both of which are essential nutrients for plants. Mycorrhizal fungi are symbiotically associated with tree roots and exude organic acids that enhance mineral dissolution and transfer nutrients to trees (e.g., Jongman et al., 1997). Understanding this process in forests of the northeastern USA is important because acid deposition has increased Ca leaching from Ca-poor soils such as those with granitic parent material.

To test the role of fungi in weathering of Ca- and/or P-bearing minerals, mesh bags containing quartz (as a control), quartz plus 1% wollastonite (CaSiO₃), or quartz plus 1% apatite (Ca₅(PO₄)₃(F) were buried in mineral soil beneath American beech (Fagus grandifolia Ehrh.), sugar maple (Acer saccharum Marsh.), and mixed spruce and basalm fir stands (Picea rubens Sarg. and Abies balsamea L.) at the Hubbard Brook Experimental Forest, New Hampshire, USA. A 50-µm mesh size was chosen to exclude roots but allow fungal hyphae to enter the bags.

Microbial community composition and biomass in the mesh bags and surrounding soil were characterized and quantified using phospholipid fatty acid (PLFA) analysis. Fungal biomass (estimated as moles of fungi-specific PLFA 18:2ω6 and 18:1ω9c) in the soil and control bags did not differ significantly among stand types. In contrast, the degree of fungal colonization in apatite- and wollastonite-amended bags varied significantly with stand type. In the beech stands, fungal biomass was significantly greater in the apatite-amended bags, suggesting that apatite dissolution stimulated fungal colonization. In the spruce-fir stands, the fungal biomass did not vary as a function of the mineral assemblage, suggesting that the natural supply of Ca and P in these stands is high enough to meet nutrient demands. In the sugar maple stands, fungal biomass was significantly lower in the wollastonite-amended bags relative to the control and apatite-amended bags. The different response in each stand type appears to be related to the type of fungi present as well as the nutrient status of the soils. These results are important for evaluating nutrient demands of vegetation, and the effects of microbial community composition on the mineral dissolution of Ca and P-bearing minerals.

H$_2$O diffusion in rhyolite at 1-2 GPa

HUAWEI NI AND YOUXUE ZHANG
Department of Geological Sciences, The University of Michigan, Ann Arbor, MI 48109-1005, USA
(hni@umich.edu; youxue@umich.edu)

Water diffusion in silicate melts is crucial for understanding various volcanic processes, including bubble formation and growth, magma degassing, and magma fragmentation. H$_2$O diffusivity in rhyolite were previously measured at 0.1-810 MPa (Zhang et al., 1991; Zhang and Behrens, 2000). To better constrain the pressure effect on H$_2$O diffusion, we conducted diffusion-couple experiments at 407-1629°C and 1-2 GPa in piston-cylinder apparatus. After experiments, samples are doubly polished to ~200 µm thickness, and H$_2$O concentration profile along the centerline is measured using FTIR microscope.

Compared to Zhang and Behrens (2000), H$_2$O diffusivity at 1-2 GPa increases less rapidly with water content. H$_2$O diffusivity in rhyolite melt decreases from one atmosphere to 2 GPa, and such negative pressure effect is more remarkable as the temperature decreases, which leads to a larger activation energy at higher pressure. If the model of Zhang and Behrens (2000) at <2 wt.% water content is extrapolated to 2 GPa, the prediction results in roughly the same activation energy, but the predicted diffusivity is systematically lower than our measurements by a factor of about 3, which suggests a smaller pressure effect and therefore a smaller activation volume. By combining previous data and our measurements and assuming total H$_2$O diffusivity is proportional to total H$_2$O concentration, a new H$_2$O diffusivity model at <2 wt.% water contents and 0.1-2000 MPa has been constructed, which better constrains the pressure dependence. We are also developing a general H$_2$O diffusivity model applicable to higher water contents and 0.1-2000 MPa.

The accuracy of $\delta^{11}$B measurements of foraminifera

Y. NI$^{1,2}$, G.L. FOSTER$^2$ AND T. ELLIOTT$^2$

$^1$Research Institute of Petroleum Exploration & Development, Beijing, China, 100083 (niyunyan@yahoo.com.cn)
$^2$Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK

The pH of seawater reflects the speciation of dissolved carbon and hence also, in part, the extent of the partitioning of carbon dioxide between the oceans and atmosphere. Reconstructions of past seawater pH therefore allow investigations of, for example, the concentration of CO$_2$ in the past and the mechanisms of glacial-interglacial CO$_2$ change.

A number of contributions have demonstrated that the boron isotopic composition of marine carbonates, such as foraminifera, record the pH of the seawater in which they grew. Sample size requirements have led to most workers measuring the small amounts of boron in foraminifera by negative-ion thermal ionisation mass spectrometry (NTIMS), which has very high ion yields. What is more, this technique uses the Ca (plus trace metals) of the dissolved marine carbonate as an activator, requiring no additional purification and/or concentration of boron, which greatly simplifies the approach. We show here, by a comparison between the $\delta^{11}$B of samples and solutions measured by both total evaporation NTIMS and multicollector inductively coupled plasma mass spectrometry (MC-ICPMS), that this latter feature, although seemingly advantageous, results in a significant bias in the $\delta^{11}$B measurement by NTIMS.

We conclude that organic carbon, probably hosted within the foraminiferal shell and hence inadequately oxidised during cleaning, has a detrimental and variable effect on the thermal ionisation of boron. This effect does not necessarily relate to the presence of CN$^-$ molecules and results in the TE-NTIMS $\delta^{11}$B measurements being shifted to heavier not lighter values as would be expected from CNO- interference at mass 42. This matrix effect may go some way to explaining the reported large $\delta^{11}$B differences between laboratories for similar foraminiferal samples (up to 6 ‰ disagreement by NTIMS). With careful treatment, reliable $\delta^{11}$B data can be generated by NTIMS. However, we hope that this realisation, along with a modified loading technique outlined here, makes $\delta^{11}$B isotope measurements by negative thermal ionisation techniques more routine and accurate.
Root zone of sheeted dike complex in Oman ophiolite-dynamical model

A. NICOLAS AND F. BOUDIER
Université Montpellier II, France
(nicolas@gm.univ-montp2.fr; boudier@gm.univ-montp2.fr)

As in many other ophiolites, there is in Oman an horizon called the root zone of the sheeted dike complex (RZSDC) located below the volcanics and the diabase sheeted dike complex and above the gabbro unit. This RZSDC is described here based on structural and petrological observations carried during the extensive mapping of this ophiolite (Nicolas et al., 2000) and on a new fine-scale mapping in a selected area. The Oman ophiolite is derived from a fast spreading ridge where a melt lens is located above the main gabbro unit and just below the RZSDC. With a few exceptions, the RZSDC thickness is rather constant, in the 100 m range, with a crude internal stratigraphy.

The base of RZSDC is a level of isotropic doleritic gabbros interpreted as a thermal boundary layer transitional between the magmatic system of the melt lens convecting at 1200°C, and a high temperature (HT) hydrothermal system convecting within the RZSDC at <1100°C. In this field of very sharp thermal gradient (~7°C/m), increasing seawater flux locally generates near total hydrous melting at the expense of these isotropic gabbros, at ~1100°C (companion abstract). The upper part of the RZSDC is richer in vari-textured doleritic and pegmatitic gabbros, with trondhjemitic intrusions, formed by a similar process at temperatures below 1000°C. The latter formations constitute screens between the lower dikes of the sheeted dike complex. At the very base of this complex a new boundary layer, with HT diabase dikes, separates the preceding HT convective system from the well known LT (T<450°C) hydrothermal system operating throughout the sheeted dike complex, to the seafloor.

Intruding the isotropic gabbros near the base of the RZSDC, protodikes with a distinctive microgranular border and a doleritic center testify that the RZSDC was generated by melt conduits issued from the melt lens. Each dike of the sheeted dike complex is thus fed by one protodike. However, protodike swarms are exceptional because, crystallizing ~1100°C, they are largely destroyed by dike-in-dike intrusions and by hydrous remelting.

Generation and emplacement of granitic magmas at the Paleocene Rum Igneous Complex, northwest Scotland

G.R. NICOLL1, V.R. TROLL1, C.H. DONALDSON2, R.M. ELLAM3 AND C.H. EMELEUS4

1Dept. of Geology, Trinity College Dublin, Dublin 2, Ireland (gnicoll@tcd.ie)
2School of Geosciences, University of St Andrews, St Andrews KY16 9AL, Scotland
3S.U.E.R.C., Rankine Avenue, East Kilbride, G75 0QF, Scotland
4Dept. of Earth Sciences, University of Durham, Durham DH1 3LE, England

The Isle of Rum is one of several igneous complexes within the British-Irish Paleocene Igneous Province that formed prior to the opening of the North Atlantic Ocean during a period of crustal stretching and thinning. An elliptical ring fault, 12km across, bounds the igneous centre enclosing remnants of an early granitic phase of intrusive and eruptive activity that is cross-cut by basic and ultrabasic intrusions. This activity consists of intra-caldera rhodacitic ignimbrites and microgranitic to granitic shallow-level intrusive bodies that are all located within, and in close proximity to the Main Ring Fault.

These early granitic magmas show a strong involvement and interaction with crustal materials. Isotopic data implies 40-90% contamination of mantle-derived magmas by upper crustal Lewisian amphibolite-facies gneiss. Some of these felsic intrusions are intimately associated with mafic magmas. 87Sr/86Sr isotope data from basaltic margins and lobate inclusions, to and within the granitic rocks, indicate that very few of these mafic components have uncontaminated mantle-like values. Most of them also show varying degrees of crustal contamination (87Sr/86Sr 0.7029 - 0.7140) by both Lewisian amphibolite-facies material and a component that is similar in isotopic composition to Lewisian granulate-facies gneiss.

This isotopic information provides a unique window into the crustal structure beneath the Rum Igneous Complex and combined with detailed field investigations allow for an integrated approach to interpreting the generation, emplacement and eruption of anorogenic granitic magmas. We propose that basic and ultrabasic intrusions at depth, migrating towards the surface, heated and partially melted the more felsic components of the surrounding crust which gave rise to a voluminous, but ultimately short-lived, episode of granitic magmatism on Rum.
Assessing the relative production rates of cosmogenic $^3$He and $^{21}$Ne in olivine, pyroxene and quartz

S. Niedermann$^1$, P. Pilz$^1$ and M. Goethals$^{1,2}$

$^1$GeoForschungsZentrum Potsdam, Germany (nied@gfz-potsdam.de)
$^2$Westfälische Wilhelms-Universität Münster, Germany (goethals@uni-muenster.de)

Currently used methods to derive cosmogenic $^3$He and $^{21}$Ne production rates ($P_3$ and $P_{21}$) for pyroxenes based on their major element composition yield inconsistent exposure ages by up to 40% (Niedermann et al., 2007), indicating a substantial flaw in our knowledge on production systematics of the noble gas isotopes, in spite of a general agreement of the models with experimental determinations of $P_3$ in olivine and $P_{21}$ in quartz. However, $P_3$(ol) has never been directly experimentally determined. Our exposure geometry may have changed during degradation of a sample is not from a well-defined surface location (the well as olivine and pyroxene phenocrysts. Although the sample is not from a well-defined surface location (the exposure geometry may have changed during degradation of a lava tube), it provides the opportunity to study the ratios of $P_3$ and $P_{21}$ in olivine, pyroxene and quartz. The resulting $P_3$(ol)/$P_{21}$(qz)=$7.80\pm0.55$ and $P_3$(px)/$P_{21}$(qz)=$8.00\pm0.62$ are $\approx30\%$ higher than the value obtained by comparing the experimental $P_3$ in olivine ($\approx116$ at g$^{-1}$ a$^{-1}$) to the experimental $P_{21}$ in quartz ($\approx19$ at g$^{-1}$ a$^{-1}$). The difference is similar to that resulting from different methods to calculate $P_3$ and $P_{21}$ from major element composition. A difference of $10\%$ at most might be assigned to unfavorable irradiation conditions, if the quartz xenocryst was located at the very bottom of the sampled rock during most of the exposure. But still the results would imply $P_3$(ol) $\approx20\%$ higher or $P_{21}$(qz) $\approx20\%$ lower than the values usually assumed. The determinations of cosmogenic $^3$He and $^{21}$Ne in our sample are robust since they are based on a value of 7.9 $R_\alpha$ for the magmatic $^3$He/$^4$He ratio and an atmospheric trapped Ne composition. Any reasonable different assumption could only increase the $P_3/P_{21}$ ratios.

The comparison of cosmogenic $^{21}$Ne in olivine (Mg-rich) and pyroxene (Mg-poor) may, in principle, be used for an experimental determination of the $P_{21}$(Mg)/$P_{21}$(Si) ratio. Our present data indicate a value of $\approx3.4$, but with a large uncertainty of 30-50% which critically depends on the uncertainty of the $^{21}$Ne(ol)/$^{21}$Ne(px) ratio. We hope to obtain a more accurate result by analyzing Ne in olivine and pyroxene from a well-defined surface sample.

Hydrothermal alkali and oxygen-isotope exchange in alkali feldspars controlled by dissolution reprecipitation mechanisms

D.R.D. Niedermeyer$^1$, A. Putnis$^2$ and T. Geisler$^2$

$^1$Institut für Petrologie, Universität Bremen, Germany
$^2$Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Germany

The re-equilibration mechanisms of solid phases in hydrothermal fluids are only poorly understood. Depending on the prevailing conditions a sequence of fluid-induced dissolution-reprecipitation or solid state processes may take place. In the present study, we have investigated the re-equilibration of albite in the presence of a fluid phase. For this, we have experimentally treated a natural albite crystal in an aqueous KCl solution at 600°C and 2 kbars. To trace the exchange between mineral and fluid, the aqueous KCl solution was enriched with $^{18}$O (95 atom %). The major aim of this study was the characterization of the chemical and physical properties of the K-feldspar reaction rim that is known to form during the interaction of albite with an aqueous KCl-rich fluid under the chosen conditions (Labotka et al. 2004). Transmission electron microscopic investigations have shown that the interface between the pristine albite and the K-feldspar product phase is sharp on a nano-scale, with a strong diffraction contrast difference between both phases, suggesting a defect-rich K-feldspar product. A porous zone also evolved near the interface. Existing crystallographic orientation as well as twinning in the albite is preserved in the K-feldspar reaction rim. Powder X-ray diffraction analyses revealed a change from triclinic Al$_2$SiO$_5$ ordered albite structure to an Al$_2$Si disordered monoclinic structure in the K-feldspar. Furthermore, Raman spectroscopy has been applied to map the mass frequency shift of the Si-O-Si bending vibration near 476 cm$^{-1}$ in the K-feldspar due to the incorporation of $^{18}$O. The frequency of this mode shifts to about 457 cm$^{-1}$ in K-feldspar formed in $^{18}$O-enriched solution, reflecting a high enrichment of $^{18}$O in the K-feldspar lattice. In the K-feldspar formed in $^{18}$O-enriched solution the highest frequency shift was found close to the interface, which coincides with an enrichment of the orthoclase component close to the interface, as revealed by electron microprobe measurements. This indicates that the higher frequency shift close to the interface results from chemical changes rather than from a higher $^{18}$O content. An important observation is that there is no gradient in the frequency shift that could be related to diffusion of $^{18}$O.

We propose that the new data are fully consistent with an interface-controlled dissolution-reprecipitation mechanism that operates at an inward moving replacement front.

Systematic thallium isotope variation in Fe-Mn crusts: A proxy for changes in ocean chemistry?
SUNE G. NIELSEN1, VERONIKA KLEMM2, DOUG LA Rowe3, ALEX N. HALLIDAY 1 AND JAMES R. HEIN4

1University of Oxford, Dept. of Earth Science, Parks Road OX1 3PR, UK
2ETH-Zurich, Dept. of Earth Science, 8092 Zurich, Switzerland
3Utrecht University, Dept. of Earth Science, 3508 TA Utrecht, Netherlands
4USGS, 345 Middleton Road, Menlo Park, CA 94025, USA

We have measured the thallium (Tl) isotope composition of samples from the Pacific Fe -Mn crust CD29-2, which have recently been dated using Os isotope stratigraphy [1]. The samples have a spatial resolution of about 1mm which equates to about 0.5 Ma. Thus far we have investigated the time interval spanning 60 to 30 Ma and large systematic Tl isotope variations ranging between $\varepsilon^{205}\text{Tl} = +6.8$ and $\varepsilon^{205}\text{Tl} = +11.4$ are apparent (where $\varepsilon^{205}\text{Tl} = 10^4 \times (^{205}\text{Tl}/^{203}\text{Tl}_{\text{sample}} - ^{205}\text{Tl}/^{203}\text{Tl}_{\text{NIST 997}})/^{205}\text{Tl}/^{203}\text{Tl}_{\text{NIST 997}}$). The most striking feature is a systematic increase from $\varepsilon^{205}\text{Tl} = +6.5$ to $+10.5$ occurring in the time interval 58 to 50 Ma. A small number of previous analyses at various depths in CD29-2 [2] are fully consistent with our more detailed investigation.

Rehkämp er et al [2] argued that these variations most likely reflected a change in the Tl isotope composition of seawater and this remains a firm possibility. However, recent theoretical calculations of the mechanism controlling Tl isotope fractionation have shown that there is a large equilibrium isotope fractionation between Tl$^{1+}$ and Tl$^{3+}$ [3]. Published Tl isotope compositions of modern Fe-Mn crusts [4] and altered mid ocean ridge basalts [5] are consistent with these two reservoirs exclusively incorporating Tl$^{3+}$ and Tl$^{1+}$, respectively. Hence, changes in the speciation of Tl in seawater may also be responsible for the observed Tl isotope variation recorded in Fe-Mn crusts. This proposition appears to be in agreement with the fact that the timing of Tl isotope change in CD29-2 coincides exactly with the massive change in atmospheric CO2 inferred from boron isotope compositions of planktic foraminifera [6].

We are currently performing thermodynamic calculations aimed at determining the speciation of Tl in seawater in order to investigate the potential for Tl isotopes to be used as a proxy for changes in the chemical and physical conditions of seawater.

Geochemical analysis of obsidian and the pattern recognition of sites spatial distribution in the chalcolithic of the Eastern Lake Urmia, Northwestern, Iran

KAMAL A. NIKNAMI1 AND AHMAD C. AMIRKHIZ2

1Department of Archaeology, University of Tehran, Enghlab Street, Tehran, Iran (kniknami@ut.ac.ir)
2Department of Archaeology, University of Tehran, Enghlab Street, Tehran, Iran (ahmadchaychi@yahoo.com)

Results presented here are the chemical analysis of significant numbers of obsidians from several Chalcolithic sites in the eastern shores of Lake Urmia, Northwestern Iran, as part of a large and most comprehensive study of obsidian sources in this region. In this study, XRF is used to generate trace element data for some elements. A number of analytical methods such as Bivariate plots of the incompatible trace elements were used to separate the obsidian sources in study area and source separation was confirmed by using linear Discriminant analysis. The existence of multiple sites containing obsidian artifacts in the area of Urmia and on some of the other nearby regions, however, has enabled the study of specific spatial patterns of source exploitation and the trade mechanisms which resulted in the distribution of obsidian hundreds of kilometers away during the Chalcolithic period (ca. 5000-3000 BC).
Extreme Pb-isotope diversity in the sources of K-rich magmas in Italy: Evidence from melt inclusions

I.K. NIKOGOSIAN1, M.J. VAN BERGEN1, J.C. DE HOOG2, M.J. WHITEHOUSE3 AND S.H.J.M. VAN DEN BOORN1

1Department of Earth Sciences, Utrecht University, Utrecht, The Netherlands (iniki@geo.uu.nl; vbergen@geo.uu.nl)
2Department of Earth Sciences, University of Oxford, Oxford, United Kingdom (cees-jan@earth.ox.ac.uk)
3Lab. for Isotope Geology, Swedish Museum of Nat. Hist., Stockholm, Sweden (martin.whitehouse@nrm.se)

We present 170 SIMS (Cameca 1270) analyses of Pb-isotope ratios of homogenized melt inclusions in Fo-rich (Fo92-88) olivines from primitive lavas in Central-Southern Italy. The samples cover the entire compositional spectrum of potassium-rich magma series erupted from major Pliocene-Quaternary volcanic centres in peninsular Italy.

The inclusions contain 1-140 ppm Pb. For inclusions with > 5 ppm Pb (80% of the population) in-run precision was 0.5-0.05% (2σ) for 207,208Pb/206Pb, and 1.5-0.15% (2σ) for 206,207,208Pb/204Pb.

Our results significantly extend the existing bulk-rock data towards more extreme compositions. A second key observation is the strong isotopic variability that appears to exist within individual volcanic centres, within magma series, and even within individual lava samples, testifying that widespread mixing in magmatic systems involved melts derived from mantle columns that are isotopically heterogeneous on small volume scales. The Pb-isotope systematics confirm that magmas were derived from mantle sources that are largely binary mixtures between components with low- and high-radiogenic 206,207,208Pb/204Pb ratios, respectively. However, extrapolation of mixing trends points to isotopic variability in each of these end-members, both in the original mantle component and in the metasomatic component that is inferred to be of upper crustal/sedimentary origin. The nature of the ‘pre-metasomatic’ mantle of the Roman and Campanian Provinces is distinct, the former being MORB-type, the latter showing a modest contribution of the FOZO-HIMU signature seen at Vulture and Etna. The Pb-isotopic signatures further indicate that in a transition zone (Roccamonfina-Ernici) the High-K-series melts are derived from the ‘Roman’ mantle, but K-series melts from the ‘Campanian’ mantle. Variations in the metasomatic agent are inferred to be related to (former) subduction, and reflect along-strike isotopic changes between Adriatic and Ionian domains of the plate. In conjunction with trace-element signatures of the melt inclusions, source mixing scenarios and implications for the regional geodynamic controls will be discussed.

Volcanic arc development due to intraoceanic subduction: Numerical model

KSENIA NIKOLAEVA, TARAS V. GERYA AND JAMES A.D. CONNOLLY

Department of Earth Sciences, ETH - Zürich, CH-8092 Zurich, Switzerland (nikolaeva@erdw.ethz.ch, taras.gerya@erdw.ethz.ch, james.connolly@erdw.ethz.ch)

We have created a new 2D coupled geochemical-petrological-thermomechanical numerical model of retreating intraoceanic subduction associated with volcanic arc development. The model includes spontaneous slab bending, subducted crust dehydration, aqueous fluid transport, mantle wedge melting and melt extraction resulting in crustal growth. This model allows us to study influence of melt extraction intensity on the dynamics of subduction, mantle wedge plumes development and magmatic arc growth and displacement. In our numerical experiments subduction nucleates across the weak transform fault separating two oceanic plates different age. Subduction rate strongly varies with time. In all studied cases there is a deceleration period of a few Myr after the beginning of subduction, during this period subduction rates decrease from ~ 7 cm/yr to ~ 4 cm/yr. Subsequently, two scenarios can be distinguished: (1) decay and, ultimately, the cessation of subduction, (2) increase in subduction rate (to up to ~12 cm/yr) and stabilization of subduction. In scenario 1 the magmatic arc crust includes large amounts of rocks formed by melting of subducted crust atop the thermally relaxing slab. In contrast, in case of stable subduction, magmatic rocks produced by partial melting of hydrated mantle wedge clearly dominate the crust. In several numerical experiments an intra-arc extension is observed during subduction. This process results in splitting of previously formed magmatic arc crust by a newly formed spreading center. The loci of magmatic activity and intensity of crustal growth is strongly dependent on the dynamics of hydrous partially molten upwellings (cold plumes) rising from the slab.
Three kinds of superstructures of wollastonite whose compositions were Ca(Ge0.65, Si0.35)O3, Ca(Ge0.50, Si0.50)O3 and Ca(Ge0.15, Si0.85)O3 were synthesized. In this abstract, they are called 65Wo, 50Wo and 15Wo. The lattice constants of 65Wo, 50Wo and 15Wo are: (angstrom, degree) a=2X8.038(4), 2X7.995(2), 4X7.949(5), b=7.451(1), 7.400(1), 7.352(1), c=7.194(2), 7.148(2), 7.093(1), alpha=89.93(2), 90.05(2), 90.06(2), beta=94.85(2), 94.97(2), 95.11(1), gamma=103.34(2), 103.43(1), 103.39(1), respectively.

65Wo consists of the neighbouring two units of the basic-wollastonite along the a-axis. The X-ray diffraction pattern showed a pseudo-C lattice. Therefore, the stacking sequence of 65Wo can be represented as AB, where A is the unit cell of the basic-wollastonite and B is the unit cell of the basic-wollastonite with b/2 displacement. The final R-value was 12%.

50Wo consists of the neighbouring two units of the basic-wollastonite along the a-axis, too. However, the X-ray diffraction pattern was different from 65Wo. Judging from the characteristics of the X-ray diffraction, the stacking sequence of 50Wo is represented as AA. The final R-value was 13%.

15Wo consists of the four units of the basic-wollastonite along the a-axis. There were four possible stacking sequences described as AAAA, ABAB, AABB and AAAB. The structure having the sequence AAAA will show the strong intensity on the h=4n diffraction. The structure ABAB will show the strong intensity on the h=2n diffraction. The structure AABB will show the extinction rule of the pseudo-C lattice. The last structure AAAB will not show any characteristic rules on the X-ray diffraction. As the result of the observation of the X-ray diffraction of 15Wo, it was clear that the stacking sequence AAAA was most reasonable. The final R-value was 14%.

In common with 65Wo, 50Wo and 15Wo, each tetrahedral site has the statistical distribution of Ge and Si atoms.

**Temporal change of a layer sequence in reaction zones in the system dolomite – quartz – H2O**

T. Nishiyama1, T. Tanoue1, A. Tominaga2 and H. Isobe3

1Dept. of Earth and Environment, Kumamoto University, (tadao@sci.kumamoto-u.ac.jp; isobe@sci.kumamoto-u.ac.jp)

2Dept. of Earth and Environment, Kumamoto University

**From an initial transient state to a steady state**

Hydrothermal experiments at 0.1GPa and 600°C were carried out with two kinds of configurations for starting materials: one is dolomite single crystal + quartz powder + H2O and the other is quartz single crystal + dolomite powder + H2O. We got the following results. (i) Reactions were incomplete in all runs and the reaction zone developed only locally on the dolomite crystal. (ii) In short duration (45 – 71h) runs metastable layer sequences involving wollastonite and talc occur in the reaction zones, whereas they disappear in longer duration (168 – 336 h) runs. (iii) The layer sequence of the reaction zones in short duration runs differ from place to place on the dolomite crystal even in the same run. (iv) The diversity of layer sequences in the short duration runs merges into a unique layer sequence of Qtz / Di / Fo + Cal / Dol + Cal / Dol in the longer duration runs. (v) No reaction zone was observed on quartz crystals. These lines of evidence show that the system evolves from an initial transient state to a steady state and that the kinetic effect is important in the development of reaction zones. This part of the work has been recently published (Nishiyama et al., 2007).

**Temporal change of a layer sequence at 800°C**

We carried out additional experiments in the same system at 0.1GPa and 800°C with run durations of 48, 109 and 357 h. In these higher temperature runs reactions were complete in all runs such that the dolomite crystal was completely surrounded by a reaction zone with a definite layer sequence. Observed conspicuous features are as follows. (i) The layer sequence Dol / Dol + Cal / Fo + Cal / Fo / Mon (Monticellite) / Di / WO / Qtz is common in all runs. (ii) The thickest layer is Di in 48 h run, Mon in 109 h run and Fo (or Fo + Cal) in 357 run. (iii) A void layer formed between Dol + Cal and Fo + Cal layers in all runs, and it becomes thicker as the duration. (iv) Reaction zones have never formed on the quartz crystal, although the quartz shows resorption after the run. These results show little change of the layer sequence but a considerable temporal change in the growth mode of the reaction zone. A steady diffusion modelling was applied to the representative layer sequence to discuss this temporal change.

Varying Ni in OIB olivines – Product of process not source

Y. NIU$^1$ AND M.J. O’HARA$^2$

$^1$Department of Earth Sciences, Durham University, Durham DH1 3LE, UK (yaoling.niu@durham.ac.uk)
$^2$Institute of Geography and Earth Sciences, University of Wales, Aberystwyth SY23 3DB, UK (mio@aber.ac.uk)

The source of ocean island basalts (OIB) has been widely accepted as resulting from ancient recycled oceanic crust (ROC) [1] although there are many more difficulties than certainties in this model [2]. Sobolev et al. [3] concluded that Ni content in olivines of Hawaiian shield basalts is too high, precluding basalt origin by partial melting of mantle peridotite, asserting that this can only be explained by melting of an olivine-free pyroxenite. This pyroxenite originated by reacting mantle peridotite with a SiO$_2$-rich melt derived from partial melting of recycled oceanic crust in the form of “SiO$_2$-oversaturated eclogite”. This is a revised version of the ROC model, but the complex behavior of Ni makes the interpretation non-unique. Sobolev et al. [4] show that while Ni content in olivines of basalts varies widely, it is conspicuously higher in basalts erupted on thick (> 70 km) lithosphere (THICK, including Hawaii) than on thin (< 70 km) lithosphere (THIN, including Iceland), and is still higher than in MORB. For primitive olivines with Fo > 89, $N_{\text{THICK}}$ (3417±452 ppm, 1937; mean±1σ, n > $N_{\text{THIN}}$ (2477±263 ppm, 746) > $N_{\text{MORB}}$ (2324±296 ppm, 1700). This lithospheric thickness control (lid effect) poses the question why recycled oceanic crust prefers to exist and participate in magmatism beneath thickened lithosphere relative to beneath thin lithosphere and ocean ridges. Melting beneath thick (> 70 km) lithosphere is largely in the garnet peridotite facies: $a_{\text{Cpx}} + b_{\text{Gnt}} + c_{\text{Ol}} = 1.0_{\text{Melt}} + d_{\text{Opx}}$, where olivine, the primary Ni host, contributes to the melt. Melting beneath thin lithosphere occurs mostly in the spinel peridotite facies: $a_{\text{Cpx}} + b_{\text{Opx}} + c_{\text{Spl}} = 1.0_{\text{Melt}} + d_{\text{Ol}}$, where olivine crystallizes and demands Ni from the melt. A common peridotite source Ni = 1900 ppm, and ~10% melting, can yield ~400 ppm and > 560 ppm Ni in melts parental to MORB and those erupted on thick lithosphere respectively. With these results and realistic magma chamber process models [5], the observed $N_{\text{THICK}}$, $N_{\text{THIN}}$ and $N_{\text{MORB}}$ in olivines can be explained without invoking the revised ROC model which still has to address the difficulties noted in [2].

Dissolution, nucleation and growth of mineral phases in aqueous solutions

C. Noguera¹, B. Fritz² and A. Clément²

¹INSP, CNRS-UPMC, Paris, France
(claudine.noguera@insp.jussieu.fr)
²CGS, CNRS-ULP, Strasbourg, France
(bfritz@illite.u-strasbg.fr)

In order to take into account the initial stages of formation of mineral nanoparticles in water-rock interaction models, we have developed a theoretical approach of nucleation, growth and ageing processes, relevant for precipitation in solution. It is based on the classical nucleation theory, on a size-dependent (algebraic) growth law allowing growth, resorption and ripening of particles simultaneously, and on conservation laws akin to a thermodynamically closed system.

We will apply it to the formation of silicate phases, and particularly kaolinite-type minerals, from aqueous solutions resulting from rock alteration processes, through the geochemical code NANOKIN that we have elaborated. The nanoparticle formation is simulated versus time in terms of populations of particles appearing successively, surviving and growing or disappearing depending on the evolution of the resulting saturation state of the solution with respect to the corresponding mineral phase.

We will show that two very different scenario may take place, depending upon whether an initial supersaturation is provoked in the solution (i.e. in an experimental approach), or whether it progressively appears as a consequence of rock dissolution. The time dependence of the supersaturation, the size evolution of the particles and the crystal size distribution functions present very specific features in these two cases.

The simultaneous precipitation of competitive secondary phases has also been tested taking into account their specific solubilities, surface energies, geometric shapes and growth rates. This allows to predict the surviving phase in long-term processes.

Work is currently under progress to include chemical variability of the produced particles in the model.

Support of the French ANR-PNANO 2006 (project “SIMINOX” 0039) is acknowledged in the last phase of this work.

Stabilisation of continental crust by dehydration melting: An example from the Västervik area, SE-Sweden

Nicole Nolte, Wiebke Baero, Bent T. Hansen and Ilka C. Kleinhanns
GZG-Isotope Geology, Georg-August University of Göttingen, Goldschmidtstr. 3, 37077 Göttingen,
icole.nolte@geo.uni-goettingen.de

The Palaeoproterozoic Västervik area (Baltic shield, SE-Sweden) is located at one major terrane boundary on the Baltic Shield. To the south lies the Transscandinavian igneous belt and to the north follows the Svecofennian domain. In addition, the Västervik area is known for lp-lH amphibolite metamorphism in combination with intensive metasomatism.

From field relationships at least three different granitoid generations can be identified that discriminate in their geochemical and isotope signatures as well. Primitive granitoides (QMD) of quartzmonzodioritic and granodioritic composition, metagranitoides (MG) of quartzmonzonotic (MGf = non fluid) and alkali-granitic composition (MGf = fluid) as well as anatectic monzogranites (AG). QMD and MGf seem to represent “normal” crust-building granitoides with geochemical signatures of rather typical continental crust. The above mentioned metasomatic fluids seem to have affected the MGf and AG as for example initial Sr isotope ratios are as high as 1.5, respectively. Such increased ratios are observed in the surrounding metasedimentary Västervik Formation as well indicating a genetic relation with the anatectically created AG. Further, geochemical signatures and fluid classifications show that both MG-groups probably share the same petrogenetic evolution with the sole difference of a fluidchemical imprint in the MGf granitoides.

Based on the results, a geotectonic model for the evolution of the different granitoides was developed. We postulate an active subduction zone beneath the svecofennian continental margin. This subduction zone was blocked leading to the evolution of a new subduction zone further southwest building up an island arc of which rocks of the Oskarshamn-Jönköping belt belong to. Our geotectonic model relates the evolution of the QMD and MGf to this maturing island arc. The accretion of this mature island arc on the continental margin of the Svecofennian terrane caused compression and folding leading to crustal thickening. Subsequently, intruding melts show higher SiO₂ contents and are more differentiated (MGf).

Pressure increase due to crustal thickening and heat input by the ascending melts finally resulted in mica breakdown. Resulting dehydration melting is thus the trigger for the crustal anatexis event that produced the AG and led to fluids that percolated through some of the MG.

Results of mineral nanoparticles in water-rock interaction models, we have developed a theoretical approach of nucleation, growth and ageing processes, relevant for precipitation in solution. It is based on the classical nucleation theory, on a size-

Radiation damage, internal textures and post-growth history of the Plešovice zircon standard

N. Norberg1, L. Nasdala1, J. Kosler2, J. Slama2,3, J. Götz4 and N. Groschopf5

1Institut für Mineralogie und Kristallographie, Universität Wien, Austria (nicholas.norberg@gmx.at; lutz.nasdala@univie.ac.at)

4Institut für Mineralogie, TU Bergakademie Freiberg, Germany (goetze@mailserver.tu-freiberg.de)
5Institut für Geowissenschaften, Johannes Gutenberg-Universität Mainz, Germany (groschopf@uni-mainz.de)

We have studied internal textures and the post-growth history of accessory zircon crystals from a granulate near Plešovice, southern Czech Republic. This zircon has recently been proposed as a new reference material for determination of U-Pb ages using the laser-ablation inductively coupled plasma mass-spectrometry (LA-ICP-MS) technique (Slama et al., 2006). Extraordinary properties of the Plešovice zircon include its uniform, concordant U-Pb age, relatively high U concentrations (>600 ppm), homogeneous Hf isotopic composition, and its availability in a large quantity.

In spite of its isotopic homogeneity, the Plešovice zircon shows heterogeneous incorporation of trace elements. Typically there is strong primary zonation, including both oscillatory growth zoning and sector zoning. About 10% of the grains show sectors (corresponding to the growth of pyramid faces) that are particularly rich in actinides; here U content may be as high as 3000 ppm. Those sectors are easily recognized, e.g., from particularly high BSE intensities. The Plešovice zircon is in general moderately radiation-damaged whereas the high-U sectors are strongly metamict. All areas are roughly as radiation-damaged as it would correspond to U and Th concentrations and an assumed accumulation of material. Consequently, these areas need to be avoided in using the Plešovice zircon as a U-Pb standard material.

Geochemical meddling, microbing, Marsing, and mitigating mine drainage

D. Kirk Nordstrom

U.S. Geological Survey, 3215 Marine St., Boulder, CO 80303 USA

Acid mine drainage (AMD) and acid pit lakes, for all their ugliness and environmental damage, provide opportunities for scientists and engineers to test their skills, push the frontiers of their research, and make a contribution to the remediation. Extreme environments such as the Rio Tinto mining district, Spain, have become favorite sites for both researchers and tourists because of the presumed analogy to the Martian surface. Rio Tinto and Iron Mountain, California, USA have also been a major focus of microbial research. The production of AMD is a complex hydrobiogeochemical process that is much better understood today because of sustained research in the fields of geology, hydrology, geochemistry, and microbiology. Mine-site remediation cannot proceed effectively without the combined expertise from these fields. Further, the most cost-effective remediation benefits from an independent technical oversight committee with such expertise.

We now know that pyrite oxidation can create waters of negative pH, that mine plugging is often an ineffective remediation method, that microbial catalysis of pyrite oxidation involves a community structure including, but not limited to, Acidithiobacillus, Leptospirillum, Ferroplasma, and heterotrophs, that surface-water contaminants are attenuated and can be modeled, that dynamic rainstorm events can cause increases in concentration destroying aquatic life, that remediation scenarios can be evaluated before executing, and that the collaboration of scientists and engineers working together on remediation is far better than just engineers working alone. Research papers on sulfide mineral oxidation to mine-site characterization have proliferated over the last two decades. We also know much more about the processes (dissolution rate, solubility, sorption) controlling mine drainage (cf. Nasdala et al., 2001), which excludes any major thermal annealing event. Heterogeneous metamicitization has resulted in zoned fracturing; fractures have been filled with secondary phases such as Fe hydroxides. First LA-ICP-MS U-Pb analyses of high-actinoid micro-areas turned out to be most difficult and unreliable. Consequently, these areas need to be avoided in using the Plešovice zircon as a U-Pb standard material.
Differentiating fluid boiling from condensation

DAVID I NORMAN¹ AND JOSEPH MOORE²

¹Dept of Earth and Env. Sciences, New Mexico Tech, Socorro, NM 87801 (dnoemangeo@yahoo.com)
²EGI, U of Utah, Saly Lake City, UT 84105 (jmoore@egi.utah.edu)

Fluid inclusion petrography cannot differentiate boiling from condensation. Inclusions formed during boiling and condensation may have liquid- and vapour-dominant types that show approximately the same Th. During boiling a vapour phase develops in response to changes in liquid P or T. Condensation occurs when a liquid is subject to a vapour flux. This may occur at any depth in geothermal systems. At shallow depths this process generates steam-heated waters. At greater depths vapour from magmatic bodies can flux through circulating meteor waters.

Modelling demonstrates that boiling and condensation changes the concentrations of gaseous species in different manners. Boiling strips dissolved gaseous species from liquids and low solubility species such as H₂, CH₄ and N₂ more strongly partition into the vapour phase. Hence a ratio of soluble species like CO₂ to N₂ increases during boiling. Condensation increases liquid concentration of soluble gaseous species (see fig.). Gas ratios from the USGS Cerro Prieto data set show positive correlations between total gas and CO₂/N₂ ratios. Sequential fluid inclusion gas analyses shows negative correlations at Guanajuato where there is other evidence of boiling and positive correlations in geothermal systems were condensation is predicted.

We know that gaseous components and liquids commonly decouple and recombine in geothermal systems. We find evidence in active geothermal systems and in fluid inclusions that both processes operate. Condensation may be an import process in the production and localization of high grade sulphide ore bodies by locally producing high fluid concentrations of H₂S.

Quantifying accelerated surface denudation as a result of external forcing

K.P. NORTON¹, F. VON BLANCKENBURG¹, F. SCHLUNEGGER², M. SCHWAB³ AND P.W. KUBIK³

¹Institut für Mineralogie, Universität Hannover, Hannover, Germany (k.norton@mineralogie.uni-hannover.de, fvb@mineralogie.uni-hannover.de)
²Institut für Geologie, Universität Bern, Bern, Switzerland (schlunegger@geo.unibe.ch, marco.schwab@geo.unibe.ch)
³Paul Scherrer Institute, ETH Hönggerberg, Zürich, Switzerland (kubik@phys.ethz.ch)

The evolution of mountain belts is a balance between forces that build topography and those that destroy topography. This study focuses on the destructive forces, weathering and mass wasting, fluvial or eolian erosion, glaciers, etc., that are inherently surfacial processes. In order to understand how orogens change through time, we need to identify and quantify the processes responsible for denudation.

We apply a combination of novel and proven techniques to address the question of how these forces modify the landsurface. Morphometric analysis based on high resolution LIDAR data is used to identify transient landscapes. These geomorphic data are then combined with cosmogenic nuclides, ⁹⁰⁰⁰Be from quartz in sediments specifically, in order to quantify process rates.

In a case study in the Alpine Foreland, we identified two adjacent drainage basins which have responded differently to the same forcing event, a fall in stream base-level at 16,000±3,000 yrs BP. One of the watersheds has a coupled hillslope-channel system, while the other is decoupled. Denudation rates in the coupled system, 380±50 mm ky⁻¹, are equal to those in the headwaters of the decoupled system, 380±50 mm ky⁻¹. However denudation rates in the decoupled system increase downstream to 540±100 mm ky⁻¹, with denudation in the incised region occurring at extremely high rates, ~1800 mm ky⁻¹. The denudation rates show that within 16,000 yrs, only the channels themselves have responded, and spatially extensive erosion occurs only after a significantly longer lag time.

The advantage of this approach is that the geomorphic response of a landscape to external forces can be identified by morphometric analysis, and the process rates that are measured with cosmogenic nuclides can be used to quantify landscape response times on the time scale of climate change or fault movement.
**Sulfur in tree rings in Central Europe: A negative $\delta^{34}S$ shift relative to regional pollution sources**

M. NOVAK$^1$, S. PEIFFER$^2$, K. ZAK$^3$, I JACKOVA$^1$, F. BUZEK$^1$, L. ERBANOVA$^1$ and E. PRECHOVA$^1$

$^1$Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic (novak@cgu.cz)

$^2$University of Bayreuth, Bayreuth D-95440, Germany (S.Peiffer@uni-bayreuth.de)

$^3$Institute of Geology, Czech Academy of Sciences, Rozvojova 136, Prague, Czech Republic (zak@gli.cas.cz)

Sulfur isotope composition in tree rings of 50-year old Norway spruce was compared with $\delta^{34}S$ values of local coal and atmospheric deposition in the Black Triangle region of Central Europe. For this purpose we have analyzed soft coal from two East German Basins (Espenheim near Leipzig, and Lausitzer region near the German-Polish border) and two Bohemian basins (Sokolov and Most, northern Czech Republic). In all, 150 soft coal samples from all stratigraphic levels of these Tertiary deposits were analyzed for $\delta^{34}S$. Sulfur isotope composition of air-borne SO$_2$ was based on 170 monthly samples (Novak et al., 2001), $\delta^{34}S$ of rainfall sulfate was based on 200 monthly samples (Novak et al., 2000). The studied spruce was one of the few surviving trees in an area affected by pollution-related spruce die-back of the Erzgebirge Mts. The tree was harvested in 2005, while most other trees at the research site died back between 1975 and 1995 due to acidification. Bedrock orthogneiss was S-deficient, and its $\delta^{34}S$ was 5.8 ‰. The $\delta^{34}S$ values systematically decreased in the order Espenheim coal (mean of 12.0 ‰) > Sokolov coal (11.7 ‰) > Lausitzer coal (9.6 ‰) > rainfall sulfate (5.4 ‰) > air-borne SO$_2$ (2.5 ‰) > Most coal (1.6 ‰) > Erzgebirge tree rings (0.4 ‰). Three of the coal basins had isotopically relatively heavy sulfur, one coal basin (Most, Czech Republic), had isotopically light sulfur. Most of the emissions from the coal-fired power plants were in the form of SO$_2$, which was partly oxidized to sulfate in the atmosphere before reaching the receptor site. The resulting sulfur became isotopically somewhat heavier than the residual SO$_2$. The spruce tree rings contained the isotopically lightest S of all studied S reservoirs. Our data indicate that (i) German coal S did not significantly influence trees on the Czech side of the Erzgebirge Mts., and (ii) assimilation of S by Norway spruce is associated with a negative isotope shift relative to ambient S.

**Quantification of stable strontium isotope variability in nature by MC-ICP-MS**

G.M. NOWELL$^1$, B.L.A. CHARLIER$^2$, D.G. PEARSON$^1$, K. W. BURTON$^2$

$^1$Dept. Earth Sciences, University of Durham, Durham, DH1 3LE, UK (g.m.nowell@durham.ac.uk; d.g.pearson@durham.ac.uk)

$^2$Dept. Earth Sciences, The Open University, Milton Keynes, MK7 6AA, UK (b.l.a.charlier@open.ac.uk; k.w.burton@open.ac.uk)

There is growing evidence that high-temperature processes, such as diffusion, condensation and evaporation can generate significant stable-isotope fractionation. Recent observations of stable isotope fractionation in elements as heavy as Tl (Z=81) raises the possibility that there may also be natural Sr isotope variation. With conventional $^{87}$Sr/$^{86}$Sr measurements, the $^{86}$Sr/$^{88}$Sr ratio is used to correct instrumental fractionation, and although the absolute value used for this correction is unimportant, implicit in its use is the assumption that $^{86}$Sr/$^{88}$Sr ratio remains constant in all analysed materials. This ‘internal’ correction for instrumental mass fractionation thereby masks the existence of any natural mass dependent fractionation of $^{86}$Sr/$^{88}$Sr. In this study, we present a new technique that allows simultaneous measurement of both radiogenic Sr isotope variations ($^{87}$Sr/$^{86}$Sr) and possible small-scale mass dependent isotopic fractionation of the $^{86}$Sr/$^{88}$Sr ratio. Radiogenic and stable Sr isotope ratios are measured on a Thermo-Finnigan Neptune MC-ICP-MS and are corrected for mass bias ‘externally’ using admixed Zr. We present $^{86}$Sr/$^{88}$Sr data for NBS 987, a range of natural rock standards and extraterrestrial samples (for which $^{86}$Sr/$^{88}$Sr fractionation has already been documented using double spike TIMS). Incomplete recovery of Sr during column separation can significantly fractionate Sr isotopes, which implies that excluding overlapping Rb and Sr tails during column procedures will introduce inaccuracies. We demonstrate that NBS987 is fractionated relative to high-T magmatic rocks (possibly resulting from the manufacturing process), and establish a precise ‘high-T’ reference line. Due to documented variation in low-T and biological samples we suggest that this high-T reference should be adopted for Sr isotope work.
3-D colloidal crystals of magnetite in the Tagish Lake carbonaceous chondrite

JUN NOZAWA1, KATSUO TSUKAMOTO1, HISAO SATOH2, KEN NAGASHIMA1 AND KENTA YAMADA1

1Graduate School of Science, Tohoku University, Sendai, Japan (nozawa@ganko.tohoku.ac.jp)
2Mitsubishi Materials Co.

Tagish Lake carbonaceous chondrite (fallen on 2000) is known as a primitive meteorite in chemical composition but the meteorite heavily suffered aqueous alteration. In the matrix, magnetite (Fe3O4) particles were reported to be present in between tiny forsterite crystals [1]. However no detailed observation of morphology from these particles has been done, though the morphology of crystals possess the growth conditions precisely in which these crystals have been growing [2].

The chondrite with a few mm, in diameter, were cleaved, so that fine crystalline particles would expose on the fractured surface. These crystal surfaces were investigated employing field emission scanning electron microscopy (FE-SEM) and transmission electron microscopy (TEM).

Magnetite crystals (Fd3m, cubic) usually exhibit an octahedron shape surrounded by the {111} faces. In this meteorite, however, magnetite fine particles, which are result of reaction of other silicate minerals with water or ice in the early stage of solar system, exhibit varieties of shapes, e.g. octahedron, rhombic dodecahedron with {110} face (Fig. 1), trisoctahedron with {211} face, 100-1000 nm in diameter (peak size, 200 nm). It is surprising to find that these fine magnetite particles form 3D colloidal crystals with varieties of structures, f.c.c. (Fig. 1), b.c.c, and h.c.p. In this colloidal system, not only the size but also the morphology of these particles determined the lattice structure of the colloidal crystal. It is very interesting to note that only the rhombic dodecahedron particles exhibit multiple twinning.

Figure 1: FE-SEM image, magnetite colloidal crystals formed by multiple-twin particles. Twin-boundaries are indicated by white arrows.

The nature of the Arabian lithospheric mantle beneath Aritain Volcano, NE Jordan

TH. NTAFLOS1, G. KURAT1 AND S. SWOBODA2

1Dept. of Lithospheric Sciences, University of Vienna, Austria (theodoros.ntaflos@univie.ac.at)
2Dept. of Chemistry, VIRIS Laboratory, University of Natural Resources and Life Sciences, Vienna, Austria

The mantle xenolith-bearing Jabel Aritain volcano in NE Jordan belongs to the As Shamah Cenozoic lava field, which is the largest in the W part of the Arabian plate extending from S Syria through Jordan into NW Saudi Arabia.

Most Jabel Aritain mantle xenoliths are spinel lherzolites but herzogites, dunites, websterites and wehrlites are also present. Calculated equilibrium P,T conditions range from 900 to 1000 °C and 12-17 kbar, respectively, and are consistent with estimations made for peridotites from other localities in this area of the Arabian platform, indicating that xenoliths were extracted from shallow depths of 40 to 60 km (Medaris and Syada, 1998).

Glasses from melt pockets present in a number of xenoliths have an unusually high mg# of 75 and secondary olivines with Fo94.5, which suggests that the metasomatic melt was probably picritic.

LA-ICP-MS analyses of cpx show that xenoliths experienced cryptic metasomatism. Three groups of xenoliths have been recognized according to REE and other incompatible trace element patterns in cpx: group 1 has depleted LREE abundances, group 2 is highly enriched in LREE (80 x chondritic) and group 3 has moderate LREE enrichments. The REE patterns in group 3 indicate that for some reason equilibrium conditions for trace elements has non been achieved as some cpx have higher LREE abundances than others within the same sample. In this group, the common Zr depletion relative to Nd and Sm implies that it is not associated to partial melting processes but rather to metasomatic processes and that the cpx was originally not depleted in Zr. Evidently, the metasomatic agent was a H2O-rich fluid (high LREE and Sr) with carbonatitic components (depletion of Zr and Ti).

The Jabel Aritain mantle xenoliths are in terms of PT equilibrium conditions similar to xenoliths from Jabel El Arab (ca. 100 km N of Aritain) and other Arabian plate peridotites suggesting a common thermal regime.

The metasomatic fluids/melts affected variably the trace element but not the major element abundances. Apparently, the metasomatic processes were interrupted before equilibration could be achieved indicating a pre-eruption metasomatic front rising from lower levels of the local upper mantle.

A geochemical baseline survey of the Collahuasi District, N. Chile has been completed based on systematic regional rock and soil sampling. The Collahuasi district hosts 3 major Cu porphyry centres, Rosaria, Ujina and Quebrada Blanca which are now being mined for Cu and Mo. Approximately 1100 lithogeochemical whole rock samples were collected on a grid averaging 1-2 sq. kms. over an area of 1500 sq. km and about 250 soil samples were collected over part of the grid, centred on Rosario and covering about 650 sq. km. Approximately 74 chemical elements were determined on whole rock samples by ICPMS and ICPOES and 65 elements on soil samples after aqua regia extraction. All the methods used were those specified by the global geochemical baseline programme for mountainous terrains.

The data are shown to be of value for exploration, lithogeochemical mapping and understanding the geochemical and metallogenic evolution of the district as well as for environmental purposes. For example high field strength elements can be used to prepare lithological maps in areas where the bedrock geology is poorly known while large ion lithophile elements can be used to map regional hydrothermal alteration. The rock and soil data have been compared to international soil guideline values for chemical elements from N. America and Europe and the ratio of the concentration in soils has been compared to that in rocks for all elements. The results show that even in rock samples away from mineralisation values for several elements exceed all guidelines for part of or the entire district. This observation is critically important in setting guideline values which should more fully take account of bedrock geology.

The results show that a lithogeochemical atlas of the Andes would define the chemistry of mineralised districts, and the potential for new exploration targets as well as providing an environmental baseline against which to study human health and environmental impacts, including from future mining.

Constraints on the exhumation history of the Torres del Paine

ROLAND OBERHÄNSLI1, UWE ALTENBERGER1, MASAFUMI SUDO1, LUKAS BAUMGARTNER2 AND BENITA PUTZLITZ2

1Institute of Geosciences, University of Potsdam, Am Neuen Palais 10, 14415 Potsdam, Germany
2Institute of Mineralogy and Geochemistry, Université de Lausanne, Anthropole, 1015 Lausanne, Switzerland

During field investigation on the contact metamorphism and intrusion emplacement on the Torres del Paine laccolith we found samples of suspiciously fresh scoria. These scoria were only found in two distinct steep gullies in the Eastern part of the Torres del Paine laccolith. They occur in the side valleys of Valle Ascencio, Northeast of Monte Almirante in Valle del Mirador as well as North of the Torre del Paine peaks in Valle del Silencio. The two localities relate to each other by a NW-SE running fault system. In Valle del Silencio the scoria is found close to a dike that can be followed from the southern side moraine in the valley running steeply upwards to form a steep cut just north of Torre Monzino. The same holds true for the Valle del Mirador. A dike is running into a notch giving access to the east crest of Monte Almirante. Samples can only be found along the dike gullies above the moraine deposits and below an altitude of 1760 m. At both sampling locations this altitude corresponds roughly to a position in the middle of the intrusion. Since we find scoriae this altitude marks a paleosurface and thus allows using the age constraints by Ar/Ar dating of the scoria in combination with data on age and the depth of intrusion of the Paine laccolith to constrain the exhumation history of the Paine laccolith. The finding of scoria indicates a surface that must be discussed in the light of the glaciation history.
Driekop platinum pipe, Bushveld Complex, South Africa: New insights

T. Oberthür1, N.S. Rudashevsky2, V.N. Rudashevsky2, L.J. Cabri3, F. Melcher4, H. Kocks4, J. Lodziak4 and D. Klosa4
1BGR, Stilleweg 2, D-30655 Hannover, Germany (thomas.oberthuer@bgr.de)
2Center for New Technologies (CNT), Grazshdansky Prospect 14, 194220, St.Petersburg, Russia
3CNT Mineral Consulting Inc., 99 Fifth Avenue, Suite 122, Ottawa, Ontario, Canada K1S 5P5 (lcabri@sympatico.ca)
4BGR, Stilleweg 2, D-30655 Hannover, Germany (f.melcher@bgr.de; h.kocks@bgr.de)

The genesis of the platiniferous pipes of the eastern Bushveld Complex is still enigmatic. Orthomagmatic, metasomatic replacement, and hydrothermal models were proposed (Scoon and Mitchell 2004), however, advance on the understanding of the pipes is hampered by the fact that these orebodies were mined out early in the last century and limited material is available from museum collections only.

Our interest in the pipes was sparked off by investigations of detrital PGM in the Bushveld river systems (Oberthür et al. 2004). The present paper reports on a sample from the Driekop Pipe (Wilhelmskopje) collected in 1926 (TU Berlin) and highlights the impact of using novel methods of ore treatment on investigations especially of noble metal ores.

The greenish-greyish, dense sample is a medium-grained dunite with accessory disseminated chromite and has an ore grade of 34.9 ppm Pt. Contents of the other PGE and gold are all ≤1 ppm. Ten polished sections investigated by ore microscopy and SEM yielded a disappointing number of only 5 PGM grains (＞50 µm), underlining theoretical data (Ney 1977) on comparable gold ores that, at an average grain size of 100 µm and at a grade of 100 ppm, about 5-10 polished sections are needed to detect one discrete grain of gold.

Therefore, a combination of novel methods was tested on a slab of the sample weighing 676 grams, namely electric pulse disaggregation (EPD), hydoseparation (HS) and preparation of monolayer polished sections (5 size fractions between <63 and >400 µm) for further studies. The results were compelling: At least 500 PGM grains were found in the fractions. Grain sizes range from ~10-330 µm (most common around 100 µm). Many grains are composite. Sperrylite is the dominant PGM (ca. 90%), followed by Pt-Fe alloy and another twelve rarer PGM species. Notably, geversite (c.f. Melcher and Lodziak 2007) is absent. Analytical procedures and new data from our ongoing studies will be presented.

Testing the hotspot record for evidence of broad melting anomalies

J.M. O’Connor1, P. Stoffers2, J.R. Wijbrans2, T.J. Worthington2 and W. Jokat3
1Vrije University Amsterdam, The Netherlands
2Institute for Geosciences, Christian-Albrechts-University, Kiel, Germany
3Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

The notion of a mantle plume has long been that of a mushroom-like ‘head’ (LIP) and thin ‘tail’ structure (hotspot chain) rising from a deep thermal boundary layer, generally depicted as the core-mantle boundary. Drifting of tectonic plates over the narrow, presumably fixed, hotspots created by such plume ‘tails’ has long provided an elegant explanation for time-progressive lines of islands, seamounts and ridges. But a major problem cited for this ‘standard’ plume model is a lack of evidence in the volcanic record for head-and-tail upwellings.

New evidence from direct dating of the oceanic hotspot record is also suggesting that hotspot melting anomalies might be much broader than commonly inferred from the ‘head-tail’ plume model and the dimensions of individual seamount chains and aseismic ridges. For example, new age data show that the Galapagos volcanic Province developed via the progression of broad regions of concurrent dispersed volcanism that we link to a correspondingly broad mantle melting anomaly (O’Connor et al., submitted, 2007). Moreover, recent thermo-chemical numerical modelling is exploring scenarios where upwelling structures are more irregular in shape and behaviour compared to a classic thermal plume ‘head-tail’ (e.g., Farnetani and Samuel, 2006).

New strategies are therefore needed for investigating the hotspot volcanic record in order to better test the ‘fixity’ of hotspots and the mantle plume hypothesis. To this end we have recently sampled multiple seamount chains and ridges scattered across a broad region of the southern South Atlantic. Our focus is on investigating multiple hotspot chains and ridges stretching across a very broad region of the South Atlantic seafloor as a potentially useful way of testing 1) the new thinking that plume upwellings may differ from the classic ‘head-tail’ structure and 2) our evolving hypothesis that hotspot melting anomalies are much broader than suggested by regions of active volcanism marking the young ends of individual hotspot trails. A key component of this strategy is our IODP proposal to drill Walvis Ridge once we have developed a fuller understanding of how Walvis Ridge fits with the predictions of the fixed hotspot and mantle plume hypotheses.
Mineralogical and geochemical study of airborne particulates (PM$_{10}$) in an urban environment

A. Oehler$^1$, R. Gieré$^1$ and P. Stille$^2$

$^1$Universität Freiburg, Germany (anja.oehler@email.de)
$^2$Université de Strasbourg, CNRS-UMR 7517, Strasbourg, France

Airborne particulate matter (PM) is known to affect human health significantly. Especially the fine PM, with sizes $<10$ µm (PM$_{10}$), poses a considerable health threat, due to its ability to enter human lungs. Sources of anthropogenic PM$_{10}$ in the atmosphere include waste incinerators, traffic, and thermal power plants. Coal-fired power plants, for example, emit various distinct phases, including several types of crystalline metal sulphates (Gieré et al., 2006). Knowledge of the identity and composition of individual particles is essential to predict their environmental behaviour.

The study focuses on PM$_{10}$ collected in the neighboured urban environments of Strasbourg (France) and Kehl (Germany). This urban area, situated on both sides of the river, Rhine is exposed to different PM sources such as a thermal power station, waste incinerators, and a steel plant. Our interest lies in the bulk chemical and mineralogical composition of the overall PM$_{10}$ in the city centre of Strasbourg and in the specific evolution of these compositions as function of distance from the steel plant. Pb, Sr and Nd isotope ratios of these emissions are already precisely identified and allow to be traced over more than 3km along the prevailing wind pathway (Lahd Geagea et al., 2007). Thus, in this special case study we have a direct control of the origin of the PM$_{10}$ and can compare the PM$_{10}$ compositions with those of filter dust from the plant. The bulk chemical composition of PM$_{10}$ trapped on teflon filters is analyzed by using ICP-MS. Identification and characterisation of the mineral phases is performed using SEM techniques, which allow us to determine morphology and chemical composition of µm-sized individual particles. Preliminary results show that, in addition to soot and various silicate particles, metal sulphates are present in the PM.

Do fluids flow through or around mineral grains?

ERIC H. OELKERS$^1$, CHRISTINE V. PUTNIS$^2$ AND ANDREW PUTNIS$^2$

$^1$Géochimie et Biogéochime Experimentale, LMTG, Université de Toulouse, CNRS, IRD, OMP, 14 ave Edouard Belin, 31400 Toulouse, France (oelkers@lmtg.obs-mip.fr)
$^2$Institut für Mineralogie, Universität Münster, Correnstrasse 24, 48149 Münster, Germany

A large body of evidence demonstrates that mineral transformation commonly occurs through a dissolution/precipitation mechanism where 1) the fluid moves into the parent phase from its original surface and 2) the crystal structure is preserved between the parent and secondary phase (Putnis and Putnis, 2007). The goal of this study is to assess if a similar dissolution/precipitation mechanism can transport fluids through mineral grains where the driving force is either a pressure or a temperature gradient.

Calculations were performed using dissolution rates (c.f. Gislon et al., 1997; Oelkers, 2001), aqueous diffusion coefficients (Oelkers and Helgeson, 1988), and mineral solubilities calculated using SUPCRT92 (Johnson et al., 1992) as a function of temperature and pressure assuming that precipitation rates are consistent with Transition State Theory and the law of detailed balancing. Results show that the degree to which fluid ‘flows’ through minerals depends on the identity of the mineral. For example the calculated logarithm of water permeability (in Darcy) through quartz, assuming fluid flow is driven by an isothermal pressure gradient, is -10 at 200°C, increasing to -5 at 600-700°C. In contrast, the corresponding log permeability through enstatite is far higher increasing from -6 to -3 over this temperature range. Note at elevated temperatures these latter values are comparable to that of sandstones in sedimentary basins. Moreover, temperature gradients are, in general, more effective at provoking fluid flow due to the relatively stronger effect of temperature on solubility.

These calculations suggest that large quantities of fluid flow can occur through mineral grains at elevated temperatures due to either pressure or temperature gradients. The consequences of this fluid flow in terms of 1) isotopic reequilibration and 2) stability of fluid inclusions will be detailed.

Accretion of terrestrial planets from oligarchs in a turbulent disk

M. OGHARA1, S. IDA1 AND A. MORBIDELLI2

1Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Japan (oghara@geo.titech.ac.jp; ida@geo.titech.ac.jp)
2Observatoire de la Côte d’Azur, France (alessandro.morbidelli@obs-nice.fr)

Introduction

We have investigated the final accretion stage of terrestrial planets from Mars-mass protoplanets that formed through oligarchic growth in a disk comparable to the minimum mass solar nebula (MMSN), through N-body simulation including random torques exerted by disk turbulence due to Magneto-Rotational-Instability. For the torques, we used the semi-analytical formula developed by Laughlin et al. (2004). The damping of orbital eccentricities (in all runs) and type-I migration (in some runs) due to the tidal interactions with disk gas are also included.

Without any effect of disk gas, Earth-mass planets are formed in terrestrial planet regions in a disk comparable to MMSN but with too large orbital eccentricities to be consistent with the present eccentricities of Earth and Venus in our Solar system. With the eccentricity damping caused by the tidal interaction with a remnant gas disk, Earth-mass planets with eccentricities consistent with those of Earth and Venus are formed in a limited range of disk gas surface density (~10^{-4} times MMSN). However, in this case, on average, too many planets remain in terrestrial planet regions, because the damping leads to isolation between the planets.

Results

We have carried out a series of N-body simulations including the random torques with different disk surface density and strength of turbulence.

We found that the orbital eccentricities pumped up by the turbulent torques and associated random walks in semimajor axes tend to delay isolation of planets, resulting in more coagulation of planets. The eccentricities are still damped after planets become isolated. As a result, the number of final planets decreases with increase in strength of the turbulence, while Earth-mass planets with small eccentricities are still formed. In the case of relatively strong turbulence, the number of final planets are 4-5 at 0.5-2AU, which is more consistent with Solar system, for relatively wide range of disk surface density (~10^{-4}-10^{-5} times MMSN).

Distribution of mercury and methylmercury in deep-sea surficial sediments of the Mediterranean Sea

N. OGRINC1*, J. KOTNIK1, V. FAJON1, D. KOČMAN1, S. ZIŽEK1, M. HORVAT1 AND N. PIRRONE2

1Dept. of Environ. Sci., “J. Štefan” Institute, Jamova 39, 1000 Ljubljana, Slovenia (nives.ogrinc@ijs.si)
2CNR IIa, Institute for Atmospheric Pollution, 87036 Rende, Italy (n.pirrone@cs.iaa.cnr.it)

This communication presents the results of the investigation of the distribution, speciation and methylation of mercury in sediments of the Mediterranean Sea. The samples were collected at different locations in the Western and Eastern Basin of the Mediterranean during the cruise of the Italian research vessel Urania in summer 2003 as part of MERCYMS project. Total mercury (HgT) and methylmercury (MeHg) in pore water and sediments were determined down the sediment profile and coupled with other biogeochemical parameters, including organic carbon content. The diffusive fluxes of HgT and MeHg were calculated to estimate the importance of sediment-water exchange as potential sources of HgT and MeHg. In addition, the radioactive isotope 197Hg was used to determine the methylation potentials. The concentrations of HgT in sediments ranged between 0.06 and 2.23 nmol g^{-1} and vary irregularly with depth, which may reflect changes or redistribution during diagenetic processes. No correlation between HgT and organic carbon content was found, but a relatively high proportion of MeHg to HgT of approx. 2.0% was observed. The integrated flux of HgT was estimated to be 109 kmol year^{-1} and agrees well with the mass balance calculation preformed for total underwater emissions of HgT in the Mediterranean Sea of 80 kmol year^{-1} by Rajar et al., 2007. The emissions of MeHg were estimated to be 14 kmol year^{-1} and indicate that deep-sea sediments could be an important source of the MeHg content in marine biota. It was found that accumulation of MeHg in surficial sediments of the Mediterranean is not directly related to the potential rates of bacterial Hg methylation. Much of the MeHg produced in the sediments is lost to the overlying water. Our results suggest that MeHg production depends on partitioning of Hg(II) influenced by the organic carbon content in the sediment. Reduction of organic carbon in sediment could increase pore water Hg(II) and enhance bacterial production of MeHg.

These are the main results of a first study performed on Hg speciation, partitioning and methylation potential in deep sea sediments, giving a new insight into deep sea Hg biogeochemical cycling.
Contrasting surface chemistry of adsorbed ions in iron oxyhydroxide coatings on feldspar grains in soils deposited over mineralized and unaltered granite in the Big Creek Mining District, Idaho, USA (ToF-SIMS analysis)

Patrick F. O’Hara1, David H. Krinsley2, Gregory T. Hill3 and Stephen Golledge4

1Kaaterskill Exploration, 3260 Tower Rd, Suite E, Prescott, Arizona, USA, 86305
2Dept. of Geological Sciences, University of Oregon, Eugene, Oregon, USA, 97403-1272
3785 Andrew Lane, Reno, NV 89521
4CAMCOR, University of Oregon, Eugene, Oregon, USA, 97403

An existing hypothesis in applied geochemistry suggests that a variety of ions are absorbed on pre-existing iron and manganese oxyhydroxide coatings formed on mineral grains in soils, and that these ions move upward and laterally by vadose zone, vapor transport, electrochemical and biogeochemical processes to these depositional sites. Desorbants are used to selectively extract these ions from the grain coatings and the analytical results are used in conjunction with geospatial techniques to identify areas of potential mineralization. Feldspar grains from both samples were used to eliminate potential effects of confounding variables that may be associated with other minerals and surface coatings on those minerals. Elemental maps created by ToF-SIMS analysis indicate that hydrothermal trace elements associated with mineralization concentrate in iron oxyhydroxide coatings on feldspar grains in b-horizon soil developed over gold-silver mineralized and altered granite. Weathered pyrite is the probable source of iron oxyhydroxide mineral coatings in this soil. Elemental maps of arsenic, antimony, lead, and copper are variably present in coatings along flat grain surfaces, and are strongly enhanced in surface coatings located on grain corners. These elements are below detection in iron oxyhydroxide coatings on feldspar grains in b-horizon soils developed over an unmineralized granite outcrop located several kilometres from known geochemical anomalies or mineralized sites. Iron oxyhydroxide coatings on soil grains at the unmineralized site are related to weathering of biotite. These observations suggest that the depositional chemistry portion of the hypothesis is valid.

Catalytic potential of silicate, oxide and sulfide minerals for the abiotic polymerization of glycine under high pressure and temperature conditions

Shohei Ohara1, Takeshi Kakegawa1 and Hiromoto Nakazawa2

1Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, Sendai, Japan (ohara@ganko.tohoku.ac.jp)
2National Institute for Materials Science, Tsukuba, Japan

Polymerization of amino acids is the essential step for the origin of life. It is still uncertain if minerals had a progressive role for polymerization of amino acids in any ancient geological environments. Polymerization experiments of glycine, catalyzed by minerals, were performed under 150°C and 100 MPa for 8 days, using a test-tube type autoclave. Various sulfides (millerite, troilite, pyrite and sphalerite), magnetite and montmorillonite were mixed with glycine monomers in order to test if these minerals behave as the catalyst to promote peptide formation. HPLC and LCMS analyses of the products showed that: (1) glycine in all the experimental runs polymerized from 2-mer to 11-mer; (2) the highest yield of oligopeptides was found in the sphalerite experiment; (3) cyclic anhydride was more abundant in the montmorillonite experiment; and (4) other minerals behaved intermediately between sphalerite and montmorillonite.

In order to examine surface processes, adsorption experiments were also performed by NH3- and CO2-TPD (temperature-programmed desorption) methods. The TPD analyses indicated that sphalerite has high adsorption capabilities both of NH3 and CO2. These results imply that sphalerite has high adsorption capabilities of amino and carboxyl groups affecting the elongation of peptides. On the other hand, montmorillonite only has the capability to adsorb NH3, thus amino group. This type of adsorption may only result in cyclization of amino acids preventing elongation of oligopeptides.
Application of compound-specific radiocarbon dating for studying West Antarctic Ice Sheet during the Late Quaternary

N. OHKOUHI1, T.I. EGLINTON2, M. TOYODA1,3, Y. CHIKARAISHI1, H. TOKUYAMA3, H. MIURA4 AND Y. YOKOYAMA5

1IFREE/JAMSTEC, Yokosuka 237-0061, Japan
2Woods Hole Oceanogr Inst, Wods Hole MA 02543, USA
3Ocean Res Inst, Univ Tokyo 164-8639, Japan
4National Inst Polar Res, Tokyo 173-8515, Japan
5Dept Earth Planet Sci, Univ Tokyo, Tokyo 113-0033, Japan

Compound-specific radiocarbon dating is a powerful tool for reconstructing chronologies in high-latitudinal sediments. Since high-latitudinal sediments generally lack carbonate, total organic matter has been used to establish sediment chronologies. However, the “contamination” of reworked sediments eroded from the Antarctic Continent leads to anomalously old core-top ages or to age reversals down-core (Ohkouchi and Eglinton, 2006).

Ohkouchi et al. (2003) first reported that the radiocarbon dating of solvent-extractable, short-chain (C14, C16, and C18) fatty acids isolated from surface sediments of the Ross Sea, Antarctica, indicated them to be consistent with the modern DIC reservoir age (Pre-bomb: $\Delta^{14}C \approx -150‰$, Post-bomb: $\Delta^{14}C \approx -100‰$). Furthermore, the radiocarbon ages of these fatty acids at five down-core intervals progressively increase with the core depth. These results clearly show a utility of the compound-specific radiocarbon dating for developing sediment chronologies in Antarctic margin sediments (Ohkouchi and Eglinton, submitted).

In this study, we determined radiocarbon ages of the fatty acids from a core recovered in the NW Ross Sea to reconstruct sediment chronologies. Furthermore, we determined hydrogen isotopic compositions of sedimentary biomarkers in the core. Around 7, 6, 4.5, and 2.5 kyr ago, the reconstructed $\delta^2$D values of paleo-seawater were -200‰ or lower, suggesting a large amount of meltwater influx to the Ross Sea. We propose that recurrent massive melting of WAIS could have occurred at least four times in the Holocene.

Mobility and transport of Nd isotopes during weathering of till in a boreal forest

BJÖRN ÖHLANDER1, MAGNUS LAND2 AND JOHAN INGRI1

1Division of Applied Geology, Luleå University of Technology, Sweden
2Department of Geology and Geochemistry, Stockholm University, Sweden

It has been suggested that the Nd transported in the large, pristine Kalix River in northern Sweden originates from organic bound REE from the uppermost soil horizons (Öhlander et al., 2000; Andersson et al. 2001). Here we present new data of the distribution of Nd isotopes in a spodosol profile developed in a till which was deposited 8700 years ago. In addition, Nd isotopes were analysed in soil water, groundwater and stream water in a small catchment situated within the Kalix River drainage basin.

The results indicate that a large part of the Nd released by weathering in the E-horizon is trapped in the B-horizon, and that the major part of the dissolved Nd exported from the studied catchment via stream water is derived from weathering in the shallow groundwater zone within the till rather than in the top soil. Due to the very low weathering rate at that depth, there is still a relatively little altered pool of reactive minerals containing Nd. It will take a very long time ($>> 8700$ years) before the Nd leaving the catchment will have an isotopic composition different from today.

The export of Nd from a large boreal drainage basin, in this case to the Bothnian Bay, is, to a large extent, controlled by selective weathering and reactions with organic matter in the upper soil horizons, and by Nd released by slow weathering in the groundwater zone.

An alteration zone (~20-80 m thick), characterized by the abundance of pyrophyllite (aluminum-rich clay) and the depletion of iron and most elements, is widely developed in pre-3.4 Ga submarine basalts that occur beneath the oldest-known (~3.4 Ga) erosional unconformity (i.e., oldest land surface) in the North Pole Dome region of the northern Pilbara Craton, Western Australia. Some previous researchers suggested this alteration zone as a product of hydrothermal activity ~3.4 Ga.

We have recently discovered more than 100 iron pods (each ~1 to ~6 m thick and ~1 to ~50 m long) within the iron-depleted pyrophyllite-rich zone at seven sites over a ~30 km expanse in the studied area. They typically occur as clusters at 0 - 30 m below and generally parallel to the ~3.4 Ga unconformity, rather than being parallel to the modern groundwater tables. These iron pods are mostly composed of well-crystalline hematite (~30 to ~90 wt% Fe2O3) and pyrophyllite.

The geometrical, geological, mineralogical, and geochemical characteristics of iron pods and alteration zone in the studied area (e.g., the rarity of quartz-sulfide veins; sizes and crystallinity of hematite; trends of Al/Ti, Mg/Ti, Fe/Ti, Ca/Ti, Na/Ti, and K/Ti ratios; trends of trace element ratios; REE behaviors) resemble those of “groundwater-type” laterites of the Phanerozoic and Proterozoic ages (e.g., the ~2.2 Ga Hekpoort and Hokkalampi paleolaterites). Groundwater-type laterites require the following conditions for formation: (i) distinct wet/dry seasons; (ii) the development of microbial mats/vegetation on/in soils during wet seasons, which produce abundant organic acids that leach both ferric and ferrous irons from the soils and create ferrous-rich groundwater; and (iii) an abundance of oxygen molecules supplied from the atmosphere to the soils and groundwater, mostly during dry seasons, to precipitate the aqueous ferrous iron as ferric (hydr)oxides. Therefore, if the North Pole Dome ironstones are indeed ~3.43 Ga laterites, they suggest the very early developments of the terrestrial biosphere and an oxygen-rich atmosphere.

Mass dependent isotopic fractionation of Ce and Nd in geochemical samples

TAKESHI OHNO AND TAKAFUMI HIRATA

Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Japan (ohno.t.ab@m.titech.ac.jp; hrt1@geo.titech.ac.jp)

The study of naturally occurring mass dependent isotopic fractionation of rare earth elements (REEs) has a potentially significant influence in geochemical research fields. Isotopic fractionation of REEs with their chemical similarities and gradual changes of ionic radius may provide new insights about chemical weathering processes. One of the most attractiveness of REEs is anomalous behavior of Ce mainly due to the existence in not only the trivalent state but also the tetravalent state. Since the valence of Ce depends on the redox conditions, differences of isotopic fractionation between Ce and the other REEs could provide information about the redox conditions of depositional environment. Among the other REEs, Nd could play an important role in the stable isotope geochemistry of REEs as a reference compared to Ce. Moreover, radiogenic growth of 143Nd can also provide chronological constraints on a sample formation process.

In this study, we have developed a new chemical and mass spectrometric procedure for the investigation of mass dependent isotopic fractionation of Ce and Nd in geochemical samples. In order to detect the small isotopic fractionation, mass discrimination effects on Ce and Nd isotopes were externally corrected by Sm and Eu, respectively. The resulting analytical precisions for δ142/140Ce and δ146/144Nd were better than 0.01% (2SD). Isobaric interferences were eliminated by an extraction chromatography using a Ln spec. resin. We examined isotopic fractionation of Ce and Nd during the separation procedure. The result of the test demonstrated that the cumulative isotopic value of the eluent showed no detectable isotopic fractionation through a few percent loss during the chromatographic separation.

Cerium and Nd isotopic compositions of GSJ geochemical reference samples (Basalt, JB-1a; Andesite, JA-2; Manganese Nodule, JMN-1; Chert, JCh-1; Dolomite, JDo-1) have been measured in order to examine the possible isotopic fractionation of Ce and Nd. The isotopic data of Ce and Nd for the samples revealed δ142/140Ce and δ146/144Nd data for JDo-1 were different from that of the igneous rock samples. Moreover, there was positive correlation between the resulting δ142/140Ce and δ146/144Nd, implying that the isotopic variation of Ce and Nd observed in JDo-1 might be caused by non-redox reactions such as preferential precipitation or dissolution processes, rather than the redox reaction. In this presentation, Ce and Nd isotopic data on several geochemical materials and possible mechanism of isotopic fractionation will be discussed.
Interactions of heavy elements with microorganisms

Introduction
The high capacity of microbial surfaces to bind actinides may affect the migration of actinides in the environment. However, we have only limited knowledge of the role of microorganisms in the migration of actinides in the environment. We have been conducting basic scientific research on microbial interactions with actinides in order to elucidate the environmental behavior of actinides under relevant microbial process conditions.

Pu(IV) sorption and reduction
Adsorption of Pu(IV)-desferrioxamine B (DFO) on bacteria indicate that Pu(IV) is dissociated by contact with cells, after which Pu(IV) is adsorbed, and that pH dependence of adsorption density of Pu(IV) on cells is dominated by the stability of Pu(IV)-DFO complexes. Study on reduction of Pu(IV) in the presence of citric acid at pH 7.0 suggested that Pu(IV) is reduced to Pu(III) by the activity of sulphate reducing bacteria.

U(VI) mineralization
Uranium mineralization by the yeast Saccharomyces cerevisiae was examined by batch experiment at pH 3.2. Analysis of the U(VI)-bearing precipitates by FESEM-EDS, TEM, and visible diffuse reflectance spectrometry demonstrated the presence of H-autunite, UO3PO4·4H2O and thermodynamic calculations suggest that the chemical compositions of the solutions were undersaturated with respect to H-autunite, but were supersaturated with ten-times more U(VI) and P than were actually observed. These findings indicate that the yeast’s cell surfaces, rather than the bulk solution, offer the specific conditions for this geochemical process.

A combined terrestrial and marine geochemical mapping project in Japan

A. OHTA, N. IMAI, S. TERASHIMA, Y. TACHIBANA, T. OKAI, M. UJHIE-MIKOSHIBA AND R. KUBOTA

Geological Survey of Japan, AIST, Tsukuba 305-8567, Japan; a.ohta@aist.go.jp

Spatial distribution patterns of elemental concentrations on land, geochemical maps, are effective for mineral exploration and environmental assessment. In Japan, the Geological Survey of Japan, AIST conducted a nationwide geochemical mapping program at 1:2,000,000 scale using fine stream sediments for these purpose (Imai et al., 2004). Japan is, however surrounded by a vast expanse of sea, so that examination of geochemical baseline in coastal-open sea is also essential for environmental assessment. Approximately 3000 surface marine sediments around Japan were collected for this purpose and analyzed for 51 elements including heavy metals (e.g. Cu, Zn, Cd, Hg, and Pb). This project is intended: 1) to elucidate background of elemental abundance in terrestrial and marine areas of young island arc; 2) to find mass transport from land to sea; and 3) to estimate diffusion processes of pollutants.

The elemental concentrations of marine sediments are determined primarily by grain size. Most elemental concentrations increase with decreasing grain size and eventually become constant. Overall, marine sediments and stream sediments show similar elemental abundance patterns, but marine sediments have lower elemental abundance than stream sediments because of dilution effects imparted by calcareous sediments and organic materials. These results suggest that marine sediments in coastal seas originate mainly from terrestial materials. However, a few examples of direct mass transport from terrestrial area to marine environment are apparent. The spatial distribution patterns of K and Cr concentrations, which are good examples of mass transport, suggest two types of high-concentration area extending continuously from land to sea: high concentration area proximal to a river mouth (20-30km) and high concentration area extending over 60 km offshore along a deep-valley.

These results suggest that sediments deposit by fanning out near shore and a part of them are further conveyed along the deep-valley by gravity movement. Diffusion of heavy metals such as Cu, Zn, Cd, Sn, Pb, and Bi is observed in coastal bays surrounded by urban and industrial areas, from which the stream sediments are extremely abundant in those elements. It is noteworthy that the materials with heavy metals seem to remain in the bay without diffusing to the outer sea. The sediments with heavy metals might not diffuse readily to the outer sea because of a strong bottom current (estuary circulation) that flows from outer sea to the inner part of the bay.

The effect of iron spin transition on electrical conductivity of perovskite and magnesiowüstite
KENJI OHTA1, SUZUE ONODA2, KEI HIROSE1 AND KATSUYA SHIMIZU2
1Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Meguro, Tokyo, Japan (k-ohta@geo.titech.ac.jp; kei@geo.titech.ac.jp)
2Center for Quantum Science and Technology under Extreme Conditions, Osaka University, Toyonaka, Osaka, Japan (onoda@djebel.mp.es.osaka-u.ac.jp; shimizu@cqst.osaka-u.ac.jp)

The electrical conductivity is one of the observable physical properties of the Earth’s mantle. The pyrolitic lower mantle mainly consists of Al-bearing (Mg,Fe)SiO3 perovskite and (Mg,Fe)O magnesiowüstite, and the electrical conduction occurs through these two iron-bearing phases. The electrical conductivity profile in the lower mantle has been estimated by extrapolating the data from 40 GPa [Shankland et al., 1993]. Recently, Badro et al. [2003, 2004] discovered a pressure-induced electronic spin transition of iron in both magnesiowüstite and perovskite. The spin transition of iron may have significant effect on electrical conductivity, but it has not been examined yet.

Here we measured the electrical conductivity of Mg0.81Fe0.19O magnesiowüstite and Mg0.91Fe0.09SiO3 perovskite at high pressures up to 135 GPa and 300 K in a diamond-anvil cell (DAC). The results demonstrate that the electrical conductivity of magnesiowüstite increases with increasing pressure to about 60 GPa and exhibits anomalous behavior at higher pressures; it conversely decreases to around 80 GPa and again increases very mildly with pressure to 130 GPa. Perovskite shows similar profile to that of magnesiowüstite; it increases to 60-70 GPa and decreases to 80 GPa, then again increases mildly with pressure up to 135 GPa.

This observed reduction in electrical conductivity may be explained by the high-spin to low-spin transition of iron in magnesiowüstite and perovskite. A smaller pressure effect on the electrical conductivity of magnesiowüstite above 80 GPa suggests that a dominant conduction mechanism changes by the electronic spin transition. The electrical conductivity of perovskite becomes higher than that of magnesiowüstite above 90 GPa. Therefore, perovskite can be a main conductor, at least in the deep lower mantle. The electrical conductivity below 2000-km depth in the mantle may be much smaller than previous estimates due to the effect of electronic iron spin transition.

Geochemistry and TEM observation of graphite in 3.8 Ga metasedimentary rocks in Isua Supracrustal Belt
Y. OHTOMO AND T. KAKEGAWA
Institute of Mineralogy, Petrology, and Economic Geology, Graduate School of Science, Tohoku University, Sendai, Japan (otomoyou@ganko.tohoku.ac.jp)

The remnant of oldest life was reported only from one outcrop at the 3.8Ga Isua Supracrustal Belt (ISB), West Greenland [1], although graphite-bearing rocks are located at several spots in the Isua area. New outcrops of graphitic schist, which graphitic contents are up to 8.8 wt %, were found through the course of this study. The graphitic schist is interbedded with banded iron formation and extended for approximately 500m from NW to SE. Major and trace element were determined on graphitic schist samples. Carbon isotope compositions of graphite were determined using the laser micro probe system. TEM analyses were also performed on the extracted graphite samples.

CI chondrite-normalized REE patterns of the new graphitic schist are similar to other Archean shales or banded iron formation. Therefore, new graphitic schist has characteristics of marine clastic to chemical sediments.

Carbon isotope compositions of graphite were determined on 50 samples. Their compositions range from –22.4 per mil to –13.2 per mil. The carbon isotope compositions change systematically, correlated to geological occurrence. Lightest carbon isotope composition was found in the most western area where complicated nano-scale textures of graphite were observed by TEM. The heaviest carbon isotope composition was found in the most eastern area. This carbon isotope shift is probably due to the more metasomatic effect compared to the western samples. Considering those all geochemical data, graphite in new graphitic schist also gives another evidence of 3.8Ga marine biota.

Wilhemine copper mine, Spessart, Bavaria: A Kupferschiefer-related, hydrothermal mineralization

MARTIN OKRUSCH¹, JOACHIM LORENZ² AND STEFAN WEYER³

¹Mineralogisches Institut, Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany (okrusch@uni-wuerzburg.de)
²Joachim A. Lorenz, Graslitzer Str. 5, D-63791, Karlstein am Main, Germany (Jo.Lorenz.Karlstein@t-online.de)
³Institut für Petrologie, Geochemie und Lagerstättenkunde, Universität Frankfurt am Main, Senckenberganlage 28, D-60325 Frankfurt am Main, Germany (stefan.weyer@em.uni-frankfurt.de)

The vein-type copper mineralization in the abandoned Wilhelmine copper mine at Sommerkahl is hosted by orthogneisses of the Spessart Crystalline Complex. These are covered by sedimentary rocks of Permo-Triassic age, including the stratabound base-metal mineralization of the Kupferschiefer. Ore textures in the sulfide veins testify to three stages of mineralization:

(i) An early stage is characterized by colloform textures, documented by spherical, garland-shaped or cockade-like aggregates of tennantite I, enargite I, pyrite I, chalcopyrite I, bornite I and digenite I.

(ii) During a subsequent recrystallization stage, these were overgrown by, or enclosed in, tennantite II, enargite II, bornite II, digenite II, pyrite II and chalcopyrite II. Fine-grained to submicroscopic digenite-bornite intergrowths, exsolved from an initial 1a-solid solution, contain up to 55 mole-% of bornite, indicating a minimum temperature of 175°C for this stage.

(iii) A late alteration stage led to the replacement of primary sulfides by yarrowite, spioncopite and rare covellite, together with goethite.

The close spatial association of the vein-type Cu mineralization with the overlying Kupferschiefer suggests a genetic relationship. In situ sulfur isotope analyses of sulfide minerals yielded negative δ²⁸S values of −12.8 to −23.9 ‰, indicating a derivation from the Kupferschiefer, presumably by hydrothermal leaching. By contrast, we assume that the metals were derived from deep-seated sources, transported upwards by hydrothermal fluids and precipitated by thermochemical sulfate reduction, due to interaction with the Kupferschiefer. Formation of the sulfide ore veins is related to a hydrothermal activity in Middle Jurassic to Early Cretaceous times.

Micro-Raman and cathodoluminescence characterization of shocked quartz from impact craters

T. OKUMURA¹, A. GUCSIK², H. NISHIDO¹, K. NINAGAWA³ AND M. SAKAMOTO⁴

Introduction
Evidence of shock metamorphism can be sufficiently proved by the existence of planar deformation features (PDFs) found in quartz. However, visual identification of the planar features under optical microscope should be unambiguous for clarifying PDFs. To characterize shock-induced planar microstructures such as PDFs in quartz from various impact craters, we used a combination of cathodoluminescence (CL) and micro-Raman spectroscopy with high sensitivity and high spatial resolution.

Samples and Methods
Quartz grains from Ries Crater, Barringer Meteor Crater, and Oikeyama Crater are employed for Raman and CL measurements. They were prepared as polished thin sections. PDFs are observed in several quartz grains under a petrographic microscope. Raman spectra were acquired with a confocal micro-Raman spectrometer at 20 mW using a Nd:YAG laser (532 nm) excitation system. CL imaging and spectral measurements were carried out on a SEM-CL (scanning electron microscope combined with a grating monochromator) with an accelerating voltage of 15 kV.

Results and Discussion
SEM-CL imaging of quartz grains from each crater shows non-luminescent or CL-dark lines related to PDFs, which can be clearly observed under polarized microscope. Raman spectra of shocked quartz from the Ries Crater exhibit a pronounced peak at around 459 cm⁻¹, which can be assigned to Si-O-Si stretching vibration, whereas unshocked quartz has a sharp and intense peak at 464 cm⁻¹. This frequency shift may arise by a distortion of the structural configuration (i.e., formation of high density silica) caused by shock-metamorphism. The Raman imaging of shocked quartz from each impact crater shows a stripe pattern suggesting layers comprised of high and low crystalline parts corresponding to the optical image of PDFs. Our results show that shock-induced amorphization might effect an alteration of electronic transition processes in defect centers that are correlated to CL emission.
Hydrogen isotope geochemistry of basalts from Samoa

³Scripps Institution of Oceanography, University of California-San Diego, La Jolla CA 92093 USA

Hydrogen is present at low concentrations (tens to hundreds of ppm H₂O) throughout the upper mantle but exerts a strong influence on the melting behavior and rheologic properties of peridotite. The distribution of hydrogen in the entire mantle is a key constraint on mantle convection that remains unquantified. The D/H ratio of hydrogen in fluids and in silicate materials can be fractionated by tens of per mil under mantle conditions and offer an opportunity to identify and describe hydrogen storage and transport processes within the mantle. To pursue this goal we examined the hydrogen isotope composition of submarine ocean island basalt glasses collected from Malumalu, Vailu’lu, and Ta’u in the Samoan island chain. Lavas from the Samoan islands contain extreme trace element and radiogenic isotope enrichments that define the EM 2 (enriched mantle 2) mantle endmember [1]. The D/H composition of Samoan lavas vary between -79 and -37 per mil, a similar range to what is found in other ocean island basalt localities and in back-arc basin basalts that are influenced by fluids released from subducting ocean crust. The lowest δD values of Samoan glasses (-79 per mil) are close to the mode of values for mid-ocean ridge basalts (-75 per mil) while the highest value is similar to the isotopic composition of serpentine in equilibrium with seawater. This range in hydrogen isotope composition suggests that the mantle source region of Samoan basalts may contain fluid derived from ancient subducted ocean crust that has retained a distinct hydrogen isotopic composition over the timescale of mantle mixing.

Correlations between La, ⁸⁷Sr/⁸⁶Sr, and water content in Samoan lavas are attributed to equilibration of initially water rich subducted materials with the ambient mantle water content [2]. Equilibration is possible due to rapid diffusion of hydrogen in mantle minerals [3]. The preservation of D-rich compositions in the source of Samoan basalts suggests that hydrogen isotopic anomalies are not diffusively lost, possibly due to high concentrations of D-rich hydrogen in subducted materials that result in large regions of the mantle with high D/H ratio.

The model structure of kaolinite in relation to surface complexation

M. OLIN, E. PUHAKKA AND J. LEHIKOINEN

VTT Technical Research Centre of Finland, P.O. Box 1000, FI-02044, Finland (markus.olin@vtt.fi)

Methods

Surface complexation modelling using the FITEQL software was applied to explain the surface acidity of kaolinite. In this context, a number of different models and modelling approaches were tested. Further, a density functional method, CASTEP (Accelrys, 2001), was used to investigate the crystal and surface structures of kaolinite, and to calculate surface charge densities.

Results and discussion

To enable the interpretation of adsorption results with surface complexation modelling, an adequate characterization of the surface charging of the adsorbent is needed. In general, titration experiments are capable of providing this information for ionisable interfaces. However, results based on experimental data give only average values of surface charge densities. Therefore, in this study, molecular modelling was used to calculate surface charge densities of likely the most reactive kaolinite crystal faces separately (see Figure 1 for the (010) surface). Based on this information, an attempt will be made to constrain the number of surface sites and magnitude of surface hydrolysis constants, often considered as adjustable parameters devoid of deeper understanding, in surface complexation models.

Figure 1: Model (010) surface of kaolinite and its surface charge density.

Conclusions

The molecular-level modelling produced invaluable background information of the kaolinite surface for further development of surface complexation models in terms of the surface charging and the adsorption of metal cations.

³IPEN, C.P. 11049, São Paulo, Brazil, (defavaro@ipen.br)

A 72-cm long core was collected from Lagoa da Viração (LV), a small pond in the Fernando de Noronha island, northern Brazil, in order to study vertical changes in major, trace and Pb isotopes concentrations with depth. Sediments from the lower section of the core (20-70 cm) contains essentially mineral matter, while in the upper section (0-20 cm) mineral matter is mixed with organic matter, which is increasingly more abundant toward the top. Lithogenic conservative elements – Si, Al, Fe, Ti, Co, Cr, Cu, Ga, Hf, Nb, Ni, Y, Zn, Zr and REE – exhibit remarkably constant values along the core, with concentrations similar or moderately higher than those of the bedrock. The vertical distribution of soluble elements – Ca, Mg, Na, K, P and Mn – is also homogeneous, but these elements are systematically depleted in relation to the bedrock. LOI, TOC, Br, Se, Hg and Pb, although showing nearly constant values in the lower section of the core, are significantly enriched in the upper section. Pb isotopic ratios are nearly constant and very similar to those of the bedrock in the lower section of the core, but are increasingly less radiogenic in the upper section. Ti-normalization allowed the separation of natural and anthropogenic Pb, indicating that the latter was restricted to the upper section of the core, and was probably added to the sediments via atmospheric transport. Se and Br appears to be originated from seawater sprays. The source of Hg seems more uncertain, but at least partially it might have been accumulated via atmospheric deposition. Whatever the source of Pb, Br, Se and Hg, their close association with TOC suggests that organic matter has played an important role in their accumulation in the surface sediments.

Molecular markers and trace-metals as proxis of biomass combustion in Central Amazon sediments

T.C.S. OLIVEIRA, A. WAGENER AND A.L. SCOFIELD

Departamento de Quimica, Pontificia Universidade Católica do Rio de Janeiro, 22453-900 Rio de Janeiro, Brazil (tcrist@rdc.puc-rio.br; angela@rdc.puc-rio.br; scofield@rdc.puc-rio.br)

Large scale forest fires occur in the region denominated “deforestation arc” circumscribing the southern area of the Amazon Region. Under certain meteorological conditions like in the dry season of 2005 clouds of particulate matter reached Manaus and the Central Amazon. The goal of the present work was to search for indicators of combustion in sediments of the Solimões River and associated lakes. For this sediments were sampled in the wet and dry seasons in 2005 and were analysed for 39 PAHs, molecular markers and trace-metals. Among other approaches, to verify the contribution of biomass combustion to the PAH pool in the sediments the diagnostic ratio Fl/(Fl+Py) was plotted versus 1.7/(1.7+2.6)DMPh, which was used as a proxy for combustion sources. The cross evaluation shows PAH in sediments deriving predominantly from mixed combustion sources. Evidently the traffic of ships along the river contributes for the pool of PAH in the sediments. Significant correlation (p<<<0.05) of perilene, the major PAH, with BbFl, BkFl, BaPy and several metals were found. These and additional correlations were confirmed in the factorial analysis in which the correlation coefficients in factor 1 were: 0.79 for Fl, 0.76 for BaA, 0.83 for BbFl, 0.66 for BkFl, 0.82 for BaPy, 0.83 for Cd, 0.77 for Pb, 0.79 for Cu and 0.73 for Zn. The association of perilene with combustion derived PAH and metals, which can also be produced in forest burning, is an indication that combustion is one of the relevant sources of this compound to the sediments. For the dry season samples, strong correlations were found between 1.7/(1.7+2.6)DMPh and trace metals (Cu, V, Zn, Pb, Cd) which confirm the contribution of forest fires for the pool of trace metals in sediments, especially in such occasions of intense combustion as in late 2005. The same approach applied to a dated core showed that biomass combustion imprint is present in sediments deposited since the end of the 19th century. In general the high values for the ratio Σ3-6 ring PAH/Σ5 Alk PAH series sustain the evidence that combustion is a major source of PAH in the examined sediments.
Seasonal variations of physical and chemical erosion: A three-years survey of the Rhône river (France)

P. OLLIVIER, B. HAMELIN AND O. RADAKOVITCH
CEREGE Aix-Marseille Université/ CNRS.

For obvious logistical reasons, most previous studies on the main world rivers were based on wide scale investigations carried out on short timescales. By comparison, much less effort has been devoted at long term monitoring, as a mean to verify the temporal variability of the average characteristics, temporal trends, and representativity of short-term investigations. Here we report the results of a three years survey (November 2000 to December 2003) of the geochemical composition of major and trace elements in dissolved and suspended matter in the lower Rhône River (France), the largest river of the Mediterranean area. Subsurface water samples were collected in Arles, 40 Km upstream of the estuary, twice a month routinely, and at high frequency during flood events.

We show that the annual average SPM flux of the Rhône River to the Mediterranean Sea (7.25 x 10^6 tons/yr) was largely controlled by the flood events (83% of the solid discharge occurred in less than 12% of the time), and that the precision on the total output flux depends strongly on the precise monitoring of SPM variations during the floods. Chemical budgets have been calculated to discriminate the respective contributions of marine aerosols in rain water, carbonate, silicate and evaporite weathering, as well as anthropogenic inputs.

Our data corroborate previous studies suggesting a strong coupling between chemical and physical erosion fluxes, during the Rhone hydrological seasonal cycle. However, the correlation observed between physical and chemical transport rates is clearly different from that reported on global compilations of annual averages in the largest world rivers.

The steady state model of Gaillardet et al. (1995) has been applied to the chemical composition of dissolved and solid products. We show that the Rhône River exports currently much less material than produced at steady-state by weathering in its watershed. The sediment flux inferred from the steady-state calculation (20 x 10^6 t yr^-1) is on the same order as those estimated in the literature for the nineteenth and the beginning of the twentieth centuries. This unbalance may suggest that the Rhône is under a transient erosion regime following climate change (i.e. significant decrease of the floods frequency). On the other hand, the unbalance may also be due to the trapping of alluvion by the numerous dams on the river and its tributaries.

Abiotic hydrolysis of glucose-1-phosphate adsorbed at the water-goethite interface

R. OLSSON¹, R. GIESLER² AND P. PERSSON¹
¹Dep. of Chemistry, Umeå University, 901 87 Umeå, Sweden (rickard.olsson@chem.umu.se)
²Dep. of Ecology and Environmental Science, 901 87 Umeå, Sweden

Phosphorus is essential to organisms. In the environment it occurs mainly as inorganic phosphates or as organophosphates. Due to the high reactivity of the phosphate group, these interact strongly with environmental particles. In order to make the phosphate in organophosphates available for uptake by organisms, hydrolysis is usually required. This process may be mineral-surface-mediated (abiotic) or enzymatic (biotic).

Glucose phosphate is one of the dominant components of the natural organophosphate pool [1]. The aim of the present work is to study the interactions between glucose-1-phosphate and goethite, with respect to adsorption characteristics and the role of the mineral surface in the abiotic hydrolytic process. The work was done in series of batch experiments, measuring ligand adsorption as a function of pH and time. The concentrations of the hydrolytic products glucose and phosphate were also measured. ATR-FTIR spectroscopy was used to evaluate the surface speciation of glucose-1-phosphate. Kinetic data will be presented which show the pH dependent surface-promoted hydrolysis, and these will be discussed in combination with molecular-level results obtained by ATR-FTIR spectroscopy.

Arsenic is a toxic metalloid involved in important health issues due to the contamination of water resources. High arsenic concentrations typically derive from the breakdown of As-bearing Fe-oxides, particularly under anaerobic conditions. A variety of microorganisms influences arsenic mobility using oxidation, reduction, and methylation reactions that strongly control arsenic speciation in the environment. In the present study, *Shewanella putrefaciens* strain ATCC 12099, an iron-respiring bacterium, was incubated under anaerobic conditions with As(V) ions, As(V)-bearing lepidocrocite, or a lepidocrocite without arsenic. Results show that strain ATCC 12099 is capable of reduction of HAs(V)O₄²⁻ to H₃As(III)O₃ when the former oxoanion is dissolved in solution (at pH 7.8), or when it is adsorbed onto the surface of lepidocrocite. Cultures in which lepidocrocite was used as the sole electron acceptor led to the formation of biogenic hydroxy carbonate green rust prior to ferrous carbonate hydroxide. In contrast, when the electron acceptor was As(V)-bearing lepidocrocite, XRD analysis revealed ferrous carbonate hydroxide to be the dominant reaction product; no green rust formation was observed in this case. As K-edge XANES spectroscopy indicated that all As(V) (K-edge(max) = 11875eV) was reduced to As(III) (K-edge(max) = 11871.3eV). These results suggest the presence of As(III) either on the surface of ferrous carbonate hydroxide, and/or in another ferrous-solid phase, and they show for the first time bacterial reduction of hydroxy carbonate green rust.

Nd Isotopic Constraints from the 3.8 Ga Nuvvuagittuq Greenstone Belt for the Degree of Depletion of the Early Earth’s Mantle

JONATHAN O’NEIL¹, DON FRANCIS¹ and ROSS K. STEVENSON²

¹Earth & Planetary Sciences, McGill University, Montreal, Quebec, Canada, H3A 2A7 (oneil_jo@eps.mcgill.ca; donf@eps.mcgill.ca)  
²GEOTOP-UQAM-McGill, PO Box 8888, St. Centre-ville, Montreal, Quebec, Canada, H3C 3P8 (stevenson.ross@uqam.ca)

Rare occurrences of Eoarchean mantle-derived crust provide the only compositional and isotopic constraints on the early crust-mantle differentiation of the Earth. There is currently considerable debate about the implications of the Nd isotopic compositions of such early Archean mantle-derived rocks. The relatively high positive initial εNd values obtained on Eoarchean rocks (Nulliak Assemblage, Labrador, Canada; Amitsok Gneisses, Akilia and Isua supracrustal assemblages, SW Greenland) are interpreted to indicate derivation from a mantle source already strongly depleted in the Eoarchean, implying that significant volumes of continental crust had formed early in the Earth’s evolution. Here we present the Nd isotope data of the newly discovered ca. 3.8 Ga Nuvvuagittuq greenstone belt (Northern Québec, Canada), and discuss their implications for early mantle depletion.

The Nuvvuagittuq greenstone belt contains numerous ultramafic and gabbroic sills. Most of the gabbro and ultramafic samples display positive εNd (3.8Ga) values ranging from -1.8 to +3.9, with an average of +1.3 ± 0.2 in 29 samples. The few samples that yield εNd (3.8Ga) values > +3 (up to +3.9) suggest that they may have been derived from a mantle source that had already experienced an extensive trace element depletion well before 3.8 Ga, equivalent to that seen in the present-day MORB source. Such a degree of depletion of the early Archean mantle, however, is not supported by the flat to slightly LREE-depleted profiles of the gabbros. Furthermore, whole rock analyses for a series of samples from an ultramafic sill and a second series of samples from a gabbroic sill fall along ~3.8 Ga isochrons with initial εNd values of +1.3 and +2 respectively, values which are similar to the mean of all the individual sample values. This suggests that the few higher εNd (3.8Ga) values are either anomalous or indicate heterogeneity of the mantle source of Nuvvuagittuq’s rocks. Nevertheless, the Nd isotopic compositions of these mantle-derived rocks suggest that the degree of depletion of the mantle recorded in the Nuvvuagittuq greenstone belt is not as extreme as that indicated by the Nd isotopic compositions of the 3.8 Ga SW Greenland rocks.
Using $\delta^{30}{\text{Si}}$ to follow the soil-plant Si cycling in a weathering sequence of volcanic ash soils, Cameroon

S. Opfergelt$^{1,2}$, B. Delvaux$^1$, D. Cardinal$^2$ and L. André$^3$

$^1$Université catholique de Louvain, Unité Sciences du sol, Croix du Sud 2/10, B 1348 Louvain-la-Neuve (opfergelt@sols.ucl.ac.be)

$^2$Musée Royal de l’Afrique Centrale, Chaussée de Louvain 13, B 3080 Tervuren

Plants take up Si as silicic acid and form phytoliths, a biogenic opal (BSi). This Si bicycling affects the availability of Si for clay formation, and for Si export through waterstreams. Si stable isotopes measurement provides a tool to quantify present and past impacts of plants on the continental Si cycle.

In order to calibrate this proxy, we report on detailed $\delta^{30}{\text{Si}}$ of plants, sand ($>50\mu$m), silt (2-50$\mu$m) and clay fractions ($<2\mu$m), and amorphous Si (ASI) in a weathering sequence of andesitic ash soils from the Mungo area (Cameroon). Plant communities consist of 50 years old banana stands. The soil sequence involves an increasing clay content from young (Y) to old (O) volcanic soils (vs). The $\delta^{30}{\text{Si}}$ values were measured by MC-ICP-MS Nu Plasma in medium resolution, operating in dry plasma with Mg doping: $\delta^{30}{\text{Si}}$ vs NBS28 $\pm 0.07‰$ ($\pm 1σ$).

Compared to fresh andesitic ash (-0.39‰), clay fractions displayed a gradient from -1.19‰ in Yvs to -1.62‰ in Ovs, thus confirming the trend of lighter isotopic compositions with increased weathering. The isotopic signatures of silts fractions (-0.44‰ in Ovs, -0.03‰ in Yvs) compared to clay fractions support that $\delta^{30}{\text{Si}}$ may reflect the ratio between primary and secondary minerals. ASI fractions (involving phytolith-rich BSi, volcanic glasses, and allophane constituents) were heavier in surface horizons than at depth ($\Delta^{30}{\text{Si}} = +0.34‰$), in agreement with the surface accumulation of phytoliths. Indeed, banana plant isotopic compositions were +0.10 and +0.55‰ respectively in Yvs and Ovs. Moreover, ASI were lighter in Yvs (-0.38‰) than in other soils (+0.44‰) pointing to a larger effect of phytoliths in ASI of weathered soils, devoid of volcanic glasses. Surrounding river waters in this area were very heavy (+1.20‰).

Our $\delta^{30}{\text{Si}}$ data thus support that plants can induce a strong isotopic imprint by rejecting phytoliths to soil surface. Numerous and successive plant cycles leading to phytolith accumulation would gradually produce a heavier signature in dissolved Si export. This plant impact was underestimated until now. It may have considerable implications on the understanding of the Si continental cycle and the quantitative assessment of Si transfer from land to sea and ocean.
Influence of acid mine drainage on aquatic life at Sar Cheshmeh copper mine

S. ORANDI¹, A. YAGHUBPUR², H. SAHRAEI AND M. BEHROUZ¹

¹Water and Environment Researchs Department, Sar Cheshmeh Copper Deposit, Kerman, Iran (orsa00@yahoo.com)
²Department of Geology, Tarbiat Moallem University, Tehran, Iran. (ayaghubpur@yahoo.com)

Introduction
Investigations on impact of waste dumps on producing of acid mine drainage at Sarcheshmeh copper mine showed a pH range of 3 - 5.5, which increase the concentration of some toxic heavy metals (Cu, Zn, Pb, As, Cd, Se, Sb …) higher than the permitted standard limits (WHO). In such degraded water some of dominant microorganisms are able to survive. The fungi (Geotrichum sp. & Aspergillus sp.), bacteria (Pseudomonas sp. & Tiobacillus sp.) and non-bacterial microorganisms (green algae) were recognized in some of acidic drainages. A kind of filamentous green algae, tolerant to acid and high dissolved elements observed. The genus of mentioned algae is Ulothrix and species is Gigas, without antimicrobial and antifungal properties. These algae are present in drainages with high total dissolved solids (TDS≈1800 ppm) and acid conditions to pH 3.

Discussion of results
This research suggest the level of acidity, type of dissolved elements and the secondary minerals formed on substrate, all are important factors in distribution of these algae. Field data show the prolific growth of Ulothrix between pH 3 – 4.5. The colloidal conditions, in particular the presence of suspended iron and aluminium, prevent the growth of them. Sampling and Chemical analysis of algae for some heavy metals (Cu, Zn, Pb, As, Sb, Cd, Se, Mo) showed the high absorption of some heavy metals (Cu 3500ppm, As 5000ppm…) to manifold in compare with soil and water samples, against their less tendency to absorption of Cd (10ppm). The bacteria especially Pseudomonas may strongly impact environmental conditions in acid mine drainages.

Conclusions
The natural presence of these algae in acid mine drainage is a factor to remove heavy metals in this mine. Further works to determine natural contributions of these algae and bacteria to mitigation of poor water quality is under investigation.

Jarosite/alunite are observed in superegen (sulfate zone of gossans) or in hydrothermal environments [1,2]. These hydroxysulfates, which were also detected on the Martian surface, can be formed abiotically [1,3] or biotically [4]. In the light of this discussion, carbonaceous matter (CM)-rich Archean cherts (0.5wt Corg., 3.5 Ga) from Marble Bar Drill core #1 (~75m depth) were studied. They represent a silt to fine sand-sized volcanoclastic silificed sediments crosscut by micro-quartz veins. CM occurs diffuse or as aggregates in the micro-quartz matrix, in pyrite, associated to Fe-oxides or as patches in quartz veins. The Raman spectra of CM show a crystallinity compatible with a temperature of at least 300°C. The black cherts, S (~3.8 wt.%) and Fe 2O3 (4.8 wt.%) rich, contain pyrite, but also sphalerite, galena, chalcopyrite, Ni-Fe-arsenides and Fe-oxides. Large pyrite grains (~100 µm) have irregular rims often characterized by nanometric pyrite spherules. When showing euhedr al grain boundaries, pyrite is rimmed by muscovite. FIB-TEM investigations show that these pyrites are composed of nano-poly- and single crystals, containing traces of Ni, As, Pb and variable Si contents. A nanofilm of amorphous carbon occurs at the interface between pyrite and muscovite. Muscovites contain N (550 ppm) and C (250 ppm) and are non-stoichiometric. The non stoichiometry is related to the presence of nanometric Fe-(K-Na)-sulfates (jarosite/alunite) indicating local acidic-oxic conditions. A hydrothermal origin and temperatures of about 300°C for these sulfates is favoured as shown by low-angle boundaries at nanoscale in micro-quartz grains and the maturity of CM.

Hercynian gabbroic intrusions from the Spanish Central System: Constraints on mantle composition under central Spain

D. Orejana1, C. Villaseca1, J.A. López-García2, C. Pérez-Soba1 and K. Billström3

1Department of Petrology and Geochemistry. Complutense University of Madrid. Spain. (dorejana@geo.ucm.es)
2Department of Crystallography and Mineralogy. Complutense University of Madrid. Spain.

Small basic to intermediate intrusions are scarce within the Spanish Central System (SCS), outcropping among abundant coeval peraluminous granitoids. Although mixing with granite magmas is very common, in this study we only deal with the most primitive basic rocks. They range from norites to olivine gabbro-norites, with some Amph-Phl-rich varieties.

Major and trace element composition suggests a low degree of magma differentiation (Mg# = 0.52-0.75; Cr = 96-1170 ppm), though some Cr-Spl + Ol fractionation might have occurred. K2O content is in the range 0.73-2.82 wt% and a medium-K to high-K calc-alkaline affinity is observed. Their sub-alkaline nature argues against their inclusion in the appinite suite, as previously suggested.

Although two groups of gabbros may be distinguished according to LILE-U-Th concentrations, these rocks show high LREE and LILE concentrations in general, indicative of an enrichment event in the mantle source. Their chondrite and primitive mantle normalised multielement plots show negative Nb, Ta and Ti anomalies and positive Pb anomalies, suggesting involvement of subduction-related fluids or crustal recycling. These patterns resemble those of continental arc-related gabbros, but with lower Ba-Sr contents.

Their Sr-Nd isotopic signatures display a slightly enriched composition close to BSE (εNd = -2.6 to 0.7; 87Sr/86Sr = 0.7045-0.7063). This is also shown by other SCS gabbroic intrusions (e.g. Bea et al., 1999). The short isotopic compositional range suggests the lack of significant crustal assimilation during emplacement. Pb isotope ratios of gabbros also define a small compositional field, similar to SCS granitic rocks. The presence of two gabbro types might be related to variable mineral modes in the mantle sources.

The late-Hercynian mantle under central Spain has been proved to show an heterogeneous composition (Villaseca et al., 2004). This new dataset reinforces that conclusion and points to the involvement of a recycled crustal component into their mantle sources.

Breaching the North African watershed: Driver for Mediterranean anoxia?

A. Osborne¹, D. Vance¹ and E. Rohling²

¹Department of Earth Science, University of Bristol, UK; (anne.osborne@bristol.ac.uk; d.vance@bristol.ac.uk)
²National Oceanography Centre, Southampton, UK; (e.rohling@noc.soton.ac.uk)

Quaternary climate change in North Africa appears to drive periodic changes in the redox chemistry of the Eastern Mediterranean, and such interactions may also be of importance for the interpretation of wider ocean anoxia. Deep Mediterranean anoxia is associated with negative oxygen isotope anomalies and the timing has been linked with northward shifts of the Inter Tropical Convergence Zone (ITCZ) and intensification of the African monsoon during Northern Hemisphere insolation maxima [e.g. 1]. These observations have led to the hypothesis that an increased flux of freshwater to the Eastern Mediterranean was a major contributing factor to the changes in deep ocean chemistry. Nd isotopes have previously been used to support a distinct increase in Nile discharge during the central periods of sapropel S1 (~9-6 ka BP) and S5 [2]. However, a Nile source alone cannot account for the entire duration of S1 and S5 (~125 ka BP) deposition. We present new evidence of a wider North African margin source of freshwater at the time of S5 from Nd isotopes in the Western Levantine and from Quaternary lake deposits in Libya.

A large oxygen anomaly of ~ -4‰ is observed across S5 in ODP core 971A from the western Ionian Sea [3]. This anomaly is much greater than that recorded in cores from close to the Nile outflow (~ -2‰) [3]. Our data from 971A show a distinct change in the εNd of planktonic foraminifera (G. ruber) towards more radiogenic values across S5. Analyses of gastropod fossils from Quaternary lake deposits in Libya also give a radiogenic Nd signal (εNd ~-2), as expected of waters rising in the range of basaltic mountains comprising the North African watershed at ~ 21°N.

These data support the hypothesis that a northward movement of the ITCZ breached the North African watershed during Northern Hemisphere insolation maxima and contributed freshwater to the Mediterranean basin. Further investigation is needed to determine the importance of this contribution in the development of anoxia, relative to Nile inputs.

Oligomerization of amino acid on mineral surface under the pH controlled conditions

Y. Ota, T. Sato and S. Tamamura

Graduate School of Engineering Hokkaido University, Japan (yukieota@eng.hokudai.ac.jp)

The role of mineral surfaces as a catalyst on the oligomerization of the amino acid, glycine, during wetting and drying cycles was investigated. Several types of montmorillonite with different interlayer cations (H, Ca, Na) and silica (quartz type) powder (10 mg) were suspended with 10 mM amino acid solution (1 ml) under pH controlled conditions. The suspensions were dried at 95°C to simulate the drying step, while addition of distilled water represents the wetting step. These wetting and drying steps were performed in several repetitions.

Amino acid oligomerization proceeded more favourably in silica as a catalyst at its point of zero charge (PZC) near pH 2.6 (Figure 1). The peptide yield was subsequently reduced under more acidic condition (i.e. pH 2) due to excess positive charges of both silica surface and amino acid ions – exerting an inhibiting effect on amino acid adsorption. At the PZC of montmorillonite and glycine (pH 6.0), the catalytic efficiency of minerals was reduced due to zwitterions forming which has a low reactivity for glycine (Zamaraev et al., 1997). The catalytic influence of minerals on amino acid oligomerization is largely influenced by the surface charge of the minerals.

Mechanism of Cr\(^{6+}\) immobilization in different soils

K. OTOMO AND N. SHIKAZONO

Laboratory of Geochemistry, Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi 3-14-1, Yokohama 223-8522, Japan (k-otomo@dance.ocn.ne.jp; sikazono@applc.keio.ac.jp)

We carried out experimental studies on the changes of Cr\(^{6+}\) concentration in the solutions with different pH which were reacted with different soils containing large amount of Cr\(^{6+}\) (1,000ppm) at room temperature. Soils used for the experiments include Kanto loam (weathered basaltic soil), weathered acidic soil and kaolinite bearing soil derived from weathered granitic rocks. The results obtained from the study indicated that Cr\(^{6+}\) released within a very short period (three minutes), but it decreased rapidly with time when the Kanto loam soil was used in the experiment and in this case the Cr\(^{6+}\) concentration in the solution (after 3 minutes) was 0.36 µg mL\(^{-1}\). This decrease may be due to the reduction of Cr\(^{6+}\) by Fe\(^{3+}\) in the soil. Therefore, this study suggests that the basaltic weathered soil (Kanto loam soil) is very useful material for the immobilization of Cr\(^{6+}\) from the soils and sediments.

Noble gases in Frontier Mountain ureilites

U. OTT\(^1\), L. FRANKE\(^1\), H.-P. LÖHR\(^1\) AND K.C. WELTEN\(^2\)

\(^1\)Max-Planck-Institut für Chemie, Abteilung Geochemie, Joh.-J.-Becher-Weg 27, D-55128 Mainz, Germany (ott@mpch-mainz.mpg.de)
\(^2\)Space Sciences Laboratory, University of California, Berkeley, CA 94720-7450, USA (kcwelten@berkeley.edu)

Introduction. We report results from noble gas analyses of four ureilites from the Frontier Mountains area, Antarctica. These noble gas data complement cosmogenic radionuclide data obtained by [1] thus shedding light on the cosmic ray exposure history of these meteorites. Of interest are also the trapped noble gases, since ureilites represent a unique class of achondritic meteorites with high abundances of carbon and trapped noble gases.

Cosmogenic noble gases. Results are summarized in Table 1. FRO 90036 and FRO 90054 may be paired, with a common GCR exposure age of ~ 9 Ma. They may belong to an extensive shower as indicated by radionuclides of additional FRO ureilites [1]. FRO 97013 and FRO 01030 are separate falls. While the latter has an exposure age of ~ 4 Ma, the former was irradiated under high shielding and possibly received the bulk of its exposure on the parent body.

Trapped noble gases. Trapped Ar, Kr and Xe abundances are listed in Table 2. Most remarkable are the low (compared to other ureilites) abundances in FRO 90054 – in line with its very low reported carbon content [2] - and the very high Ar/Xe and Kr/Xe ratios of FRO 01030, which even exceed those for the previous record holder Goalpara [3].

Evolution of anoxic aquatic systems under urban environments: Case of "Lac Sud" Tunisia

N. OUERTANI, R. HAMOUDA AND H. BÉLAYOUNI
Faculté des Sciences de Tunis, Département de Géologie, Laboratoire de Géochimie organique (nizarouertani@yahoo.fr)

The "lac sud" of Tunis, is an anoxic confined environment evolving under the direct control of an urban environment that affects him to various degrees (Didyk, B.M., et al 1978).

The quantitative and qualitative study of the organic matter contained in surface sediments, by the determination of the total organic carbon (TOC), the free and potential hydrocarbon compounds (S1 and S2), the total hydrocarbons and specially the saturated fraction (analyzed by gas chromatography) permit to distinguish 3 principal zones in the lake characterized by various degree of anoxia.

The western zone is characterised by an advanced and irreversible anoxic state, with an exceptional rate of conservation of organic matter (TOC > 6 %) and an exceptional enrichment in hydrocarbon compounds of biogenic and anthropological origin (HT > 2033 ppm).

The zone situated in the east of salt works is characterized by anoxic state less accentuated with a rate of organic matter conservation (TOC < 3 %) and a total hydrocarbon content (HT < 820 ppm), less important. Hydrocarbons present are of mixed origin continental and marine (Jaffé R. et al 2001).

Finally, in the central and north-eastern zone the anoxic state is in way of installation, the contents in organic matter and in total hydrocarbons are the weakest.

In addition, the analysis of the lipidic fraction allowed to show that the whole system is under direct influence of the urbanization (Medeiros P.M. and Bicego M.C., 2004). The development of the anoxia in preferential zones of the lake is evolution of aquatic systems in urban environments must be considered with a lot of interest to avoid the risk of controlled by the low reactivity of organic matter of anthropological origin.reaching an irreversible state.

In situ geochemical data from metamorphic rocks in the active Mariana subduction zone

S. PABST1, T. ZACK1, I.P. SAVOV2, D. ROST3 AND E.P. VICENZI3

1Mineralogisches Institut, Universität Heidelberg, Germany (spabst@min.uni-heidelberg.de)
2DTM, Carnegie Institution of Washington DC, USA
3Department of Mineral Sciences, Smithsonian Institution, Washington DC, USA

The active serpentine mud volcanism of the Izu-Bonin-Mariana (IBM) forearc exposes variably serpentined harzburgites and blueschist-facies mafic fragments to the ocean floor. The latter indicate that some of the fragments are derived from depths corresponding to the slab-mantle interface (20-40 km), i.e. between the actively subducting Pacific oceanic crust and the IBM subarc mantle.

In the past, only a few blueschist-facies mafic fragments (up to several cm in diameter; [1]) were analyzed petrologically in great enough detail. For example [1] estimated that PT-metamorphic conditions for key mineral assemblages (lawsonite + quartz, aragonite, lawsonite + pumpellylite) reveal low temperatures (150-250 °C) at pressures reaching 0.5-0.6 GPa. But to date, no in-situ trace element data exist on mafic blueschist-facies clasts from any serpentine mud volcano.

We will present abundant petrological descriptions of several newly discovered mafic fragments from the South Chamorro Seamount, ODP Leg 195. The mineral assemblages of the blueschist-facies clasts include (a) Na-amphibole + chlorite ± apatite ± sphene ± spinel ± rutile, (b) Na-amphibole + chlorite ± sphene ± rutile ± epidote ± allanite ± chlorite ± spinel ± pumpellylite ± pyroxene (Acm-Di-Jad) ± zircon, (c) chlorite ± epidote ± allanite ± Na-amphibole ± sphene ± garnet ± Fe-oxide ± rutile ± apatite and (d) phengite + Na-amphibole + chlorite ± spinel. Albite and quartz are always absent.

For studying the light elements boron and lithium we used Time-of-Flight SIMS imaging capability with a µm-scale resolution. Our multi-element maps with high spatial resolution show that in the shallow subducted slab Li resides in phengite ≥ chlorite > amphibole and that boron preferentially resides in both phengite and chlorite. SIMS analyses verify the high concentration in B and Li in these phases (with ~35 µg/g B and ~80 µg/g Li in phengite). Interestingly our images also show that boron is strongly enriched in parts of chlorite, possibly due to B remobilization from circulating fluids. Thanks to the high concentration of B in phengite and chlorite, we will measure 11B by SIMS and evaluate existing models of early B-release and subsequent isotope fractionation by forearc slab fluids.

Topographic and hydrologic controls of spring water travel times and plagioclase weathering rates in solid rocks

F.A.L. PACHECO1 AND C.H. VAN DER WEIJDEN2
1UTAD, Vila Real, Portugal (fpacheco@utad.pt)
2Utrecht University, The Netherlands (chvdw@geo.uu.nl)

Two sets of springs, one associated with watersheds on average smaller than 10 ha (short hydraulic circuits) and discharging 10 L/min and the other linked to watersheds on average larger than 50 ha (longer circuits) and discharging 24 L/min, were selected for this weathering study in North Portugal. Using hydrograph analysis methods it could be calculated for the first set (30 springs from the Sordo river basin, characterized geologically by granites and schists), hydraulic conductivities $K = 2 \times 10^{-6}$ m/s and drainable porosities $n_e = 5 \times 10^{-2}$, which were found to be 4 and 5 times larger than the $K$ and $n_e$ values of the second set (14 springs from amphibolites of the Morais massif). Subsequently to the estimation of $K$ and $n_e$, hydrologic travel times ($t$) were determined by a numerical (finite differences) method assuming the system to be at steady-state and the transport of solutes to be advective. In the Sordo basin $t = 3.7$ yr whereas in the Morais massif $t = 13.6$ yr. The conclusion was: the longer paths in Morais conducted amphibolite water deeper into the fractured massif, where $K$ and $n_e$ were smaller, and as result longer times were necessary to complete the corresponding hydraulic circuits. The hydrograph analysis methods also produced numbers for the surface area of plagioclase ($A_{Pl}$, m$^2$) reacting with aquifer water in unit time (1 yr), while concentrations of dissolved plagioclase at spring site ($[\text{Pl}]$, mol/L) were determined by the SiB Algorithm [1]. Finally, plagioclase weathering rates ($W_{Pl}$, mol/(m$^2$.s)) were calculated by the formula: $W_{Pl} = [\text{Pl}]/t \times V/A_{Pl}$, where $V$ is the volume of groundwater with steady-state concentration $[\text{Pl}]$ that discharges at the spring site in unit time. The weathering rates span three orders of magnitude on a secular basis (Fig. 1). The drop in the rates follows a power function described by $W_{Pl} = 1.5 \times 10^{-13} \times t^{-1.37}$, suggesting control by transport-limited reaction. A similar power function was used by [2] to describe silicate weathering.

Solar nebular fractionation of refractory elements Y and Ho

ANDREAS PACK1 AND SARA S. RUSSELL2
1Geowissenschaftliches Zentrum, Universität Göttingen, Goldschmidtstraße 1, D-37077 Göttingen, Germany (apack@uni-goettingen.de)
2Department of Mineralogy, The Natural History Museum, Cromwell Road, London, SW7 5BD, UK

The geochemical twins Y and Ho are both trace elements in chondrites and most of their components. Both are highly refractory and condense at high temperatures. No or only little fractionation between Y and Ho is expected in igneous or metamorphic processes. This makes the Y/Ho-ratio a suitable tracer for chemical heterogeneity in solar nebula reservoirs. We report Y/Ho-ratios of CAIs, chondrules and bulk chondrites.

Bulk samples were fused by means of a containerless technique to small (~2 mm) sheres, which were embedded into resin for EPMA and LA-ICPMS.

Fusion in combination with LA-ICPMS allows determination of Y/Ho-ratio with a relative error $<0.5\%$ (2$\sigma$). CCs (C11, CM2, CV3, CK4) have uniform Y/Ho $= 25.94 \pm 0.08$ (2$\sigma$). LL-, L-, H- and E-chondrites have increasingly elevated Y/Ho-ratios (see figure).

CCs have a Y/Ho-ratio that is suggested to represent the ratio of the solar system. Elevated Y/Ho-ratios of OCs and ECs are interpreted as result of loss of a fractional condensate with subsolar Y/Ho. This component may have been similar to CAIs with Group-II REE patterns, which have subsolar Y/Ho. Removal of fractional condensates may also be responsible for elevated Re/Os in ECs relative to CCs. Data of terrestrial rocks (herzolite, basalt) show that partial melting fractionates Y and Ho. The bulk Earth is suggested to have a solar Y/Ho-ratio, which excludes ECs as parental material to the Earth.

Figure 1: Relation between weathering rates and time.
Atypical SHRIMP II REE data in zircons: A positive Eu anomaly

I.P. PADERIN1, L.E. MORDBERG1, V.R. VETRIN2, B.V. BELYATSKI3 AND S.A. SERGEEV1

1Centre of Isotopic Research, VSEGEI, St.Petersburg, Russia (paderin@vsegei.ru)
2Geological Institute, Kola Scientific Center, RAS, Apatity (vetrin@geo.ksc.apatity.ru)
3VNIIOkeangeologia, St. Petersburg, Russia (bbelyatsky@mail.ru)

Distribution of REE depends on some factors:
- temperature and pressure of melt
- interaction with enclosing strata
- sequence of crystallization
- crystalchemistry of the host mineral

Enrichment in HREE as well as depletion in LREE with contrast negative Eu and positive Ce anomalies are typical for zircon structure in common case (fig.1a).

Unusual REE distribution patterns were recorded in zircons at recent investigations. They show a positive Eu anomaly with portion of LREE enrichment (fig.1b).

**Figure 1:** Chondrite normalised REE patterns: a. typical for zircon; b. atypical REE distribution.

Such REE distribution patterns were observed in the following cases: 1) in zircons from low crustal eclogitic xenoliths from an eruption pipe at Elový Island (White sea), 2) in zircons form Kalaknda massif granulites (Kola peninsula), 3) in zircons from Antarctic alkaline pegmatites. The U-Pb data show the discordant ages of these zircons as well as high magnitude Th/U ratio variation. Thus, the effects of REE pattern deviations are connected with metasomatic and metamorphic processes. These influences have an effect in Eu and LREE increaseng. Hence, these REE patterns could be considered as secondary processes affecting.

Laser ablation study of trace elements in chromite: Thetford Mines ophiolite chromitite ores

PHILIPPE PAGE1, SARAH-JANE BARNES2 AND RICHARD COX3

1Université du Québec à Chicoutimi, Sciences de la Terre, 555, boulevard de l’Université, Sagueneay, PQ, G7H 2B1, Canada (Philippe_Page@uqac.ca)
2Université du Québec à Chicoutimi, Sciences de la Terre, 555, boulevard de l’Université, Sagueneay, PQ, G7H 2B1, Canada (Sarah-Jane_Barnes@uqac.ca)
3Université du Québec à Chicoutimi, Sciences de la Terre, 555, boulevard de l’Université, Sagueneay, PQ, G7H 2B1, Canada (Richard_Cox@uqac.ca)

This study aims to identify compositional contrasts between chromitite ores from the Thetford Mines Ophiolite (TMO), Canadian Appalachians, which contains more than 30 chromitite deposits grouped into 3 principal types, and to better understand the mechanisms of their formation.

The 3 types of chromitite are: 1) podiform chromitite found in mantle peridotite, 2) stratiform chromitite from rocks formed at the base of the crust, and 3) intracrustal discordant chromitite close to, or in crustal pyroxenites. Fractional crystallization, magma mixing, country rock assimilation, melt-rock reaction, or a combination of these processes have been proposed as important in chromitite formation. There is also a relationship between chromitite deposits and platinum-group elements (PGE) deposits.

Chromitite deposits from ultramafic-mafic layered intrusions are frequently associated with high concentrations of PPGE (Rh, Pd, Pt). Ophiolite chromitite deposits contain intermediate levels of IPGE (Os, Ir, Ru) and laser ablation analysis of PGE in chromite allows us to verify that these elements are not incorporated in chromite structure (solid solution) with the exception of Ru with concentrations from 38 to 134 (± 20) ng/g. The high PGE concentrations of ophiolite chromitites are principally related to the observed platinum-group minerals (laurite – erlichmanite series) included in chromite grains.

Our trace element analysis include Mn, Ni, Co which appear to have reequilibrated with the olivine of host dunite rocks as have Fe and Mg, therefore it is difficult to determine whether fractional crystallization or contamination (magma mixing or host rock assimilation), processes trigger chromite precipitation. On the other hand, our preliminary analysis of Ti, V, Ga and Zn, which are less sensitive to reequilibration with olivine, show an evolutionary trend compatible with fractional crystallization (negative correlation with Cr#).

Our trace element analysis include Mn, Ni, Co which appear to have reequilibrated with the olivine of host dunite rocks as have Fe and Mg, therefore it is difficult to determine whether fractional crystallization or contamination (magma mixing or host rock assimilation), processes trigger chromite precipitation. Equilibration of the Earth-Moon system following the giant impact

KAVEH PAHLEVAN AND DAVID J. STEVENSON
Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, USA
(kaveh@gps.caltech.edu, djs@gps.caltech.edu)

The energy released in the Moon-forming giant impact is sufficient to melt and partially vaporize both the Earth and the impactor. The timescale to eliminate this heat by radiation is \( \sim 10^3 \) years. Hence, the Earth and protolunar disk are expected to be molten and enveloped by a convecting silicate vapor atmosphere for the first thousand years following the giant impact.

To explain the striking similarity of the oxygen isotopic composition of the Earth and Moon [1], we have previously proposed that the terrestrial magma ocean and the protolunar magma disk underwent equilibration in the aftermath of the giant impact through exchange with the common silicate vapor atmosphere [2]. Recent support for this idea comes from precise measurements of silicon isotopes that reveal the Moon to have a composition similar to the silicate Earth, a property not shared with Mars, Vesta, and chondrites [3].

Due to the liquid/vapor partitioning of the elements [4], such a model does not imply a chemical composition for the Moon that is identical with the silicate Earth. The ability of the vapor to exchange between the Earth and lunar disk, to undergo more vigorous turbulent motions than the liquid, and to preferentially escape in a hydrodynamic outflow will effect the chemical composition of the resulting Moon. We are presently undergoing an investigation of the consequences of the equilibration hypothesis to explore the extent to which this scenario can explain the similarities and differences in the Earth-Moon system.

The total Fe content of chondritic meteorites is variable, reflecting separation of metallic iron in the early solar system. Such metal-silicate fractionations should be accompanied by fractionations of Hf from W and, hence, their timing can be studied using $^{182}$Hf/$^{182}$W chronometry. Here we present Hf-W and bulk chemical data of large, homogenized samples for various groups of chondrites with the ultimate goal to date the metal-silicate fractionation in the early solar nebula. Both, Hf/W and $^{182}$W/$^{184}$W ratios increase in the order of H-L-LL chondrites, as expected from the abundance of metal in these chondrites. However, there are substantial variations in the Hf/W ratios within the H and LL chondrite groups, which may indicate W mobility during parent body processes. These currently hamper precise dating of the Hf-W fractionation among the chondrites. All LL chondrites studied here (including type 3) plot below the CAI isochron [1], suggesting that the Hf-W fractionation, i.e., metal silicate separation post-dated formation of CAIs by a few Myrs. More data, particularly for the most primitive chondrites are needed to confirm this observation. An important aspect of our new data is that H chondrites, on average, have lower Hf/W ratios than carbonaceous chondrites, whereas L chondrites have Hf/W ratios indistinguishable from carbonaceous chondrites [2,3]. This is unexpected given the fact that H chondrites have Fe/Mg ratios similar to those of CI chondrites, but L chondrites have lower Fe/Mg ratios. This and the relatively low W contents in metals from type 3 ordinary chondrites [4,5] could indicate that a significant part of the W did not condense as metal. If this is true, conditions in the chondrite formation region must have been rather oxidizing.

Lead origin and fate in soils:
Geochemical records in buried soils over the past 3500 years

T. PAMPURA1, V. DEMKIN1 AND A. PROBST2

1Institute of Physicochemical and Biological Problems in Soil Science RAS, Russian Federation, (pampura@mail.ru)
2Laboratoire d’Ecologie Fonctionnelle (ECOLAB), ENSAT/CNRS, France (anne.probst@ensat.fr)

Methods
The effect of climate fluctuations and anthropogenic impact on lead origin and fate in Chestnut soils (Low Volga region, Russia) over the past three and a half millennia has been investigated. We compared the morphology, organic matter, soluble soil, gypsum, carbonates, total lead content and Pb isotope ratios in the profiles of modern soils and soils buried under the burial mounds, dated using archaeological methods. Buried soils form a chronological sequence from XVI-XV centuries BC till nowadays.

Results and discussion
Comparison of buried soils and their modern analogues demonstrated that during the past 3500 years the cyclic reversible changes of climate took place in this region. Drought epoch had started 4500 years ago with maximum between 2000 BC and 3000 BC. The most moist climate conditions were found in XII-XIV cent.

We observed an increase of total lead concentration in upper soil horizon along soil chronological sequence probably reflecting a growing anthropogenic input of lead. However the difference in total lead content and isotope ratios between modern and buried soils is statistically significant only for soils buried before the middle ages. Lead isotope ratios in upper horizons of modern soils ($^{207}$Pb/$^{206}$Pb and $^{208}$Pb/$^{206}$Pb) fit to European Standard Pollution Line and Russian-GDR gasoline line (Haack et al., 2003), reflecting the influence of airborne Pb, deposited from a continent-wide mixing system or local sources of Pb-gasoline.

Financial support was provided by the Russian Foundation of Basic Research (grant 06-05-65307a).
Evolution of Manzanillo batholith Complex: Structural data, thermobarometry and geochronology

M. PANSERI1, A. TUNESI1, P. CORONA-CHAVEZ2 AND M. BERGOMI1
1Università degli studi di Milano Bicocca, Milano, Italia (matteo.panseri@unimib.it)
2Università degli studi di Milano Bicocca, Milano, Italia

The Manzanillo batholith Complex (MBC) occurring along the south-western shores of Mexico is related to the Latest-Cretaceous convergence between the Farallon and North-America plates. The MBC is composed of metalluminous granodiorite and granite, with a gabbro-diorite core, which intruded into the Cretaceous volcano-sedimentary arc sequences of the Guerrero terrane.

Structural, geochemical as well as SHRIMP U/Pb zircon geochronology data suggest that the MBC is a composite batholith and it was formed by several magmatic bodies. They were emplaced at different depths and different times ranging from 74 to 62 Ma: five Granite Complexes (GCs), a Granodiorite Complex (GrdC) and a Gabbro Complex (GbC).

i) The main rock-type is a medium grain size granite associated with minor granodiorite and porphyry dikes (GrCs). They are typically calc-alkaline and relatively K-enriched. The oldest granitic complex was emplaced 74 Ma ago and the depth emplacement ranging between 6 and 12 km.

ii) Grain coarse Granodiorite Complex (GrdC) shows a discrete internal foliation and it is compositionally homogeneous with LILE enrichment, fractionated LREE with a distinct negative Nb anomaly and flat HREE patterns. It apparently was emplaced at shallow crustal level (< 2.8 kbar) and at 62 Ma ago.

iii) Massive gabbros and minor isolated small cumulitic bodies (associated with brown Am replacing Cpx) and diorite rocks constitute the Gabbro Complex (GbC), which occurs essentially in the central part of the MBC. GbC magmatic textures are preserved apparently in place, but locally subsolids reactions and plastic deformation are observed. Near the contact between the GrdC and GbC the gabbros are affected by melt infiltrations with a growth of Bt, Qtz, Kfs. Pl presents rounded and corroded rims. GbC is slight older (68 Ma) and deeper than GrdC.

On the basis of field, geochemical and geochronological data we argue that GbC intruded at about 15 km depth and successively was affected by subsolids recrystallization and deformation before or during fast uplift. Chemical composition support a fluid slab-related contamination and a tectonic emplacement at shallow crustal levels for these bodies.

High primary productivity in stromatolitic phosphorites from the Paleoproterozoic Aravalli Supergroup

D. PAPINEAU1, R. PUROHIT2, P. MEHTA2, S.B. SHIREY3 AND M.L. FOGEL1
1Geophysical Laboratory and NASA Astrobiology Institute, Carnegie Institution of Washington, Washington D.C., U.S.A. (dpapineau@ciw.edu; m.fogel@gl.ciw.edu)
2Department of Geological Sciences, M.L. Sukhadia University, Udaipur, Rajasthan, India (ritesh_purohit@rediffmail.com)
3Department of Terrestrial Magnetism, Carnegie Institution of Washington (shirey@dtm.ciw.edu)

Paleoproterozoic biogeochemical cycles were fundamentally changed by glaciations and the accumulation of atmospheric oxygen. Higher levels of seawater sulfate and atmospheric oxygen have been inferred from Paleoproterozoic interglacial sedimentary sulfides with sulfur isotope compositions characterized by large ranges of δ34S values and the absence of mass-independent fractionation (Papineau et al., 2007; Bekker et al., 2004). Carbon isotope excursions in Paleoproterozoic interglacial carbonates from the Transvaal Supergroup and in post-glacial carbonates on most continents indicate high burial rates of organic carbon and suggest a significant production of atmospheric oxygen (Bekker et al., 2001; Karhu and Holland, 1996). Because atmospheric oxygen is primarily produced by oxygenic photosynthesis, these observations suggest enhanced primary productivity during the Paleoproterozoic. This was perhaps modulated by higher nutrient availability in seawater, such as phosphate, which could have resulted from post-glacial greenhouse conditions and accelerated weathering of continental crust.

We present new carbon isotope data from dolomite, carbonate fluorapatite and organic matter in stromatolitic phosphorites from the Paleoproterozoic Jhamarkotra Formation of the Aravalli Supergroup, India. Carbonate fluorapatite from columnar stromatolites is systematically depleted in 13C (-1.8 to -0.2‰) compared to intercolumnar dolomite (-0.3 to +0.6‰). These results suggest late diagenetic substitution in carbonate fluorapatite by HCO3 from the oxidation of organic matter. Total organic carbon extracted from these two phases overlaps in ranges of abundance and δ13C values, but are characterised by unusually heavy δ13C values up to -15‰. These carbon isotope data may reflect high levels of primary productivity during phosphorite deposition in the Jhamarkotra embayment. No carbon isotope excursion was found in stratigraphically lower and higher dolomites in the embayment, but excursions up to +5% exist in contemporary carbonates from nearby localities. Ongoing work with Re and Os isotopes could provide better age constraints for this unique phosphate deposit and relate it to other events of that time. In the context of Paleoproterozoic biogeochemical evolution, these phosphorites appear to record high biological primary productivity associated with post-glacial climate change.
Origin and evolution of ultrapotassic plutonic rocks (Durbachite series, Třebíč Massif, Czech Republic): An experimental approach

F. PARAT1, F. HOLTZ2, M. RENE3 AND R. ALMEEV2
1Mineralogisch-Geochemisches Instituts, Albertstraße 23b, D-79104 Freiburg, fleurice.parat@minpet.uni-freiburg.de
2Institute of Mineralogy, Callinstraße 3, D-30167, Hannover
3Institute of Rock Structure and Mechanics, CR-18209 Prague

To address the question of the origin of K-rich magmatism at the end of major orogenic episodes, an experimental study was conducted to constrain the crystallization conditions of mafic durbachite from the Třebíč Massif in the Bohemian Massif, Czech Republic. Durbachites are coarse-grained, porphyric plutonic rocks, typically containing large phenocrysts of K-feldspar, with high amounts of biotite, plus plagioclase, amphibole, augite and orthopyroxene. The durbachite series are abnormally K- and Mg-rich volcanic rocks and evolve from mafic to felsic end-members (SiO₂=52-70 wt.%, K₂O=7.3-5.5 wt.%, MgO=10-2.5 wt.%).

Crystallization experiments were performed in internally heated argon pressure vessels at 200 MPa, 900-1100°C, log ƒO₂=NNO and NNO+3.6, and various water activities (XH₂O of the coexisting fluid=0.3 to 1), using the most mafic natural durbachite as starting material. At 1100°C, only olivine crystallized (close to liquidus for XH₂O=1), whereas olivine + biotite + augite crystallized at 1000°C. At 900°C, only biotite and augite (+apatite, zircon and magnetite) are stable phases in the investigated range of XH₂O and ƒO₂. K-feldspar, plagioclase, amphibole and opx are absent in all experimental products even at subsolidus conditions (~900°C and low XH₂O). Thus, the natural mineral assemblage was not reproduced for the investigated range of T, ƒO₂ and XH₂O. Only biotite (Ti-rich: TiO₂=3-5 wt.%; mg#=75-80) and augite (Wo₄₄En₄₂), present in natural sample, could be reproduced.

Our results indicate that the mineral assemblage of the mafic durbachite may not be the product of the crystallization of a melt with the investigated bulk composition at 200 MPa. If we consider that partial melting of enriched, heterogeneous subcontinental lithospheric mantle beneath the Variscan Orogen lead to the formation of the mafic durbachite (Holub, 1997; Gerdes et al., 2000), the observed mineral assemblage may indicate that (1) crystallization occurred at pressures or volatile activities significantly different from those investigated in this study (200 MPa, XH₂O in the range 0.3 to 1) and/or that (2) incongruent reactions involving olivine, biotite and augite as reactants occurred at hypersolidus and subsolidus conditions. This hypothesis is supported by the presence of scattered clots of fine-grained actinolite mantled by biotite (“pilite”) that may be interpreted as pseudomorphs of olivine (Holub, 1997) and by the presence of augite as relics in amphibole. Another explanation is that the investigated mafic sample is not an end-member composition but a hybrid composition, contaminated by crustal material.

Interaction of copper with humic-coated gibbsite

J. PAREDES, J. ANTELO, F. ARCE, S. FIOL AND S. MARIÑO
Physical-Chemistry Department. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain (susopr@usc.es)

Both humic substances and mineral oxides exert important effects on chemical speciation and the transport of nutrients and contaminants in soils and sediments. Although most of the studies regarding chemical speciation in natural systems have been developed for individual reactive surfaces (mineral oxides, humic substances, clays), a better understanding on the subject could be achieved with mixtures of these components. The aim of this study was to compare the copper adsorption on gibbsite and HA-coated gibbsite.

First, the interaction of copper with the single systems humic acid (HA) and gibbsite was studied at different HA concentrations and pH. In order to explain the experimental results, the NICA-Donnan and the CD-MUSIC models were applied for Cu-HA and Cu-Gibbsite interaction, respectively.

The gibbsite was covered with different HA concentrations to study the copper interaction in a system that resemble more to the reactive surfaces present in natural systems. The adsorption of copper on the HA-gibbsite was higher than the adsorption on the single systems individually at the different pH values studied. This result was interpreted in a linear aditivity model basis. The copper adsorption on the HA-coated gibbsite was also compared with a system consisting of HA, gibbsite and copper simultaneously added into the reaction vessel.
Mineralogical, geochemical, and microbial characteristics of marine sediments at Tempelfjorden Fjords, Svalvard, Norway

4University of Tromso, Tromso, Norway

Svalbard fjords, affected by turbid overflow emanating from outlet glaciers, are modern analogues for Quaternary deglacial settings. To better understand the response of the discharge of glacial meltwater including suspended sediments to the mineralogy, geochemistry, and microbial community, we sampled the subsurface sediments at 8 stations along the axis of Tempelfjorden fjords. The sediment samples were obtained using a gravity core at 1 station and a giant box core at 7 stations. The sediment samples were used for geochemical and mineralogical characterizations as well as for microbial community by genomic analysis. Iron-oxidizing and -reducing bacteria were enriched from the marine sediments at 8°C and the development of bacterial and archaeal structures in the sediments of fjords was examined using cloning and denaturing gradient gel electrophoresis analysis of rRNA gene. The water mass and marine sediments are influenced by the runoff from the glaciers at the fjord head in Tempelfjorden. X-ray diffraction analysis of the sand and silt fraction of the sediments revealed the predominance of quartz, mica, calcite, and dolomite with lesser amounts of feldspars and chlorite. Their clay mineralogy was dominated with illite, kaolinite, chlorite, and dolomite with lesser amounts of quartz, feldspar, and iron oxides. Iron-oxidizing and -reducing bacteria enriched from the marine sediments at 8°C and the development of bacterial and archaeal structures in the sediments of fjords was examined using cloning and denaturing gradient gel electrophoresis analysis of rRNA gene. The water mass and marine sediments are influenced by the runoff from the glaciers at the fjord head in Tempelfjorden. X-ray diffraction analysis of the sand and silt fraction of the sediments revealed the predominance of quartz, mica, calcite, and dolomite with lesser amounts of feldspars and chlorite. Their clay mineralogy was dominated with illite, kaolinite, chlorite, and dolomite with lesser amounts of quartz, feldspar, and iron oxides. Iron-oxidizing and -reducing bacteria enriched from the marine sediments showed active Fe(II) oxidation and Fe(III) reduction at 8°C and 25°C. Iron-reducing bacteria enriched from the sediments were formed nm-sized magnetite at both 8°C and 25°C using lactate as an electron donor and a ferric iron oxide, akaganeite, as an electron acceptor. Dynamic bacterial community succession was observed at 8 stations. Although only one type of archaeal community profile was observed, archaeal community was quite distinct in the sediments and affected by deglaciation compared to control sediments. This confirms previous study that arctic sediment microorganisms participate in biogeochemical cycles remain in active at low temperatures.

Developing extraction method for mercury analysis in soils with different mineral composition

MISUN PARK, MIYOUNG SHIN, HYEON YOON and CHEOLHO YOON

Korea Basic Science Institute, Seoul Center (dunee@kbsi.re.kr)

The toxicity of elements depends not only on their total concentrations but also on their chemical forms. In real environment where mercury was considered as contaminant, we often experience difficulty in measuring mobility of mercury from constituents soils. The final goal of this project is speciation of mercury in contaminated soils and sediments. Preliminary tests for reference materials were performed to find out simple and more efficiency method to extract mercury. The reference materials with different mineral composition were selected and used. One is composed of mostly with Al-silicate minerals and another is mostly composed with calcite and ferrosilite. Same extraction method was applied to reference material of two types. The extraction efficiency for three methods was compared with certified values of reference material. The two extraction methods of three were acid digestion with aqua regia and mixed acid. The other extracted with mixture solution methanol and HCl using microwave at 40W and 80W for 20min respectively. The most high efficiency of sample including Al-silicate mineral was microwave method using methanol and HCl, while the calcite-based sample was observed that the aqua regia extraction method is good than the others. But this sample wasn’t detected with microwave method. The developing extraction method of the microwave using methanol and HCl will be possible to analysis of mercury more easily and rapidly. Also this can be applied to mercury speciation analysis in soils and sediments.
Geochemistry of basalt from the Eastern Woodlark Basin: Its implications for the mantle heterogeneity

SUNG-HYUN PARK1, PETER J. MICHAEL2, JONG IK LEE1 and KYEONG YONG LEE3

1Korea Polar Research Institute, Incheon, South Korea
   (shpark314@kopri.re.kr)
2Department of Geoscience, The University of Tulsa, 600 College Avenue, Tulsa, Oklahoma, 74104, USA
   (pjm@utulsa.edu)
3Deep-Sea Resources Research Program, Korea Ocean Research and Development Institute, Ansan P.O. Box 29, Seoul, South Korea (kylee@kordi.re.kr)

A section of the active spreading center in the eastern Woodlark Basin (EWLB) is subducting beneath the New Georgia Group, a volcanic arc. Basalt from the axis of EWLB were analyzed to investigate the processes in the region where ridge subduction and reversal in subduction polarity occurred in the past. They are similar to N-MORB in their major oxides, but are more depleted in incompatible elements. Incompatible element ratios such as Zr/Y and La/Sm show a large variation, which may be explained by mantle heterogeneity where an N-MORB source became mixed with or coexists with a different, mantle source that was depleted at an earlier time (Fig. 1a). The negative correlation between Ba/La and Zr/Y ratios indicates that the prior depleted end member is more enriched in the subduction component than the N-MORB mantle source and therefore may have originated from a subduction environment (Fig. 1b). The source of the subduction component remains to be explored by further studies.

Assessment of phosphorus and PAHs accumulation in the Suyoung river area in Busan, South Korea

S.W. PARK1, M.H. KIM2, J.G. KIM1 and C.W. KIM1

1Korea institute of Geoscience and Mineral Resources, South Korea (Spark@kigam.re.kr)
2hungbuk National University, South Korea (gsaver@lycos.co.kr)

Method
Sediment samples (0-50 cm in depth) were collected from the Suyoung river and the Hoedong drinking water reservoir area in Busan, South Korea to assess the accumulation of phosphorus and PAHs. Phosphorus was analyzed by an ICP-ES and a Spectrophotometer, and PAHs were analyzed using a GC/MSD. The phosphorus results are shown in the table below.

Table 1. Phosphorus contents in the river- sediments.

Discussion and Results
Most of the inorganic phosphorus was present being adsorbed onto the sediments and its concentration pattern was very similar to that of PAHs indicating the presence of phosphorus and PAHs were influenced by the geological characteristics of the area.

Concerning the source of PAHs, the upper part of Suyoung river may be influenced by pyrolytic inputs, where the middle or down part may be influenced by petroleum inputs, which can be the vehicle emission from fossil fuel combustion.

Geochemical and isotopic investigations of surface waters in Chuncheon, Korea

Y. PARK1, K.S. LEE1 AND J.-Y. YU2

1Korea Basic Science Institute, 113 Gwanghangno, Yusung-gu, Daejeon 350-333, Korea (pyy@kbsi.re.kr; kslee@kbsi.re.kr)
2Dept. Geology, Kangwon Nat’l Univ., Chuncheon, Kangwon-do 200-701, Korea (jyu@kangwon.ac.kr)

The Han River is the largest river in South Korea in terms of the size of watershed and water discharge, and consists of two major tributaries: the North Han and South Han Rivers (NHR and SHR). The Soyang River (SR) is one of the major tributaries of the NHR, and joins the NHR at the Euiam Lake. In order to investigate geochemical and isotopic characteristics of river waters affected by a medium-sized city, Chuncheon, we have collected a total of 109 surface water samples from the NHR, the SR and the Euiam Lake. Of these surface waters, the SR is directly influenced by the city of Chuncheon, and it is characterized by much higher concentration of dissolved ions in the lower reaches relative to the NHR the Euiam Lake waters. Especially, it is observed that the concentration of dissolved ions of the SR is the highest in summer. Compared to the SR, the NHR is much lower in concentrations of dissolved solutes, indicating little contamination by anthropogenic sources. The Euiam Lake is located at the confluence point of both rivers, thus this lake waters plot between chemical compositions of both rivers indicating a mixing relation. On a plot of oxygen and hydrogen isotopic compositions, all water samples plot in a similar range near the local meteoric water line (LMWL) of Park et al. (2006), and this indicates all surface waters originate from similar sources of meteoric origin. Most samples are enriched in oxygen isotopic compositions, and thus slightly deviate from the LMWL, implying slight evaporation from reservoir surfaces.

Figure 1. Oxygen and hydrogen isotopic compositions of the surface water samples collected in the Chuncheon area.

Diel biogeochemistry of the Rio Agrio, Argentina

STEPHEN R. PARKER 1 CHRISTOPHER H. GAMMONS 2 AND FERNANDO L. PEDROZO 3

1Department of Chemistry and Geochemistry, Montana Tech, Butte, MT, USA (sparker@mtech.edu)
2Department of Geological Engineering, Montana Tech, Butte, MT, USA (cgammons@mtech.edu)
3Centro Regional Universitario Bariloche, Universidad Nacional del Comahue, San Carlos de Bariloche, Argentina (fpedrozo@crub.uncoma.edu.ar.)

Rio Agrio in Argentina is a geogenically acidic stream that derives its low-pH waters from springs on the flanks of the active Copahue Volcano. These springs are fed partially by off-gassing (SO2, HCl, HF) of the magma-chamber beneath the volcano. This study reports the results of three diel (24-h) water samplings in three different pH regimes (3.2, 4.4 and 6.3) along the river which is acidic for ~40km. Changes in the concentration and speciation of Fe dominated the diel chemical changes at all three sites. At the two lower pH sites, dissolved Fe(III) concentrations decreased during the day and increased at night, while dissolved Fe(II) showed the inverse temporal pattern. These cycles are explained by Fe(III) photoreduction, as well as a diel, temperature-dependent change in the rate of precipitation of hydrous ferric oxide (HFO). A correlation was observed between Fe(III) and As at the pH 3.2 site, most likely due to co-precipitation of As with HFO. At the downstream (pH 6.3) location, Fe(II) concentrations increased at night, as did concentrations of rare earth elements. Photoreduction does not appear to be an important process in this reach, although it may be indirectly responsible for the observed diel cycle of Fe(II) due to advection of photochemically produced Fe(II) from acidic upstream waters. These results are very similar to diel trends recently obtained from mining-impacted streams receiving acid rock drainage (Parker et al., 2007). The results help form a link between geochemistry and microbiology in acidic riverine ecosystems. For example, Fe(III) photoreduction produces chemical potential energy (in the form of metastable Fe2+) that helps support the bacterial community in this unique extreme environment.

Vertical tectonics in the Neoarchean: Evidence from U-Pb detrital zircon age distribution in “Timiskaming type” sedimentary rocks in the Island Lake greenstone belt, Superior Province, Canada

JEN PARKS1, SHOUFA LIN1, LARRY HEAMAN2, ANTONIO SIMONETTI2 AND TIM CORKERY3

1University of Waterloo, Waterloo, ON, Canada
2University of Alberta, Edmonton AB, Canada
3Manitoba Geological Survey, Winnipeg, MB, Canada

Two distinct tectonic regimes have been proposed to have been operating in the Archean, vertical and horizontal (“modern style”) tectonics. Most authors see these as separate processes that would have operated exclusively from each other, although recent work has suggested that they could be contemporaneous and that the Neoarchean represents a transition from a time dominated by vertical tectonics to one dominated by horizontal tectonic processes (Lin, 2007, and references therein).

Studies on Archean greenstone belts can help to test these ideas, and this study investigates a clastic sedimentary package that is characteristic of Neoarchean greenstone belts, the “Timiskaming-Type” sediments. Traditionally these sequences are interpreted to have been deposited in strike-slip basins opened by horizontal tectonic processes. More recent studies have suggested that these sediments were deposited in inter-diapiric basins formed by vertical tectonic processes.

This study investigates the distribution of U-Pb detrital zircon ages within the Island Lake Group, a “Timiskaming type” sedimentary succession located in the Island Lake greenstone belt. The distribution of observed ages is distinct from unit to unit throughout the succession, and correspond to the ages of supracrustal and plutonic rocks in the belt. The data are consistent with a model that involves erosion down through a supracrustal pile in the early stage of basin formation and sedimentation followed by unroofing of plutons in the latter stages. The model presented here involves sagduction and diapirism processes that produce an inter-diapiric basin as a result of vertical tectonics.

A petrologic view of mantle geochemistry: Os and He evidence for ancient depleted mantle heterogeneities

S.W. PARMAN

Dept. of Earth Sciences, Durham University, South Road, Durham DH1 3LE, (stephen.parman@durham.ac.uk)

Osmium isotopes in MORB and OIB appear to give a very different picture of the chemical history of the mantle than traditional isotope systems such as Sr, Nd and Pb. In particular, Os isotopes suggest that depleted, harzburgitic heterogeneities persist in the both the OIB and MORB source for at least 2 Ga, much longer than generally suggested by Sr, Nd or Pb isotopes. Recent partitioning experiments imply that He isotopes also record ancient depleted heterogeneities in the mantle [1]. In this talk I will show that the He and Os records of mantle depletion agree very well, with both indicating large melting events at 1.2, 1.9 and 2.7 Ga, corresponding well with peaks in the age distribution of continental crust. The agreement of these two independent mantle isotopic systems with the crustal record of melting is strong evidence for large melting events in the Earth’s past.

Why don’t we see this history in Sr, Nd and Pb? One possible explanation is that the mantle is largely heterogeneous, consisting of 15-20% subducted basaltic crust (eclogite) set within a matrix of depleted olivine-orthopyroxene rich matrix (harzburgite). This is essentially the marble-cake model of Allegre and Turcotte [2], and is supported by seismic scattering results [3] showing about 17% of the mantle consists of 10 km sized heterogeneities (presumably the eclogitic components).

If so, the eclogitic components would contain nearly all of the Sr, Nd and Pb in the mantle, while the harzburgite matrix would contain most of the Os and He (and probably the other noble gases). The eclogitic components have low melting temperatures and would melt readily if brought into a mid-ocean ridge system. Those melts would form the oceanic crust, which would eventually be subducted, turn back into eclogitic heterogeneities, which would then melt in a ridge again... This is the cyclic, young history recorded by Sr-Nd-Pb, the history of enrichment. In contrast, the refractory harzburgite would not easily melt again, even if brought into a ridge system, and so should be quite persistent in the mantle. As these refractory heterogeneities are relatively inert, they should record the timing of ancient melting events more readily than isotopes in low melting temperature phases. Thus from a petrologic viewpoint, the difference in histories recorded by Sr-Nd-Pb versus Os-He may be a natural consequence of the different minerals in which they reside.

The hidden history of mantle depletion: Os isotopes reveal a link between mantle depletion and crustal growth

S.W. Parman, D.G. Pearson and G.M. Nowell

Dept. of Earth Sciences, Durham University, South Road, Durham DH1 3LE, (stephen.parman@durham.ac.uk, d.g.pearson@durham.ac.uk, g.m.nowell@durham.ac.uk)

Two recent studies [1, 2] have provided new arguments in favor of pulsed growth of the continental crust (CC), with the main growth periods at 1.2, 1.9, 2.7 and 3.3 Ga. These CC growth pulses should be recorded as melt-depletion events in the mantle, but are not seen in the isotopic systems most commonly used to study the mantle (Sr, Nd, Pb). It is likely that the depletion history of the mantle is ‘hidden’ from these systems due to the subduction of enriched oceanic crust. Osmium, on the other hand, is compatible during mantle melting, and is a robust recorder of the timing of mantle depletion [e.g. 3].

Here we present over 400 new Os isotopic analyses (by laser-ablation multi-collector inductively coupled mass spectrometry: LA-MC-ICPMS) of osmiridium grains from three locations (Urals, Tasmania and Tibet). The data show a recurring peak at a $^{187}\text{Os}/^{188}\text{Os}$ value of 0.12±0.01, corresponding to a mantle depletion age of 1.2±0.1 Ga, and matching the youngest of the proposed CC growth events. The 1.2 Ga peak is also present in published data on osmiridiums from Oregon, USA [4] and from whole rock analyses of abyssal peridotites. Mixing models confirm the position from these systems due to the subduction of enriched oceanic crust. Osmium, on the other hand, is compatible during mantle melting, and is a robust recorder of the timing of mantle depletion [e.g. 3].

The older events, at 1.9 and 2.7 Ga, also appear to be recorded in the Os data, though the number of data points is small. In sum, the Os isotopic composition of the mantle records global melting events that correspond to peaks in CC age distributions, confirming the episodic model of CC growth and planetary differentiation.

Irradiation of organic matter by uranium and thorium: From mineral deposits to extraterrestrial environments

J. Parnell¹ and R.W. Court²

¹Dept. of Geology & Petroleum Geology, University of Aberdeen, Aberdeen AB24 3UE, UK
(J.Parnell@abdn.ac.uk)
²Dept. of Earth Science & Engineering, Imperial College, London SW7 2BP, UK

Many occurrences of solid organic matter in ore deposits are directly related to the distribution of uranium and thorium minerals. This relationship reflects a mutual precipitation: irradiation from the minerals causes polymerization and solidification of fluid hydrocarbons, and the organic matter can cause the concentration of uranium to the scale of an ore deposit. Irradiation progressively alters the organic matter, by dehydrogenation, oxidation, and increasing aromaticity, and also causes fractionation of carbon isotopes. Studies of this alteration in samples from mineral deposits are contributing to an understanding of how organic matter is processed by irradiation in a range of other environments, from hydrocarbon reservoirs to interstellar space.

Data from mineral deposits show two opposite trends of carbon isotope fractionation with irradiation. New experimental data explains this in terms of two distinct mechanisms: (1) a decrease in alkylation and increase in oxygenated compounds related to reactions of complex hydrocarbon mixtures with free radicals, and (2) increase in polyaromatic hydrocarbon (PAH) size and alkylation due to polymerization from a methane-rich source. Both processes are expected to occur similarly in hydrocarbon reservoirs. The data also support a model for extraterrestrial PAH formation due to cosmic irradiation of simple hydrocarbons in interstellar ices, and more widely an improved understanding of the response of organic matter to irradiation will help interpret the organic compositions of carbonaceous meteorites, cometary ices, and icy moons such as Titan. As irradiation can result in increased molecular complexity and the precipitation of heavy compounds, it is possible that it played a role in the prebiotic chemistry essential as a prelude to the evolution of life.

On Mars, mineral radioactivity is relatively low but would still cause long-term damage to any microbial spores. Other forms of irradiation (solar, cosmic, UV) have a greater effect in the near-surface, and would severely alter or destroy any organic matter down to 3m depth.

Impact of earthworms on metal mobility and availability

SAM PARRY, HEATHER ASHTON AND MARK E. HODSON

Department of Soil Science, School of Human and Environmental Sciences, University of Reading, RG6 6DW, UK (m.e.hodson@reading.ac.uk)

It has been suggested that earthworms may be of use in enhancing phytoremediation or alternatively that earthworms may enhance metal mobility at contaminated sites thereby increasing risk of exposure for receptors. In this study earthworms were cultivated for 28 days in two different metal contaminated soils at differing earthworm number to soil mass ratios. Swaledale soil contained 16 ppm Cd, 28 ppm Cu, 5164 ppm Pb, 3433 ppm Zn, 6 % organic matter, had a pH of 6 and a sandy texture. Wisley soil contained 5 ppm Cd, 110 ppm Cu, 910 ppm Pb, 260 ppm Zn, 10 % organic matter, had a pH of 5.4 and was a loamy sand. Earthworm number to soil mass ratios ranged from 1 :200 to 1 :5. After 28 days earthworms were depurated on filter paper and metal body burden was determined. Soil solution was extracted from soils using rhizon soil solution samplers and analysed for metals and dissolved organic carbon. Cold and hot water extractable carbon were measured on the soils. Soils were extracted with K2SO4 to estimate microbial numbers. The European 3-stage sequential extraction was applied to the soils.

Earthworm metal body burden and BCR Step 1 extractable metal decreased with increasing earthworm density. Metal and organic carbon soil solution concentrations and cold and hot water extractable soil C increased with increasing earthworm density. There were no significant changes in microbial activity with earthworm density.

The data are consistent with earthworm-derived organic compounds complexing metals and bringing them into solution off soil particle sorption sites. Thus metal concentration in soil solution and therefore metal mobility increases with earthworm density. However, the metals present as organo-metal complexes are not available for uptake by the earthworms so that metal body burden is unaffected or decreases, i.e. metal bioavailability decreases.

Corroded Magnox sludge and plutonium waste cementation

S.A. PARRY¹, F.R. LIVENS¹ AND L. O’BRIEN²

¹Centre for Radiochemistry Research, School of Chemistry, University of Manchester, M13 9PL, UK (stephen.parry@manchester.ac.uk; francis.livens@manchester.ac.uk)
²Nexia Solutions, Sellafield, Cumbria, CA20 1PG, UK (luke.o'brien@nexiasolutions.com)

Corroded Magnox sludge waste

Corrosion of spent Magnox fuel rods in water filled storage ponds has produced magnesium-rich sludges contaminated with fuel and fission products. We have experimentally investigated the composition and evolution of an inactive corroded Magnox sludge (CMS) simulant.

Our characterisation of the sludge using infrared spectroscopy, X-ray diffraction, and environmental scanning electron microscopy (ESEM) has determined that CMS is mainly composed of brucite, Mg(OH)2, and additionally artinite, Mg2CO3(OH)2.3H2O.

Plutonium association with CMS

It has been suggested that Pu adsorption onto CMS colloids may provide a mechanism to enhance Pu mobility. Therefore, we have determined the associative behaviour of plutonium in solution with CMS in a model storage pond/effluent treatment system. Using a full-factorial design, we have quantitatively determined the effects of CMS, and other components of the storage pond and effluent treatment system, on Pu solubility. This provides an important first approximation to true Pu solubility.

The addition of carbonate in solution had the largest influence over Pu solubility, allowing >90% of the Pu to pass through a filter membrane. The presence of CMS, and polyelectrolyte increased Pu filter hold-up. Silica at 1 ppm produced no observable effect. Solution pH was also found to have a significant influence over Pu filterability. Over the pH 7 to 11.5 range examined, more Pu was held up on the filter at higher pH.

Cementation of Pu contaminated CMS

For long-term storage it is intended that the CMS waste be immobilised in a cementitious wasteform. Our current research is intended to extend our understanding of the structure and behaviour of these cemented wasteforms. Our investigation of CMS evolution is continuing, and additionally we have begun to examine the microstructure of ordinary Portland cement (OPC) based samples. Our cement samples doped with CMS, Zr, U (and later Pu) have been analysed using SEM to establish the hydrated calcium silicate (C SH) phases present and with which phases the Zr and actinide elements associate. Further work will determine the evolution of these phases and co-ordination chemistry of the actinides. Eventually this data will be included with those from actinide leaching experiments to relate the cement microstructure with immobilisation performance.
Adsorption of heavy metal in contaminated surface water onto Limestone and Coconut Coir pith

V. PARTH AND N.N. MURTHY
National Geophysical Research Institute, Hyderabad, India.

Geo-environmental studies were conducted in Katedan Industrial Development Area, Hyderabad, India, where the industrial effluents has contaminated the fresh water lakes.

To treat the effluent through a Permeable Reactive Barrier (PRB), the contaminated lake samples were collected to carry out the column tests in the laboratory to identify the appropriate reactive material to reduce the concentration of toxic/heavy metals like Lead, Zinc, Chromium, Arsenic, Copper etc. to an environmentally acceptable limit by their adsorption on to the reactive material.

The column experiment was conducted for one week to treat the contaminants in the surface water from Katedan Industrial Area using various reactive materials such as Zero Valant Iron, Coal, Limestone and other organic materials like Coconut coir pith, Hey, Cow dung cakes and plant materials like leaves, barks and stems etc.

The contaminated water was passed through the column made of Polyvinyl Chloride (PVC). The column is 50 cm long with diameter of 10cm. It was filled with 70% (14cm) height of 2-4 grain sized limestone and 30% (6 cm) of fibrous coconut coir pith.

The flow rate of 55 rpm was kept constant through out the column experiment. The effluents from the column were quantitatively analysed using Inductively Coupled Plasma – Optical Emission Spectrometry (ICP-OES).

The concentration of certain heavy metals at the effluent was reduced to the environmentally acceptable limits eg. (Cr 43.52 µg/kg to 21.49 µg/kg), (Cu 30.4 µg/kg to 4.62 µg/kg), (Ni 27.44 µg/kg to 12.54 µg/kg), (Pb15.62 µg/kg to 9.92 µg/kg), (Zn 98.25 µg/kg to 0.80 µg/kg) by limestone and coconut coir pith.

The electrical resistivity of nano-crystalline geikielite decreases from 2.246 X 10^8 Ω m at room pressure to 2.0 X10^6 Ω m at 7.8 G Pa, whereas the electrical resistivity of natural geikielite decreases from1.098 X10^8 Ω m at room pressure to 1.74 X 10^5 Ω m 7.8 G Pa, indicating more compressibility of natural geikielite in the pressure range of investigations. The present shows that the geikielite does not undergo any pressure induced phase transition up to 7.8 G Pa, indicating its stability in the earth’s mantle pressure conditions [3,4].

Stalagmite records of tropical Pacific climate since the Last Glacial Maximum

J.D. Partin¹, K. Cobb¹, J.F. Adkins², B. Clark³
and D.P. Fernandez²

¹Dept. of Earth and Atm. Sciences, Georgia Inst. of Technology, Atlanta, GA 30332
²Dept. of Geological and Planetary Sciences, Caltech, Pasadena, CA 91125
³Gunung Mulu National Park, Sarawak, Malaysia

Long, high-resolution, well-dated paleoclimatic records from the western tropical Pacific are scarce, obscuring the response of tropical Pacific climate to changes in global boundary conditions, abrupt climate changes, and external radiative forcing. Here we present three absolutely-dated stalagmite oxygen isotopic records from Northern Borneo that track fluctuations in Western Pacific Warm Pool hydrology over the last 27,000 years. Over 70 U-series dates and 11 isochrons provide excellent chronological control for the over 1200 stable isotope measurements. Our results suggest that rainfall in northern Borneo during the Last Glacial Maximum was similar to present. However, a pronounced maximum in stalagmite δ¹⁸O values occurs ~16.3 thousand years ago, consistent with dry conditions in the WPWP during the Heinrich 1 abrupt climate change event. The deglaciation is also marked by a 1000-yr-long oxygen isotope plateau centered at 13.2 thousand years ago that coincides with the Antarctic Cold Reversal, but there is no evidence for the Younger Dryas event observed in many other deglacial records. A broad minimum 5,000 years ago reflects the sensitivity of Warm Pool hydrology to spring/fall precessional insolation forcing. The new records demonstrate dynamic linkages between northern and southern high-latitude climate and tropical Pacific convection, and highlight the sensitivity of tropical Pacific convection to external radiative forcing.

Multiple redox states in the Archean-Proterozoic hydrosphere

M.A. Partridge, S.D. Golding, E. Young and K.A. Baublys

Earth Sciences, University of Queensland, QLD 4072, Australia (m.partridge@uq.edu.au)

The late Archean deep water environments of Western Australia’s Hamersley Group Marra Mamba Iron Formation and Mount McRae Shale are characterised by extremely light organic carbon and relatively enriched, even positive, carbonate carbon δ¹³C values consistent with the presence of methanogens (Schidlowski, 2001). Positive mass independently fractionated (MIF) sulfur isotope values are found in fine-grained pyrite disseminated throughout these organic rich mudstones, while negative sulfur MIF is seen in rare pyrite nodules. This suggests that the fine-grained pyrite was formed abiotically, whilst the formation of the nodules was microbially mediated (Farquhar and Wing, 2003).

Multiple pyrite morphologies are not common in the Hamersley Group’s late Archean shallow water Wittenoom Formation; however, positive sulfur MIF in fine-grained pyrite in these dolostones suggests the absence of sulfate reducing microbes. The lack of very light organic carbon and positive carbonate carbon δ¹³C values implies that late Archean shallow water environments were too oxic to support anaerobic metabolisms, potentially in favour of more oxygen tolerant species.

Paleoproterozoic sulfur MIF in the Dales Gorge Member and Whaleback Shale of the Brockman Iron Formation Group shows good correlation between fine-grained and nodular pyrite in the same sample, with both demonstrating either negative or zero MIF, regardless of depositional environment. Furthermore, organic and carbonate carbon δ¹³C trends toward more modern values. This suggests that after the Archean-Proterozoic boundary, both deep and shallow water environments were sufficiently oxic for sulfate reducing microbes and thus marks the transition to a more uniformly oxidised hydrosphere capable of supporting aerobic life.

Tailings oxidation and mineralogy of Haveri Au-Cu mine, SW Finland – Preliminary results

A. PARVIAINEN1 AND M. EKLUND2

1Helsinki University of Technology, Geoenvironmental Technology Unit, P.O.Box 6200, FIN-02015 TTK, Finland (annika.parviainen@tkk.fi)
2Geological Survey of Finland, P.O.Box 96, FIN-02151 Espoo, Finland (mikael.eklund@gtk.fi)

The Haveri Au-Cu deposit, situated in SW Finland, composes mainly of pyrrhotite, chalcopyrite and pyrite with accessory Fe-Co-Ni sulfoarsonides, sphalerite, molybdenite, iron oxides and native gold (Mäkelä, 1980). The tailings were piled during the active mining period from 1942 to 1961 covering ca. 18.5 ha and having an average depth of 7 meters.

In May 2006, a total of 40 profiles were drilled. Three profiles, and 17 tailings samples at intervals of one meter, were selected for mineralogical feasibility study. They were studied by optical reflected-light microscopy and by scanning electron microscope (SEM-EDS). Furthermore, the samples will be examined by X-ray diffraction (XRD), and geochemical analyses from selective leachates are planned.

The tailings are exposed to air, rainwater and meltwater which oxidize the primary sulfides remaining from the ore processing. Consequently, the tailings present zoning with oxidized vadose layer closest to the surface and unoxidized water-saturated layer below 3 to 4 meters. In May 2006, a total of 40 profiles were drilled. Three profiles, and 17 tailings samples at intervals of one meter, were selected for mineralogical feasibility study. They were studied by optical reflected-light microscopy and by scanning electron microscope (SEM-EDS). Furthermore, the samples will be examined by X-ray diffraction (XRD), and geochemical analyses from selective leachates are planned.

The oxidation process will continue for decades or even hundreds of years until reaching the groundwater surface.

The research is part of the EU LIFE Environment project “Risk Assessment and Risk Management procedure for Arsenic in the Tampere region” or RAMAS (www.gtk.fi/projects/ramas).

Chemical weathering of basaltic rocks in the tropical environment

C.S. PASCUA1, A. ASAI2, C. ARCILLA3, H. YAMADA1 AND T. SATO2

1Nanostructure Control Group, Photocatalytic Materials Center, National Institute for Materials Science, Namiki, tsukuba, Ibaraki, Japan
2Graduate School of Engineering, Hokkaido University, Sapporo, Japan
3National Institute of Geological Sciences, University of the Philippines, Diliman, Quezon City, Philippines

The chemical weathering of basaltic rocks under tropical conditions was marked with the generation of moderate to highly alkaline and reducing hot spring. Only a few similar occurrences has been reported in the Philippines where most of the hot springs are highly acidic and volcanic in nature. In Sira-an hot spring along the coast of Antique province, flammable gas (i.e. CH4(g)) accompanies the hot springs waters. Its pH, redox state, temperature, and dissolved constituents are considerably different from a nearby groundwater well and seawater such that it can be considered an anomaly. The mineral assemblage of the fracture fill materials comprises calcium-aluminum-silica-hydrate (CASH) phases, zeolites, and chlorite suggesting highly alkaline conditions.

The local hydrogeology of the area is responsible in the formation of the alkaline and reducing hot spring (Figure 1). Limestones at elevated areas dissolve to form dissolved calcium and carbonate enriched groundwater which percolates through the fractured basaltic rocks. Dissolution of minerals in the basaltic rock under anoxic conditions generates a highly reduced and alkaline aqueous conditions which converts the dissolved carbonate to methane. The dissolved components (i.e. Ca, Si, Fe, Al, Mg) in turn precipitates into CASH phases, zeolites, and chlorite.

Figure 1. A schematic presentation of the alkaline and reducing Siraan hot springs, Antique, Philippines.
Arsenic and Mercury in brown and hard coals from deposits of Poland

A. PASIECZNA¹, I. BOJAKOWSKA² and A. PAULO³

¹Polish Geological Institute, Warsaw, Poland,
(anna.pasieczna@pgi.gov.pl)
²Polish Geological Institute (izabela.bojakowska@pgi.gov.pl)
³AGH - University of Science and Technology, Krakow,
Poland (paulo@geol.agh.edu.pl)

Problem of the environmental pollution by As and Hg emitted during coal combustion is important. The aim of the study was a determination of As and Hg concentrations in coals extracted in Poland and mostly burned there.

Material and methods

Concentration of arsenic and mercury have been determined in 250 samples of brown and hard coals from deposits of Poland. Hard coal samples were collected from Carboniferous Upper Silesian (USCB), Lower Silesian (LSCB) and Lublin Coal Basins (LCB) and brown coal samples were collected from mined deposits in Poland – Turów, Belchatów, Koźmin, Lubstów, Adamów and Kazimierz. Arsenic contents have been determined with the ICP-MS spectrometry and mercury contents by AAS method.

Results

The mean arsenic concentration in the hard coals is 16 mg/kg. Coals from LCB contain in average 47 mg/kg of arsenic, coals from LSCB – 61 mg/kg. In coals from USCB mean concentrations of As range from 2 mg/kg (NW part of the basin) to 20 mg/kg (SW part of the basin). The average As contents in brown coals is 9 mg/kg (Turów 29 mg/kg, Belchatów – 3 mg/kg, Konin-Adamów – 1 mg/kg). The average mercury content in the hard coal samples is 85 ppb. The mean Hg content in hard coal from the LSCB is 399 ppb, USCB 60 ppb and 105 ppb in coals from LCB deposit. Coals from the eastern part of USCB contain higher mercury concentration than coal from western part of basin. They might be caused by sulphide mineralization in Triassic dolomites overlying this part of USCB. The average Hg concentration in all tested brown coal samples is 322 ppb and it is four times higher than average Hg concentration in hard coals. The highest average Hg content in lignite is observed from Belchatów deposit - 416 ppb and the lowest - 199 ppb from Lubstów deposit. Coals from tectonic grabens are enriched in Hg in comparison with lenticular deposits which were not tectonically influenced.

Conclusion

Obtained results permit to estimate that about 28t/a of mercury and about 2000t/a of arsenic are excavated and emitted with hard and brown coals burned in Poland.

Melt mixing and crystallisation in the plumbing system of the 1783 Laki eruption

E. PASSMORE¹, J. MACLENNAN², J.G. FITTON¹ and T. THORDARSON¹

¹School of GeoSciences, University of Edinburgh, EH9 3JW, UK (e.passmore@ed.ac.uk, godfrey.fitton@ed.ac.uk, thor.thordarson@ed.ac.uk)
²Department of Earth Sciences, University of Cambridge, CB2 3EQ, UK (jmac05@esc.cam.ac.uk)

The 1783 Laki fissure eruption of SE Iceland is the second largest basalt eruption in recorded history, extruding ~15 km³ of lava and minor tephra over the course of 8 months and producing a notorious ‘dry haze’ of poisonous volcanic smog, leading to famine, disease and the death of 25% of Iceland’s population [1]. Large scale basalt eruptions are common in Iceland (e.g. Eldgjá, 934 AD and Thjórsá, ~8000 yBP; 19 km³ and 21 km³ respectively) and are fed by discrete batches of magma accumulating in large crustal reservoirs. The relationship between crystallisation and mixing in the storage reservoirs that give rise to such voluminous, long-lived eruptions has been the focus of recent SIMS analysis at the University of Edinburgh.

The concentrations of REEs and selected trace elements, including Zr, Y, Nb and Sr, were measured for 90 olivine-hosted melt inclusions from Laki using a Cameca 4f ion microprobe. The range of REE concentrations measured in the melt inclusions (representing discrete batches of parental melt) is not seen in whole rock compositions, implying that this variation is destroyed by mixing in the storage reservoir prior to eruption. Olivine compositions vary from Fo₈₇ – Fo₇₃, corresponding to a 50°C drop in crystallisation temperature. The standard deviation of La/Yb in melt inclusions hosted in olivine with Fo>85 mol% is 0.75 (n=40), but only 0.25 (n=16) in olivines with Fo<78 mol%, showing that cooling, and subsequent crystallisation of less forsteritic olivine, was therefore concurrent with mixing. The variation in La/Yb reflects variation in the composition of mantle melts being supplied to the crust under SE Iceland. A similar relationship between mixing and cooling has been found in a smaller, more primitive flow from northern Iceland [2], indicating that coupled mixing and crystallisation is common in the plumbing systems of Icelandic volcanoes.

(beate.orberger@u-psud.fr)

The study of organometallic complexes in ancient geological environments can explain mechanism of accumulation of metals and provide clues for the evolution of the earth life. For example, many synthesized complexes of aryl phosphines and aryl phosphites with platinum metals proved to have important mechanistic implications for homogeneous and heterogeneous catalysis.

Anomalous metal concentrations up to ore grade were reported from black shales that occur in different geological environments throughout the geological record. Besides major ore minerals and elevated metal concentrations in base metal sulfides, many authors suggested empirical relationship between various metals and organic matter.

Using HPCL-MS analysis, we found Co-, Cu-, Ni- and Pt-organometallic compounds in chloroform extract of organic matter from Ni-Mo polyelement sulfide ore bed hosted in lower Cambrian black shales whose organic matter was derived mainly from algae and cyanobacteria and whose formation coincided with the famous Cambrian biological explosion and world phosphate deposition. Beside organometallic compounds sulfur, polycyclic aromatic hydrocarbons and free-metal porphyrines were identified.

Our results demonstrate how biological activity was important for primary metal entrapment in hydrothermally enriched marine environment around medium temperature (<300°C) hydrothermal vent in semi-restricted basin.

This work was financially supported by the EC in the frame of Bioshale European project (6th Framework program - NMP2-CT-2004-505710).

Re-Os study of the Polish Kupferschiefer: Implications for source and timing of metal enrichment

J. PAŠAVA1, A. VYMAZALOVÁ1, W. QU2 AND W. KORZEKWA3

1Czech Geological Survey, Prague, Czech Republic
(pasava@cgu.cz)
2Institute of Rock and Mineral Analyses, Chinese Academy of Sciences, Beijing, China
3KGHM Cuprum Ltd. Pl. Jana Pawla II 1, 50-136 Wroclaw, Poland (wkorzekwa@cuprum.wroc.pl)

The age and genesis of world-class copper deposits of the Kupferschiefer-type have been a subject of much debate with proposed synsedimentary to postdepositional models. The 187Re-187Os isotope system has been successfully applied to generate whole rock isochrons in differently aged organic carbon-rich sediments.

Six samples of typically Cu-mineralized Upper Permian calcareous black shale and limestone of the Kupferschiefer type from the Lubin mining district (Poland) were studied for Re-Os isotopes, platinum group elements (PGE), and selected major and trace elements.

Mineralized black shales (Cu_avg. = 4.9 wt.%, Ag_avg. = 242 ppm, Pb_avg. = 138 ppm and Zn_avg. = 87 ppm) display low PGE values (Pt = <2 – 3.2 ppb, Pd = <2 – 2.8 ppb, Ru = <10 ppb, Rh = 0.4 – 5.2 ppb and Ir = <0.1 ppb) and c(Re) = 249.4 – 22174 ppb, c(Os) = 0.4831 – 1.0009 ppb and 187Os/188Os = 10.26 – 426.7. Lower base metal but comparable PGE, Re and Os values are typical for basal limestone. Calculated correlation coefficients indicate preferential Re affinity to Cu-sulfides and Os affinity to organic matter.

In a 187Os/188Os vs 187Re/188Os plot the entire data set defines an isochron corresponding to an age of 240 ± 3.8 Ma, which most likely reflect late diagenetic/epigenetic metal enrichment.

The initial 187Os/188Os ratio of 0.99 ± 0.22 is slightly less radiogenic but within the variation range of present-day seawater and excludes any significant contribution from hydrothermal/mantle or meteoritic PGE sources.

This work was financially supported by the EC in the frame of Bioshale European project (6th Framework program - NMP2-CT-2004-505710).
Three decades of Hf isotope research

P. JONATHAN PATCHETT
Dept. of Geosciences, University of Arizona, Tucson AZ 85721 (patchett@email.arizona.edu)

Following early experiments with the Lu-Hf system in the 1950’s to 1970’s, we established routine chemistry and TIMS measurement in 1980. TIMS Hf measurement is a “brute force” technique, involving use of a Re ionizing filament at the limit of its range. Practitioners can testify to the strain that high filament temperatures and high Re ion beams place on the ion source and collectors of the mass spectrometer. Nevertheless in this period many of the important areas of Lu-Hf isotopic studies were identified and developed. These included meteorites, crust-mantle differentiation, and the use of dated zircons to determine initial Hf isotopic signatures.

The advent of MC-ICPMS allowed analysis of up to 100 times less Hf, so that samples like chondrites and komatiites became truly accessible. High precision was obtained on small rare meteorites, and oceanic tholeiites could be analyzed in large numbers. ICP techniques also allowed a reduction of chemistry and much more rapid mass spectrometry. Somewhat intricate and/or empirical corrections needed to obtain accurate Lu and Hf data in ICP measurement are manageable. The large database now existing shows that Hf isotopic data do mirror patterns from Nd in many cases, but that Hf has considerable importance where behavior differs from Nd. Examples are oceanic sedimentation and mantle partitioning, particularly in higher-pressure mineral phases.

It seems inevitable that one of the main future applications of Hf will be in determination of initial $^{176}\text{Hf}/^{177}\text{Hf}$ in zircons U-Pb dated by laser MC-ICPMS. The initial Hf data are powerful in discriminating crustal sources, and the opportunity to acquire hundreds of Hf values is tempting. However, non-specialists often do not realize that 10 to 40% of the 176 mass signal has to be subtracted to remove Yb and Lu and arrive at the abundance of $^{176}\text{Hf}$. This is an enormous correction when epsilon-unit (i.e. 0.01%) variations of $^{176}\text{Hf}/^{177}\text{Hf}$ are the target. Intricate and empirical correction procedures are needed to account for differences in mass fractionation behavior of Yb, Lu and Hf, as well as the Er sometimes employed, and the accuracy of the 10-40% interference correction is critically dependent on these. Parallel analysis of zircon Hf by solution ICP has been employed in some critical studies, but this may not be practical for groups who measure large numbers of zircons, particularly detrital zircons. Probably, many who will measure and present laser Hf data for zircon will not be even partly specialized in isotope geochemistry. We must place a high priority on establishing robust, globally-agreed standards and procedures for laser Hf analysis of zircons.

The concentration, variations and sources of air borne carbonaceous particulate matters: volatile organic carbons (VOC10, VOC10-2.5 and VOC2.5) nonvolatile organic carbons (OC10- OC10-2.5 and OC2.5) and black carbons ( BC10, BC10-2.5, and BC2.5) in most polluted area of chhattisgarh Raipur have been studied for one year, June 2005-May 2006. The PM2.5 and PM10 samples were collected on pre-heated quartz fiber filters with the Partisol model 2300 Sequential Speciation Sampler (Rupprecht & Patashnick Co., Inc., USA) simultaneously. The combustion method equipped with the non-dispersive infrared detector (NDIR) is used for measurement of the volatile organic carbon (VOC), nonvolatile organic carbon (OC) and elemental carbon (EC) in the terms of CO2. The annual mass concentration of PM10, PM10-2.5, and PM2.5 was ranged from 62 – 975,17-602 and 20 – 373 $\mu$g m$^{-3}$ with arithmetic mean, median and STD values of 242, 139 and103; 222, 129 and 100; and ± 164.6,100.2 and 73.4 $\mu$g m$^{-3}$, respectively. The annual mass concentration of their carbons i.e. VOC10, VOC10-2.5, VOC2.5 and OC10- OC10-2.5 and OC2.5; and EC10- EC10-2.5 and BC2.5 was ranged 2.1 – 47.9, 1.6 – 32.2, 4.1 – 80.2, 10.3-160 and 0.1 – 35.0, and1.6 – 23.1 and 2.6 – 65 and 4.6-123 $\mu$g m$^{-3}$ with arithmetic mean, median and STD values of 10.4, 48.8, 6.9, 7.9, 19.1, and 33.9, 6.7, 11.8, 25.6, 40.9, 5.0, 7.8, 17.2, and 30.7; and 9.8, 7.4, 16.5, 32.1, 7.4, 5.5, 14.0, and 25.6 respectively.

Keywords: particulate matters, carbonaceous particulate, Partisol model 2300 sequential speciation Sampler
**Chemical and isotopic (C and S) composition of groundwaters from the Mt. Vulture volcanic system**

M. PATERNOSTER AND G. MONGELLI

Università degli Studi della Basilicata - Dipartimento di Scienze Geologiche– Campus Macchia Romana, 85100 Potenza, Italy (michele.paternoster@unibas.it)

Mt. Vulture volcano is located in the most external part of the Apennine orogen (southern Italy), almost at the edge of the Apulian foreland. The volcanic activity occurred up to 130 Kys ago. The volcano is formed by a main feldspar-bearing series of pyroclastic rocks and subordinate lava flows, ranging in composition from basanite and fooidite to phonolites (Schiattarella et al., 2005). Rare lava flows and dykes, with distinctly more silica-undersaturated composition melilitites, melilitite ankaratrites, and the ‘Melfi’ haüynophyre, were also emplaced. Carbonatite-melilitite magmas fed the final phase of volcanism producing maar-type craters. The large Na and S contents of the Vulture magmas (Marini et al., 1994) result in the widespread presence of sodalite-group phases among the feldespathoids (De Fino et al., 1982; Di Muro et al., 2004).

Most groundwaters are characterized by gas bubbling. In order to investigate the origin of solutes a total of 25 springs and wells were analyzed for the major and minor element contents, the isotopic composition of carbon in the total dissolved carbon (TDC) and sulfur in the aqueous sulfate. The chemical data suggest that the effects due to water-rock interaction are largely controlled by the input of CO₂. The dissolution of CO₂ in the water causes a substantial increase in its acidity, thus promoting the alteration of the rocks. Good correlations exist among alkalinity, electric conductibility and Na⁺, Ca²⁺, SO₄²⁻ concentrations. The alkaline-earth-bicarbonate and alkaline-bicarbonate compositions of the waters are in keeping with the major role played by CO₂ in the alteration processes.

The δ¹³C values of TDC corroborate the involvement of two carbon sources. The first one is biogenic CO₂, while the second one is magmatic. The δ³⁴S values of SO₄²⁻ are all positive and similar to those measured by Marini et al. (1994) in the haüynophyre magma, thus supporting for aqueous sulfate a main origin from leaching of volcanites. In few springs, however, some contribution of SO₄²⁻ from dissolution of Triassic evaporite at depth cannot be excluded.

**1⁰Be and clay mineralogical studies on lagoonal sediments from Kaluveli, Pondicherry, India: Significance to paleoclimate**

J.K. PATTANAIK AND S. BALAKRISHNAN

Department of Earth Sciences, Pondicherry University, Puducherry, India (jitetendra.bapi@gmail.com)

Lacustrine and alluvial deposits of clayey sediments of 4.3-meter long core sequences from Kaluveli lagoon (N 12° 06’ 29”, E 79° 51’ 39”) situated 15 km north of Pondicherry, India, has been studied for clay minerals and ¹⁰Be abundance. This lagoon, 25 km long and 6 km wide, runs parallel to the east coast adjoining Bay of Bengal. Lake sediments contain ¹⁰Be mostly from two sources; one deposited directly from atmosphere and adsorbed to the surface of the sediments and the other is in situ produced. The adsorbed ¹⁰Be have been used to estimate rate of sedimentation in the Kaluveli Lagoon.

Upper part of the core (0 to 2.2 m) consists of gray clay unit indicating fresh water sediments, with sandy-clay horizons, quartz pebble and small amounts of calcite. Lower part of the core sequence (2.2 to 4.3 m) includes dark silty clay sediment with marine shells indicating brackish environment. Kaolinite and smectite in different proportion have been observed at various depths, which probably reflect variation in climate and/or paleogeography of this region.

Adsorbed ¹⁰Be was leached from four selected samples of this core and analyzed using newly developed AMS facility at Inter University Accelerator Center (15 UD pelletron), New Delhi, India. Concentration of ¹⁰Be varies between 3.32 x 10⁸ to 1.52 x 10⁹ atom g⁻¹ (dry sample) from 85 cm to 400 cm depth. The average sedimentation rate of 1.8 ± 0.18 x 10⁻³ mm y⁻¹ has been calculated using ¹⁰Be concentration in the sediments. Dominance of smectite over kaolinite between 40 to 50 cm depth (corresponding to age ~ 0.29 Ma) and below 220 cm (> 1.18 Ma) indicates that semiarid conditions prevailed at the time of their formation (Figure 1). Kaolinite abundance is higher in the sediments found at depth of 80 to 220 cm (0.5 to 1.18 Ma), which were possibly deposited under relatively humid climate. During this wet period laterites could have formed all along the east coast of India now preserved as discontinuous belt.

**Figure 1:** Variation of smectite / kaolinite as a function of depth and age determined using ¹⁰Be abundances.
Osmium groundwater flux from the Bengal basin: Implications for the osmium marine budget

M. Paul1, L. Reisberg1, N. Vigier1, Y. Zheng2 and L. Charlet3

1CRPG-CNRS, Vandoeuvre-lès-Nancy, France (mpaul@crpg.cnrs-nancy.fr)
2LDEO & Queens College, NY, USA
3LGIT-OSUG, Univ. Grenoble, France

The osmium residence time in the oceans is currently poorly constrained, in part because the sources of Os to ocean water have not yet all been explored. One such source, potentially important, may be groundwater flux. Basu et al. [1] suggested that Bengal Basin groundwaters may provide a large flux of radiogenic Sr to the oceans. By analogy, and considering that the Ganges has the most radiogenic 187Os/188Os ratio yet measured in the world's rivers [2], groundwater of the Ganges alluvial plain may provide a significant flux of radiogenic Os to the oceans.

We present Os isotopic and concentration data for groundwaters collected along a traverse in the Bengal alluvial plain. As these waters are highly reducing, a specific method was developed (heating with CrVI in a high pressure asher, HPA-S at 250°C) to allow complete oxidation of all of the Os, and thus equilibration with the Os isotopic tracer. Oxidation at lower temperatures, in the HPA-S or in teflon vessels [3], led to underestimation of the Os concentration by as much as a factor of two.

Os concentrations are high (30-250 pg/l) and display 187Os/188Os ratios (2.2-2.6) in agreement with those of Ganges water and sediments. Os contents correlate strongly with those of Sr and several other elements, which allows us to roughly estimate the groundwater Os flux from the Bengal alluvial plain. Assuming conservative behaviour and both the mean Sr concentration and the groundwater flux of [1], we estimate an 188Os groundwater flux of ~9 M/yr. This estimate represents more than three times the Os flux from the Ganges and a radiogenic contribution similar to that of the Amazon [2]. If realistic, this estimate would significantly reduce the estimate of the Os residence time in the ocean, and may suggest that Himalayan derived Os has had an important effect on the 188Os/189Os ratio of seawater. On the other hand, preliminary results on groundwaters from the fresh/salt water transition area show that a substantial quantity of Os could be trapped here. This may indicate non-conservative behaviour which would significantly reduce our estimate of the groundwater Os flux that reaches the ocean.

Sub-segment scale mantle heterogeneity beneath the Mid-Atlantic Ridge near Ascension Island from combined Hf-Nd-Sr isotope evidence

H. Paulick1, C. Münker1,2 and K. Haase3

1Mineralogisch-Petrologisches Institut, Universität Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany
2Institut für Mineralogie, Universität Münster, Correnstrasse 24, 48149 Münster, Germany
3Department of Earth Sciences, University of Aarhus, Høegh-Guldbergsgade 2, 8000 Aarhus, Denmark

The Mid-Atlantic Ridge (MAR) between 7°30’S and 11°30’S shows prominent bathymetric along-axis variations with a shallow central part (segments A2 and A3) and deeply incised segments to the north and south (segments A1 and A4). These topographic variations are mirrored by a large compositional variations spanning the entire range of Atlantic MORB analyzed so far in εHf-SrNd and εHf-87Sr/86Sr space. Ascension Island is located in the immediate vicinity (80 km west of the MAR), indicating voluminous off-axis partial melting in the mantle. We analysed near primitive samples (MgO> 5 wt%) for Hf-Sr-Nd isotope and trace element compositions and our data for the submarine and subaerial portions of Ascension Island and the different segments along the MAR show that there are systematic changes in terms of εHf, εNd, and 87Sr/86Sr characteristics. In 176Hf/177Hf vs. Lu/Hf, 143Nd/144Nd vs. Sm/Nd, and 87Sr/86Sr vs. Rb/Sr spaces, the different segments define linear arrays. These arrays do not have any age significance but are mixing lines.

The central segment (A3) shows enriched mantle characteristics (εHf ~+12.5; εNd: +7.5 to +8; 87Sr/86Sr: 0.70267 to 0.70277). Segment A2, located immediately to the north, has higher values in εNd (+10.2 to +11.7) and εHf (+13.2 to +14.5) but lower 87Sr/86Sr ratios (0.70244 to 0.70237). In contrast, the data from segments A1 and A4 define distinctive linear arrays. This involves a depleted end-member with high εNd (up to +13), high εHf (up to +22), and low 87Sr/86Sr ratios (0.70244 to 0.70237) and an enriched end-member with low εNd and εHf and high 87Sr/86Sr ratios. Since there are no consistent trends with water depth or along axis position of the samples, sub-km scale mantle heterogeneities must be present beneath segments A1 and A4. The samples representing subaerial volcanism of Ascension Island mark the isotopically enriched extension of the linear array defined by MAR segments A1 and A4 (εNd: +6.8, εHf: +9.9; 87Sr/86Sr ratio: 0.70284). Samples from the submarine stage of Ascension Island are displaced towards higher εHf (+13.1 to +13.5), indicating that the volmetrically dominant volcanic basement was fed from a distinctive, enriched mantle source. Hence, all of these observations imply that mantle material, representing the enriched end member component for segments A1 and A4, replaced the mantle domain responsible for submarine Ascension Island volcanism prior to the onset of subaerial volcanism (≤ 1 Ma). Altogether, these relationships argue against a mantle plume origin for Ascension Island.

Thallium in brown and hard coals of Poland

A. PAULO¹, I. BOJAKOWSKA² AND A. PASIECZNA²

¹AGH - University of Science and Technology, Krakow, Poland (paulo@geol.agh.edu.pl)
²Polish Geological Institute, Warsaw, Poland, (izabela.bojakowska@pgi.gov.pl; anna.pasieczna@pgi.gov.pl)

Introduction
Main anthropogenic source of thallium in the environment is high-temperature processing of raw materials, in which it occurs at small concentrations.

Material and methods
Concentration of thallium and Ag, Cu, Pb, Rb and Zn contents have been determined in 214 samples of brown and hard coals with the ICP-MS spectrometry. Hard coal samples were collected from Carboniferous in Upper Silesia (USCB), Lower Silesia (LSCB) and Lublin Coal Basins (LCB) areas, and brown coal samples were collected from mined deposits in Poland – Turów, Belchatów, Koźmin, Lubstów, Adamów and Kazimierz.

Results
Contents of thallium in brown coals ranges from 0.2 mg/kg (detection limit) to 2.4 mg/kg. It was noticed that coals from Belchatów and small town Adamów-Konin region deposits - Koźmin, Lubstów, Adamów, and Kazimierz characterize very low concentration of thallium. In these coals Tl contents not exceed 0.4 mg/kg and average contents is <0.2 mg/kg. Turów deposit coals distinguish by increased Tl contents. Thallium concentrations in brown coals from these deposits average 0.7 mg/kg. Distinctly higher Tl contents in Turów deposit coals are caused by overall lithology of the sedimentation basin and its alimentation area and may be connected with cropping up granites and granitoids of crystalline basement and Tertiary alkali basalts. High correlation between Tl and Rb concentrations in brown coals was observed.

Contents of thallium in hard coals ranges from 0.2 mg/kg to 5.3 mg/kg. Samples of hard coals from USCB characterize higher thallium concentration in comparison to two others coal basins. Average concentrations of that element in USCB coals is 0.5 mg/kg, whereas in samples from LCB is 0.4 mg/kg and in samples from LCB is 0.3 mg/kg. Our results shows diversification of thallium contents in coals from USCB. The highest concentrations were observed in coal from upper seams of SE part of the deposit. They might be connected with Zn-Pb (and Fe sulphide) mineralization in Triassic dolomites overlying this part of USCB. In these coals the high correlation between Tl and Pb contents was observed, and somewhat smaller correlations were noticed with Ag, Cu and Rb.

Conclusion
Obtained results permit to estimate that about 60t/a of thallium are excavated with hard and brown coals in Poland.

Hydrogen abundance in the prebiotic atmosphere. Reducing or weakly reducing?

A.A. PAVLOV, S. STEVENSON AND R. YELLE

LPL University of Arizona, Tucson, USA
(pavlov@lpl.arizona.edu; samantha@lpl.arizona.edu; yelle@lpl.arizona.edu)

The atmospheric hydrogen abundance was crucial for the organic synthesis on the prebiotic Earth. For decades a common assumption of the fast (diffusion-limited) hydrogen escape lead to a belief that the prebiotic atmosphere had to be weakly reducing and therefore organic synthesis should have occurred only in the special locations such as hydrothermal vents.

However, the recent study of the hydrodynamic hydrogen escape from the anoxic hydrogen-rich planetary atmospheres suggested that hydrogen could have been lost at a very slow rate and a hydrogen-rich (reducing) prebiotic atmosphere could have been maintained by a reasonable volcanic hydrogen source. This calculation was incomplete though because we did not show how the atmosphere could get to the hydrogen-rich state in the first place.

Here we will report on the atmospheric conditions under which the hydrodynamic escape had to occur. We found that the switch between the reducing and weakly reducing atmosphere was a strong non-linear function of the ancient solar ultraviolet (UV) flux.

UV fluxes > 5 times the present UV flux favor the fast diffusion-limited escape and cause the atmosphere to be weakly reducing. UV fluxes < 3 times the present UV flux always result in a slow hydrodynamic escape and the hydrogen-rich atmosphere should be expected. We conclude that the rate of the organic production on the prebiotic Earth could have been directly dependent on the evolution of the UV flux of the ancient Sun.

We will also report on how the rate of the hydrogen escape would have changed when the first biosphere would provide a significant methane source in the Archean atmosphere.
Investigating the biogenic synthesis of chalcogenide-based nanomaterials

CAROLYN PEARCE¹, VICTORIA COKER², RICHARD PATTRICK², NICOLAS LAW², JOHN CHARNOCK², JONATHAN LLOYD¹ AND RONALD ZUCKERMANN²

¹SEAES, The University of Manchester, Manchester, UK (carolyn.pearce@manchester.ac.uk; vicky.coker@manchester.ac.uk; richard.pattrick@manchester.ac.uk; nicholas.law@postgrad.manchester.ac.uk; john.charnock@manchester.ac.uk; jon.lloyd@manchester.ac.uk)
²The Molecular Foundry, Lawrence Berkeley National Lab, US (rnzuckermann@lbl.gov)

The future of materials science is closely linked to nanotechnology and, as such, there is a need to improve the manufacture of nanomaterials in terms of environmental and economic impact. Using the capability of microbes to manufacture potentially useful bionanominerals offers new methods of material synthesis that eliminate toxic organic solvents, minimize expensive high-temperature processing and can involve the use of industrial waste as the starting material, thereby incorporating a remediation step.

This research involves (i) identification of biomolecules associated with different bacterial strains that act as templates to direct bionanomineral nucleation and growth; (ii) investigation of enzyme-mediated electron transfer reactions resulting in precipitation of nanoparticles; (iii) harnessing and scaling up these processes for biomimetic materials synthesis.

The biotransformation of selenium and tellurium oxyanions by four diverse organisms (Veillonella atypica, Bacillus selenitireducens, Geobacter sulfurreducens and Geobacillus stearothermophilus) has been selected as a model system to study bionanomineral formation by a range of reduction processes. These organisms produce size- and shape-constrained Se/Te nanoparticles with different structural and spectral characteristics to their chemically formed counterparts (Fig. 1).[1]

Figure 1: Biogenic Se and Te nanoparticles

[Image]

The elemental Se/Te is then further reduced to form reactive selenide/telluride, which is precipitated to produce chalcogenide-based fluorescent nanoparticles, such as CdSe.

Factors controlling ¹⁴C contents of organic compounds in oceans and sediments

ANN PEARSON

Department of Earth and Planetary Sciences, Harvard University (pearson@eps.harvard.edu)

Fourteen years ago, Hayes published a review entitled “Factors controlling ¹³C contents of sedimentary organic compounds: Principles and evidence” (Hayes, 1993). It described four processes governing the distribution of the stable isotopes of carbon in individual molecules: “(1) the carbon source utilized, (2) isotope effects associated with assimilation of carbon,…, (3)…effects associated with metabolism and biosynthesis, and (4) cellular carbon budgets”. To a first-order approximation, only the first of these would apply in an analogous discussion of “factors controlling ¹⁴C”. The ¹⁴C content of organic samples is reported in terms of fractionation-normalized values of Δ¹⁴C or f¹⁴C (fraction modern). This practice erases all of the biosynthetic fractionations discussed above. Compound-specific ¹⁴C (CSRA) approaches were developed in part because of this apparent simplicity: values of Δ¹⁴C for individual compounds should depend only on the ¹⁴C content at t = 0 and radioactive decay since then. Calibration records determine ¹⁴C/¹²C ratios at t = 0, in principle allowing calculation of absolute chronologies. However, this applies only to organic matter produced directly from fixation of atmospheric CO₂; biosynthetic reactions that draw upon other pools of the carbon cycle automatically begin with the imprint of a “reservoir correction”. In practice, this means that the value of Δ¹⁴C rarely = 0 at t = 0. Now, after more than ten years of CSRA, it is becoming apparent that reservoir correction is just one of several challenges facing the application of individual-compound measurements. These challenges can be classified broadly as analytical or interpretational. Problems of analysis include: (1) difficulty obtaining adequate quantities of sample, (2) tedious laboratory separations, (3) balloononing uncertainties in values of Δ¹⁴C at small sample sizes, and (4) the difficulty of obtaining authentic standards and measuring realistic processing blanks. Nearly all obstacles to interpretation are due to the problem of heterogeneous mixing: there can be (1) multiple sources of the same compound, each having a different initial reservoir age but mixed in the same terminal reservoir, (2) a single source for a compound, but scrambling of its age by post-depositional mixing, and (3) in the case of prokaryotic metabolism, uncertain contributions of presumed planktonic molecules by deep-pelagic or benthic populations. Despite the challenges, there have been numerous, successful applications of CSRA. Here I will show several recent examples from the literature and discuss how further work promises to illuminate new information about fluxes and residence times throughout the global carbon cycle.

Recent models of mantle convection combined with seismology have caused a paradigm shift in Earth Sciences away from two-layered convection of the mantle, towards models that involve convective stirring throughout most of the mantle depth. Such models are now being supported by a variety of new geochemical data. This makes the study of our only samples of the lower mantle, ultra-high pressure inclusions in diamonds, imperative as one of the few ways of directly testing predictable outcomes of these models.

To do this we have applied ultra-low blank Sr isotope chemical techniques along with carbon isotope analyses to a suite of diamonds from the Rio Soriso, Mato Grosso, Brazil to investigate the isotopic characteristics of the lower mantle. The suite of diamonds were kindly supplied by Dr F. Kaminsky and contain inclusions of Mg-silicate perovskite (MgSiO3), Ca-silicate perovskite (Ca-Pv; CaSiO3) and ferropericlasite, among other minerals. Ca-Pv inclusions contain several hundred to >1000 ppm Sr making it possible to analyse small inclusions of this mineral for their Sr isotopic composition, hence providing the first reliable Sr isotope determinations for the lower mantle environment. Our technique also allows determination of trace element compositions, including rare earth elements.

Two Ca-Pv inclusions have Sr isotopic compositions significantly less than the model “Primitive Mantle” 87Sr/86Sr composition (~ 0.7045) suggested for the lower mantle in two-layer convection models. The values obtained overlap with the MORB compositional spectrum which is taken as reflecting the long-term depletion history of the upper mantle. We interpret the Sr isotope results to indicate that the lower mantle, at the depths sampled by inclusions within diamonds, is not distinct from the upper mantle in terms of its Sr isotope composition. Carbon isotope data for these ultra-deep diamonds will also be presented to examine differences between “shallow” mantle carbon and ultra-deep carbon.
Ni signatures from the Dales Gorge Member of the Hamersley Group, Australia: Constraints on the origin of Banded Iron Formations

E. PECOITS, M. GINGRAS AND K.O. KONHAUSER

Department of Earth and Atmospheric Sciences, University of Alberta, 1-26 Earth Sciences Building, Edmonton, AB, T6G 2E3 (epecoits@ualberta.ca)

The deposition of Precambrian banded iron-formation (BIFs) has been linked to significant compositional changes in the Earth's atmosphere hydrosphere, and biosphere. Previous geochemical studies have measured the isotopic composition and the concentration of major, trace and rare earth elements in BIFs. Those studies have focused on the source of the metals (Fe, Mn, and Si) but others also have considered the role of the microbial activity and the nature of the primary precipitates. In this study we present the results of microscale geochemical analyses, coupled with high-resolution petrography, with the aim of establishing the controlling factors in the source and distribution of trace elements in BIFs.

As primary precipitates, hydrous amorphous silica would have crystallized as pure chert and cationic silica gels as siderite and greenalite, the latter entirely transformed into ferroan-talc. In addition, ferroan-talc is arguably a reaction product of siderite and chert. The presence of platy hematite is accompanied by an increase of ferroan-talc and a diminished siderite content. There is no evidence of magnetite as a primary precipitate, rather, it tends to occur as overgrowths on hematite and may have also formed at the expense of disperse platy hematite. Early diagenetic apatite and late diagenetic ankerite-ferroan dolomite crystals constitute the remaining mineral phases.

We conclude that the distribution and concentration of trace elements in different mineral phases were influenced by hydrothermal activity. Considering the high concentration and strong correlation with Fe, it is suggested that Ni represents a reliable indicator of element contribution from hydrothermal vent systems, which is consistent with previous models based on REE and Nd isotopic signatures. Furthermore, by comparing the Ni:Fe ratios of the Dales Gorge Member with other major BIF types (Algoma-, Superior-, and Rapitan-type), it appears that hydrothermal input was a major source of some trace metals to the BIF depositional setting, particularly Ni.

Comparison of δ¹³C and δD values of n-alkanes from angiosperms and gymnosperms in Western Europe

N. PEDENTCHOUK¹, T. WAGNER², M. JONES², M. PELLEGRINI³, E. BRUGNOLI³, M. LAUTERI³, P. POLLEGIONI³ AND H. BEHLING⁴

¹Dep. of Geology and Geophysics, University of Calgary, Calgary, AB T2N 1N4, Canada (nikolai@ucalgary.ca)
²School of Civil Engineering and Geosciences, University of Newcastle, Newcastle, NE1 7RU, UK
³CNR-Istituto di Biologia Agroambientale e Forestale, Porano (TR), Italy
⁴Dep. of Palynology and Climate Dynamics, University of Göttingen, Untere Karspüle 2, 37073 Göttingen, Germany

Successful applications of stable isotopes of terrestrial plant leaf waxes in paleoclimate research depend on a thorough understanding of isotopic composition of different plant types contributing to sedimentary organic matter. The primary objective of this project is to investigate the effect of environmental conditions on δ¹³C and δD values of leaf wax n-alkanes from modern gymnosperm and angiosperm species throughout a north-south climatic gradient in Western Europe.

The initial nC₂₇-alkane data from Newcastle, UK, Bremen, Germany, and Porano, Italy (3 to 5 species per location) indicate that, overall, there is a strong negative correlation between δ¹³C and δD values. While there is a definite ¹³C-enrichment of gymnosperms in comparison with deciduous angiosperms (at least 1‰, but mostly from 2 to 6‰ in δ¹³C), a significant relative D-depletion of gymnosperm species (between c. 14 to 42‰ in δD) was observed only in Porano. Gymnosperms in Newcastle and Bremen were characterized by much more similar δD values in comparison with deciduous angiosperms, the D-depletion being only between 0 and 21‰ and 0 and 14‰, respectively.

The observed isotopic variations between angiosperm and gymnosperm species in relatively warmer and drier Porano most likely resulted from physiological differences among the species. Relative ¹³C-enrichment and D-depletion of gymnosperms may have resulted from their lower stomatal conductance and greater water use efficiency. The δD data from Newcastle and Bremen, however, suggest that differences in plant physiology were not sufficient to cause appreciable variations between angiosperm and gymnosperm species in these colder and wetter locations.

The results of this study have important implications for interpreting stable isotope data of sedimentary n-alkanes. Large shifts in δ¹³C and δD values may result not only from changes in paleoenvironmental parameters but also from shift in plant communities. The magnitude of isotopic differences between plant types may also depend on climatic conditions, so that δ¹³C and δD differences between angiosperms and gymnosperms are greater in warmer and drier locations.
Mineral chemistry of pyrochlore in residually inherited Fe-P-Nb-laterite ore bodies at Sokli carbonatite complex

A-R. PEHKONEN-OLLILA AND S. GEHÖR

Department of Geosciences, FI-90014 University of Oulu, Finland (anna-riikka.pehkonen-ollila@oulu.fi)

The Sokli carbonatite complex in Northern Finland has undergone extensive laterization and a vertical profile through the sequence varies from 0 to 70 metres. It contains a partially weathered saprock, saprolite, laterite covered by glacial deposits. The laterite is strongly enriched in phosphate, niobium and tantalum.

Locally the weathering profile is covered by a black Fe-P-Nb-REE enriched bed, 5 – 30 mm thick, which is situated directly beneath the glacial deposits and is interpreted to be residually inherited.

The residual bed contains pyrochlore which deviates texturally and chemically from the pyrochlores in main laterite and in fresh rock by being smaller (20µm) in diameter and by their euhedral crystal habit. These grains typically contain high density of fluid inclusions. SEM-EDS and microprobe study indicate that A-site occupancy is dominated Ca and Na of the pyrochlore structure while, along with the weathering, those two ions are detected to become partially replaced by K, Sr, Ba in laterite profile. Contradictory to the pyrochlores in fresh carbonatite-phoscorite and in laterite profile, the pyrochlore in residual bed lack uranium and has extremely low contents of thorium.

The role of Iron redox cycling for the natural acidification of ground water

S. PEIFFER1, C. OLDHAM2, U. SALMON2 AND K. KÜSEL3

1 Dept. of Hydrology, University of Bayreuth, Germany (s.peiffer@uni-bayreuth.de)
2 School of Environmental Systems Engineering, University of Western Australia, Perth (carolyn.oldham@uwa.edu.au, salmon@sese.uwa.edu.au)
3 Institute for Ecology, University of Jena, Germany (Kirsten.Kuesel@uni-jena.de)

In wide areas of Western Australia (WA) springs are occurring that release acidic ground water (pH<3) into gypsum-rich playas. The origin of the acidity is related to the oxidation of Fe(II) and the subsequent precipitation of ferric (hydr)oxides (McArthur et al, 1991). The similarity of these systems to acidic mining lakes (AML) is striking. AML are forming upon oxidation of Fe(II) and sulfate-rich ground water, the pH typically ranges between 2.7 and 3.3 and is buffered by the solubility of schwertmannite (Regenspurg et al., 2004). Acidic conditions in AML are stabilized by an acidity-driven iron cycle at the sediment-water interface, where oxidation and reduction of Fe balance each other with respect to the alkalinity budget (Peine et al, 2000).

We therefore determined Fe(III) reduction rates, Fe(III) mineralogy and the Fe(III) reducing microbial community at three sites from iron-oxide rich (up to 7 % dithionite extractable Fe) soil material fully saturated with acidic ground water. The maximum Fe(III) reduction rate was 4.8 nmol g⁻¹ h⁻¹, a value similar to AML. Jarosite was the only Fe(III) XRD detectable mineral, schwertmannite appeared to be missing. The occurrence of Acidiphilium cryptum, an acidophilic Fe(III)-reducing bacteria could be proved. These observations suggest that also in the acidic ground waters an acidity driven iron cycle exists. They further imply the question how such a low pH can develop in a system that, contrary to AML, is not affected by pyrite oxidation.

Significant acidification from Fe(II) oxidation occurs only, if the corresponding anion originates from a strong acid, such as sulfate. Fe(II) in the ground waters from WA are regarded to be generated during weathering of Fe(II) bearing minerals and/or reductive dissolution of Fe(III) minerals. Both processes, however, generate HCO₃⁻ as the corresponding anion. We therefore postulate that HCO₃⁻ has been replaced by sulfate through the dissolution of gypsum and deposition of CaCO₃ as so-called calcrites:

\[
\text{Fe(HCO_3)_2 + CaSO_4 \rightarrow CaCO_3 + FeSO_4 + 2 H}^+ \]

Microbial mobilization / volatilization of selenium sorbed on soil minerals

MIRKO PEITZSCH, DANIEL KREMER AND MICHAEL KERSTEN

Institute for Geosciences, Environmental Geochemistry, Johannes Gutenberg University, Becherweg 21, D – 55128 Mainz, Germany (peitzsch@uni-mainz.de)

Selenium has major nutritional and biological function but the range between essential and toxic concentration is very small. The more toxic Se(IV) and Se(VI) are water soluble and hence bioavailable. The iron oxide and clay content of soils can affect the bioavailability through adsorption reactions, whereby Se(IV) is stronger adsorbed than Se(VI) [1]. The most reliable natural attenuation process of enriched Se in the environment is microbial methylation [2].

In order to investigate the alkylation / methylation process, Alternaria alternata, known as a Se resistant and active methylating saprophytic fungus [3], was used for incubation studies. First we observed the alkylation of dissolved inorganic selenium (SeO_3^{2-}, SeO_4^{2-}) and found different alkylated species over a wide pH range. Then, different selenium enriched minerals, e.g. goethite enriched by SeO_3 or SeO_4 adsorption, were incubated with A. alternata inoculums to study the dependence of solid selenium binding on alkylation reactions. For Se speciation studies we used different analytical tools. Volatile selenium species were measured with a cryotrappping / cryofocussing gaschromatographic system coupled with ICP-MS. Beside the dominantly occurring dimethyl selenide (DMSe) and dimethyl diselenide (DMDSe) we found also other alkylated species like diethyl selenide (DESe) and diethyl diselenide, especially in dissolved selenium experiments. In adsorption experiments the aqueous inorganic selenium species were measured by hydride generation – atomic absorption spectroscopy. In incubation experiments we used a hyphenated HPLC-ICP-MS to separate the dissolved selenium species.

In our incubation studies we found different patterns of alkylation of dissolved and adsorbed selenium. For dissolved Se, Se(IV) were alkylated in higher amounts and we found more volatile species than for Se(VI) caused by a lacking reduction step in the methylation mechanism [4]. In the opposite we found a higher methylation for Se(VI) than for Se(IV) adsorbed on soil minerals because of different kinds of adsorption [5].

Speciation of Cd, Cu and Pb by DPASV in unpolluted soil solutions

A. PELFRENE, N. GASSAMA AND D. GRIMAUD

Laboratoire GéEAC, Université de Tours, Parc de Grandmont, 37200 Tours, France (aurelie.pelfrene@etu.univ-tours.fr, nathalie.gassama@univ-tours.fr, daniel.grimaud@univ-tours.fr)

The mobility and the bioavailability of trace elements in soils are largely dependent upon their interactions with various organic and mineral ligands. These interactions control trace metal concentration and speciation in complex geochemical systems. The aim of this work is to determine the chemical speciation of cadmium, copper and lead in subsurface waters circulating in an unpolluted soil (Planosol). The study area is located on the Aigurande plateau in the northern part of the Massif Central (France). The substratum is composed of Paleozoic gneiss and intrusive granitic rocks. Soil solutions were collected in a gravely and concretion-rich horizon (Fe- and Mn- oxyhydroxides) from 2004 to 2006 during the soil saturation period.

Chemical speciation of Cd, Cu and Pb was obtained by titrating the filtered water samples using differential pulse anodic stripping voltammetry. Cd, Cu and Pb have been chosen principally because of their various behaviours in the soil solutions. The aim of these experiments is to determine the apparent stability constant K and the corresponding apparent ligand concentration (i.e. complexation capacity CC) using graphic method and the linear transformation method described by Ruizic (1982). A 1:1 complexing model was applied for result interpretation. Polarographic curves of Cd and Cu show significant peaks which may be associated with metal complexes. However, the copper titration curves underline different processes (complexation, adsorption and both processes) and provide evidence for “slow” kinetic reactions (in the experimental conditions). The cadmium titration curves show complexation processes and fast kinetic reactions. Results for measurement of complexation parameters are differently discussed for both metals. To evaluate the copper potential binding in all cases, potential distribution coefficients (Kd) are calculated based on (1) the estimation of K (complexation processes) and (2) the estimation of the number of sites available for metal association using potentiometry (adsorption processes). Potential Kd indicate that copper has a stronger affinity for complexation processes on organic compounds than adsorption processes. No significant seasonal variation pattern in the potential Kd parameter is observed. For cadmium, CC and K results show seasonal evolutions which can be linked to soil solution modifications and/or presence of various ligands. Pb experiments are actually in progress.

As a conclusion, voltammetry data give evidence about relationships between trace metals, organic matter and soil compounds.
Rates of weathering rind formation from $^{238}\text{U}-^{234}\text{U}-^{230}\text{Th}$ chronometry: Application to basalt weathering

E. Pelt\textsuperscript{1}, F. Chabaux\textsuperscript{1}, C. Innocent\textsuperscript{2}, A. Navarre-Stitchler\textsuperscript{2}, P. Sak\textsuperscript{4} and S. Brantley\textsuperscript{3}

\textsuperscript{1}EOST-CGS Strasbourg France (fchabaux@illite.u-strasbg.fr)
\textsuperscript{2}BRGM Orléans France (c.innocent@brgm.fr)
\textsuperscript{3}Earth and Environmental Sciences Institute, Penn State University, Univ Pk, PA, USA (brantley@eesi.psu.edu)
\textsuperscript{4}Department of Geology, Dickinson College, Carlisle, PA, USA (sakp@dickinson.edu)

Weathering rinds developed on fresh rocks provide an opportunity to constrain the processes and rates of weathering as a function of parameters such as lithology and climate [1]. Such information requires first to develop reliable dating methods for such materials, which have been rarely studied, up to now, by radiochronometric techniques.

In this study we propose to evaluate the potential of $^{238}\text{U}-^{234}\text{U}-^{230}\text{Th}$ chronometry to constrain the age and the formation rate of weathering rinds. We worked on a rind developed on a basaltic clast from a Costa Rican alluvial terrace, which has been extensively studied for mineralogy, geochemistry and petrology [1]. Nine subsamples of this clast were collected along a 2 cm transect, from the center of the fresh basalt core to the outer rind boundary, by drilling samples (2.5-mm in diameter and 5-mm depth) on one section of the split clast. Major and trace element concentrations, as well as Sr isotope ratios and $^{238}\text{U}/^{234}\text{U}-^{230}\text{Th}$ disequilibria have been analysed in each subsample.

The data are inconsistent with immobility of Th and removal of mobile elements such as Ca, Mg, and Sr during weathering. Additionally, the increase of $^{87}\text{Sr}/^{86}\text{Sr}$ isotope ratios, $^{234}\text{U}/^{238}\text{U}$ activity ratio and $\text{U}/\text{Th}$ ratios from the fresh core to the outer rind boundary implies an input of U, with $^{234}\text{U}/^{238}\text{U} \geq 1$, and an input of radiogenic Sr into the rind. These U and Sr inputs could both be ascribed to an external flux of dissolved U and Sr transported by the upper soil waters and adsorbed on or incorporated into Fe-Al oxy-hydroxides. Modelling $^{238}\text{U}-^{234}\text{U}-^{230}\text{Th}$ disequilibria in the rind by using an U gain-and-loss model classically applied for the interpretation of U-Th data in weathering profiles [2] give an advance rate of 4-mm/10ka for this 1.5cm-thick rind. This age is in close agreement with other independent methods [1]. This study highlights the potential of the U-series dating method to constrain the timescale of weathering rind formation and therefore to provide new information about the rate of bedrock conversion to saprolite.

Tracking mobile niobium in the boreal environment with a “multi-survey” approach

P. Peltola\textsuperscript{1}, M. E. Åström\textsuperscript{1}, J.J. Virtasalo\textsuperscript{2}, A.T. Kotilainen\textsuperscript{3} and R. Salminen\textsuperscript{3}

\textsuperscript{1}Kalmar University, School of Pure and Applied Natural Sciences, S-39182 Kalmar, Sweden (pasi.peltola@hik.se, mats.astrom@hik.se)
\textsuperscript{2}University of Turku, Department of Geology, FIN-20014 Turku, Finland (jojovi@utu.fi)
\textsuperscript{3}Geological Survey of Finland, FIN-02151 ESPOO, Finland (aarno.kotilainen@gsf.fi, reijo.salminen@gsf.fi)

Niobium is mainly found in weathering-resistant minerals and generally considered as an immobile element and a recent soil (Echevarria et al 2005) and hydrochemical (Lutfi et al 2007) study has not changed this view. Still very little is known about the behaviour of Nb in various soils or in continental surface- and ground water environments. Nb has one stable ($^{94}\text{Nb}$) and several unstable isotopes found in radioactive wastes, e.g. $^{95}\text{Nb}$ and $^{96}\text{Nb}$ ($t_{1/2}=350$ and 2400a).

We examined dissolved and acid-available particulate fractions of Nb in boreal stream and ground waters and “non-detrbral” Nb in sediments. The data consists of both speciation experiments and time–series of a small stream, large scale regional geochemical data sets and brackish/lacustrine environment sediments.

In streams spatial patterns, temporal trends and speciation experiments all point to dissolved humic substances and colloidal Fe as the main carriers and controls of Nb. Clay-silt and ore deposits may be responsible for producing local stream-water Nb anomalies. In groundwater in glacial till overlying Proterozoic granitoids, dissolved (0.45 µm) Nb concentrations were about an order of magnitude higher than in stream water and strongly correlated with dissolved Fe. In the brackish-water sediments, the Nb concentrations (1.3-4.2 ppm) were clearly higher than in the lacustrine ones (0.25-0.53 ppm). To explain this, we assessed the potential role of organic material, biological processes, mineralogy and input factors. However, no satisfactory explanation for the change was found.

The use of multiple surveys was a successful approach for studying the behaviour of Nb. Although this metal is relatively immobile our results show that certain conditions favour Nb enrichment in the aquatic environment which also has implications for the behaviour of radioniobium.

Microbial manganese oxidation is the dominant pathway for Mn oxide precipitation in many environments. Several strains of Pseudomonas putida, a common soil and freshwater bacterium, oxidize soluble Mn(II) via a multicopper oxidase enzyme, producing a poorly-crystalline layer-type Mn(IV) oxide, which is deposited in matrix of extracellular polysaccharides. These reactive nanoparticles have a remarkably high sorption capacity for metals due to their large surface areas (100 - 220 m² g⁻¹), permanent structural charge (~16% Mn(IV) vacancies), and redox activity.

Our research is directed towards understanding the formation of biogenic Mn oxide minerals in metal-contaminated environments and their capacity to immobilize metals during active microbial precipitation. We have determined the effects of varying concentrations of cobalt, nickel, copper, and zinc on rates of bacterial growth and kinetics of enzymatic Mn(II) oxidation by P. putida GB-1. In addition, we have applied X-ray absorption spectroscopy and X-ray diffraction to probe the mechanism of metal sorption to the biooxide-biofilm assemblages. The results from these experiments are interpreted in light of sorption experiments performed with freshly precipitated biogenic Mn oxides.

This work elucidates the dynamic and complex interactions between aqueous species, oxide minerals, and microorganisms encountered in natural systems. The results from this research have important implications for determining the role of biogenic manganese oxides in regulating the concentrations and distribution of trace and contaminant metals in aquatic and soil systems.

Petrology and P-T path of the Guyang mafic granulites: Implications for tectonic evolution of the Western Block of the North China Craton

TOUPING PENG, GUOCHUN ZHAO, MIN SUN, CHANG QIN
AND ALLEN LEUNG

Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong (tppeng@gig.ac.cn)

In the last few years, two Paleoproterozoic continent-continent collisional belts, named the Trans-North China Orogen and Khondalite Belt have been recognized in the North Chia Craton. The Khondalite Belt formed by the collision between the Yinshan Block and the Ordos Block to form the Western Block at ~1.92 Ga, which then collided with the Eastern Block to form the North China Craton along the Trans-North China Orogen at ~1.85 Ga. In the last few years extensive investigations have been carried on the granulite-facies rocks in the Eastern Block, Trans-North China Orogen and Khondalite Belt, but few studies have been done on the late Archean granulites in the Yinshan Block. In this study, we present detailed textural and compositional data for various symplectites or coronas observed in the mafic granulites from the Guyang Complex in the Yinshan Block.

Petrological evidence from the Guyang mafic granulites indicates four stages of metamorphic evolution (M1 to M4). The M1 assemblage is preserved as mineral inclusions within minerals of the peak assemblages, represented by hornblende + plagioclase + quartz ± biotite in the mafic granulites, with P-T conditions of ~0.6 GPa and ~750 ºC. The M2 assemblage is represented by orthopyroxene + clinopyroxene + garnet + plagioclase + quartz at 8.0-10.0 kbar and 800-900 ºC. The M3 assemblage is characterized by garnet+quartz or garnet+clinopyroxene symplectic coronas surrounding orthopyroxene, clinopyroxene and plagioclase grains, with P-T of 9.0-10.0 kbar and 700-750ºC. The M4 assemblage consists of cummingtonite + plagioclase replacing clinopyroxene and orthopyroxene. These assemblages and the estimated P-T conditions indicate that the Guyang mafic granulites underwent medium-pressure granulite-facies metamorphism with an anticlockwise P-T path involving near isobaric cooling following peak metamorphism, which reflects a metamorphic event related to the intrusion and underplating of large amounts of mantle-derived magmas rather than a continent-continent collisional environment.

Climate fluctuations during the last 3000 years in Guizhou, China: Evidence from the TIMS-U series ages and oxygen isotope composition of stalagmite

ZICHENG PENG1, ZHAOFENG ZHANG2, CHAO LUO1, YI LIU1 and CHEN-LIN ZHOU3
1School of Earth and Space Science, University of Science and Technology of China, Hefei 230026, P.R. China (pzc@ustc.edu.cn)
2Department of Geology, University of Illinois-Urbana Champaign, Urbana, IL 61801, USA
3Illinois State Geological Survey, Champaign, IL 61822-6113, USA

The TIMS-U series ages and the δ¹⁸O values of stalagmites from the Qixing Cave, Guizhou (26°35’N, 107°16’E) have been determined using the MAT-262-RPQ and Delta-S mass spectrometers. The results indicate that the stalagmite was deposited during the period of 3145-200 a B.P. and experienced four stages of the climate-environmental change.

(1) The first stage is in the range of 3145-2927 a B.P., which has δ¹⁸O values from –5.61 to –5.16‰. This stage corresponds to the late Megathermal Period (7-3 ka B.P.);
(2) The second stage is in the range of 2927-1196 a B.P., which has δ¹⁸O values from –5.51 to –4.59‰. Those values are higher than that in the first stage, indicating that the climate has become colder and dryer;
(3) The third stage is in the range of 1196-545 a B.P., which has the δ¹⁸O values from –5.98 to –3.92 ‰. This stage corresponds to the Medieval Warm Period (MWP);
(4) The fourth stage is in the range of 545-200 a B.P., which has the δ¹⁸O values from –5.39 to –3.51 ‰. It had the coldest and driest climate during the period of last 3000 years. This stage corresponds to the Little Ice Age from 1555 A.D. to 1800 A.D.

A regressive equation δ¹⁸O (‰) = −2.20 × 10⁻⁴ year (a.B.P.) - 4.54 by fitting the two data sets of the δ¹⁸O values and the age (years). It indicates that the δ¹⁸O values become higher from 3145 a B.P. to 200 a B.P. which corresponds to lower precipitation. The warm and wet climate in the late Megathermal Period changed to the cold dry climate in the Little Ice Age. It is interesting to note that on the basis of the climate records during 1951-2000 A.D. measured at the Guiyang Meteorological Observatory (26°35’E, 106°43’N), two regressive equations of the temperature values and the age (years), the precipitation values and the age (years) have the negative slopes, implying that the temperature gradually decreases with an amplitude of 0.2°C and the precipitation gradually decreases with the amplitude of ~7 cm during the last 50 years. Thus, the modern climate pattern in Guizhou Province, China, may be continuing from the last 3000 years.

Mass-independent sulfur isotopes trace magma-wall rock interactions in the Bushveld Complex

SARAH PENNISTON-DORLAND1, BOSWELL WING2, JAMES FARQUHAR1, MICHAEL BROWN1 AND PAUL NEX3
1Department of Geology, University of Maryland, College Park, MD 20742 (sarahpd@geol.umd.edu; jfarquha@essic.umd.edu; mbrown@geol.umd.edu)
2Department of Earth and Planetary Sciences, McGill University, Montreal QC H2S 2C3 (wing@eps.mcgill.ca)
3Umbono Group of Companies, Johannesburg SA (pnex@umbono.co.za)

Abundant metasedimentary xenoliths in the Platreef, the ore horizon of the northern limb of the Bushveld Complex, South Africa, suggest significant interaction between the Bushveld magma and the surrounding country rock during emplacement. Fluid-mediated concentration of Platinum Group Metals and sulfur into the Platreef ore zone likely occurred as a result of this interaction. We use measurements of ⁳⁴S/³²S and ⁳³S/³²S to test hypotheses of material transfer between the Platreef and the surrounding country rock.

Solid-earth fractionation processes of ⁳⁴S/³²S and ⁳³S/³²S are mass-dependent, characterized by: δ⁳³S = 0.515 x δ⁳⁴S. Deviation from mass-dependent isotopic fractionation is quantified as Δ³⁴S (= δ³⁴S–1000/(1+ δ³⁴S/1000)⁰⁵¹–¹). Proxies for ‘primary’ igneous sulfur (meteorites, peridotite xenoliths) possess Δ³⁴S values near 0 ‰. Similarly, relatively pristine Bushveld igneous rocks have Δ³⁴S values ≤ 0.2 ‰. On the other hand, sedimentary country rocks surrounding the Platreef exhibit substantial non-zero Δ³⁴S values. As Δ³⁴S is a chemically-conservative tracer, non-zero Δ³⁴S values in Platreef sulfide ore minerals are an indication of material transfer from the surrounding country rock.

We have performed a S isotope study along two profiles through the Platreef into underlying metapelitic and metacarbonate country rocks. In both profiles, far-field igneous rocks have Δ³⁴S values ≤ 0.2 ‰, while far-field metasedimentary rocks have significantly mass-independent S isotope compositions (Δ³⁴S ranging up to ~0.9 per mil in the pelitic rocks and up to ~5.0 per mil in the carbonate rocks).

In the metapelitic profile, Δ³⁴S values from the country rocks show only a weak positive correlation with distance from the igneous contact while S isotope compositions within the Platreef are consistent with mass-dependent S isotope compositions (Δ³⁴S ≤ 0.2 ‰). Both features suggest little magma-wall rock interaction. In the metacarbonate profile, however, Δ³⁴S values in both the country rock and the Platreef define a classic advective-dispersive tracer geometry. This geometry is not present in the associated Δ³⁴S values, revealing their susceptibility to post-transport alteration. Displacement of the Δ³⁴S front suggests fluid advection into the country rocks; this was accompanied by back-diffusion of S isotope species into the Platreef. Counterintuitively, then, mineralization may have occurred as a by-product of fluid transport out of the Platreef ore-forming zone.
The presence of excess $^3\text{He}$, which cannot result from air contamination, is strong evidence that indigenous noble gases exist in Stardust samples. The $^3\text{He}/^4\text{He}$ ratio can in principle point to when comets acquired their noble gases, and from what volatile reservoir—the early protosolar nebula, near the evolving sun during or just after the deuterium burning that elevated the level of protosolar $^3\text{He}$, or by later implantation of solar-wind-like radiation. Jupiter’s $^3\text{He}/^4\text{He}$ ratio of $1.66 \times 10^{-4}$ (Mahaffy et al., 1998) likely reflects the protosolar value. $^3\text{He}/^4\text{He}$ is $\sim 3.6 \times 10^{-4}$ in the sun after deuterium burning (Heber et al., 2004), and $4.82 \times 10^{-4}$ in the solar wind (Heber et al., 2007). Our preliminary measured ratio of $\sim 2.7 \pm 0.3 \times 10^{-4}$ falls between the protosolar and solar D-burning values.

Production of the excess $^3\text{He}$ by galactic cosmic ray (GCR) spallation reactions is unlikely. While measured $^3\text{He}$ contents are small (< 600,000 atoms), abundances/gram are not; the minimum grain concentration is estimated to be $\sim 6 \times 10^{5}$ cm$^3$/g. GCR production rates in a fosterite/enstatite particle, on the Wild-2 surface or buried under 1 m of ice, are $\sim 7-5 \times 10^9$ cm$^3$/g per Ma, requiring GCR exposures of $\sim 1000$ Ma, in either location, to generate only 10% of the $^3\text{He}$ concentration. Estimated mass loss from Wild-2 just since its 1974 appearance is $\sim 1$ m (Brownlee et al., 2004), and was probably significantly more in the Wild-2 jet sources if they were active on previous apparitions. The collected particles were therefore likely buried until very recently at depths where GCR production is essentially nil. While ancient surfaces may be preserved on Wild-2 (Brownlee et al., 2004), only $\sim 50\%$ of the observed $^3\text{He}$ could be produced in them by GCR spallation over the 4500 Ma age of the solar system.

The dynamic Archean Earth
JOHN A. PERCIVAL
Geological Survey of Canada, 601 Booth St. Ottawa, Ontario, Canada K1A 0E8 (joperciv@nrcan.gc.ca)

Archean cratons stand distinct from younger orogens as a result of their refractory lithospheric keels and relatively abundant komatiite and tonalite-trondhjemite-granodiorite (TTG) rock types. Yet detailed petrogenetic and structural studies within well constrained geochronological frameworks point to the operation of plate-tectonic-like processes as far back as 3.8 Ga. Modern geodynamic settings provide a template for interpretation of igneous rock sequences based on the assumption that melt compositions are governed by mantle mineral assemblages, dependent on depth and temperature, mediated by fluid fluxes. Application of the modern template to the Phanerozoic and Precambrian record has been validated through consideration of multiple characteristics including depositional setting, and timing and duration of magmatic and structural events. The Superior Province of North America records the formation of several independent protocontinental fragments between 3.8 and 2.8 Ga. Continental margin rift sequences suggest plume-driven magmatism, which was followed by production of plateau-type juvenile basaltic crust in the early Neoarchean. Consumption of oceanic domains of undetermined extent is recorded in $\sim 2750$ Ma oceanic and continental arcs with subduction signatures including pre-orogenic boninite, calc-alkaline basalt and adakite, and syn-to post-orogenic shoshonite and sanukitoids. Five discrete collision events between 2720 and 2680 Ma united the oceanic and diverse protocontinental terranes. Evidence from the western Pilbara craton supports the operation of subduction by 3.12 Ga, whereas the 3.51-3.24 Ga sequences of the eastern Pilbara appear to have evolved in a plume setting (Smithies et al. 2005). However, evidence for even earlier sea-floor spreading within a plate-tectonic framework derives from the 3.8 Ga Isua belt (Furnes et al. 2007). It is likely that plumes were a common heat-release phenomenon early in Earth history, and once may have been dominant, but evidence for Neoarchean plume-arc interaction (Dostal and Mueller 1997) suggests that as in the modern Earth, plumes were not incompatible with organized convection. Evidence from the Hadean record is scant and views of Earth’s very early evolution are guided by thermal models and insights from planetary geology.

Many features of Archean terranes appear to be directly (komatiites, charnockites) or indirectly related to higher mantle temperatures. The highly depleted compositions of lithosphere keels may result from fluxed melting of depleted mantle in high-temperature suprasubduction-zone wedges.

TEM evidence for lead transport by bacteria in atmospheric deposition

N. PERDRIAL, F. ELSASS AND N. LIEWIG
1Centre de Géochimie de la Surface, CNRS-ULP, Strasbourg, France (perdrial@illite.u-strasbg.fr)
2PESSAC, INRA, Versailles, France (elsass@versailles.inra.fr)
3IPHC, Ecologie Physiologie Ethologie, CNRS-ULP, Strasbourg, France (Nicole.Liewig@c-strasbourg.fr)

Particulate matter (PM < 5) present in atmospheric deposition and subsurface soil water has been monitored during one year in two different, polluted and non polluted environments located in France. One site is a vineyard and the other one is a forest considered as an unpolluted reference site. Coupling TEM and EDX permits single-particle characterization (composition, structure, size and morphology).

PM in rainfall, leachate and soil solution show similar characteristics for both sampling sites: among more than 10000 characterized particles, 10 to 20% of the relative surface area is of biological type. Different morphotypes of bacteria and associated amorphous organic matter are regularly and significantly concentrated in lead. Lead is always associated with phosphor forming one or several granules confined inside the bacteria cell (Figure 1).

![Figure 1. a) Bacteria with internal granules (arrow). b) EDX spectrum corresponding to arrow in figure 1.a)](image)

Such lead enrichments inside internal granules have been previously shown (Roane, 1999; Suh et al., 1999) in laboratory experiments. Our study proves for the first time such an occurrence in natural environments. The presence of bacteria in both rain water and soil water suggest an ubiquitous behaviour of microorganisms and an atmospheric origin for the lead. Even if the source of lead is not known, our result furnishes evidence for a microbial airborne lead transport.

Estimating geochemical impacts of uranium mining exploitation: The evaluation of the natural background in the Beiras metallogenetic province (Central Portugal)

1IMAR, Department of Earth Sciences, University of Coimbra (apereira@dct.uc.pt)
2Department of Earth Sciences, University of Coimbra (jmatosdias@mail.telepac.pt)

The evaluation of the geochemical and radiological impacts associated with uranium mining activities requires a comparison, for each environmental compartment, of data taken before and after the end of mining works. With a few exceptions, no environmental data is known for Portuguese old uranium mines regarding the natural background before exploitation. A possible way to overtake this limitation is to obtain data from areas which constitute a natural analog of those that were mined for uranium ores, but where exploitation did not occur. The Oliveira do Hospital area, located in Central Portugal, fulfil such requirements; here, late-tectonic Hercynian granites and pre-ordovician metasedimentary rocks dominate. 24 samples of surficial and groundwaters were collected in the region, as well as 14 samples of soil and 5 of stream sediments. These samples were analysed for more than 40 chemical elements, using several analytical techniques. The results obtained allowed to establish reference values for the geochemical background, taking into consideration central tendency and variability parameters. An important conclusion is that several elements are frequently concentrated by natural processes above the limits referred in the literature and/or legislation as indicating anthropogenic contamination (e.g. Ba, As, P and Be in soils, $^{226}$Ra in waters), which reinforces the interest of the evaluation of the local geochemical background, as an alternative to the use of global reference values.
Hydrogeochemistry of water resources from abandoned Freixeda gold mine (NE Portugal)

M.R. PEREIRA¹, M.E.P. GOMES¹ and R. MONTES²

¹Dep. of Geology, University of Trás-os-os-Montes e Alto Douro, Vila Real, Portugal (rpereira@utad.pt; mgomes@utad.pt)
²Secondary School Dr. Ramiro Salgado, T. de Moncorvo (ricardmot@portugalmail.com)

Freixeda mine is located in NE Portugal and was exploited for Au, Ag and Pb. It belongs to the Auriferous Methalogenic Province of NW of Iberian Peninsula. The mineralization is associated with sulphide minerals in quartz veins, located in metasedimentary paleozoic formations.

Water samples were collected from a gallery with acid mine drainage (AMD), 3.5 <pH< 4.0, and from groundwater and surface water, upstream and downstream from the mine influence. Water from Ribeira de Freixeda upstream from the AMD confluence is not affected by the mineralization and has Ca-HCO₃ type, slightly basic pH with no detectable As and no significant concentration of trace metals. Downstream from the AMD, surface water becomes Ca-Mg-SO₄ type with elevated concentrations of As, Zn and Mn.

Groundwater from a spring outside the influence of the mine has a pH of 6.5 and is of Ca-Na-HCO₃ type with no anomalous trace element concentrations. Groundwater exploited from a deeper well is of Mg-SO₄ type, pH about 7 and has high concentrations of As, Zn, Mn and Fe.

Conclusions from this study are that water resources of Freixeda are affected by sulphide mineral oxidation which releases cations, SO₄²⁻ and H⁺ ions. These free H⁺ ions contribute to the dissolution of carbonates (present in cement of metasedimentary rocks) and to the hydrolysis of silicate minerals (plagioclases) promoting the alkalinity and pH increase.

Concentration of As in surface water is much lower than in groundwater probably do to adsorption of As on Fe oxyhydroxides, that precipitates in stream sediments. This suggestion is supported by the absence of dissolved iron in surface-water samples. Even so, the amount of As (190 ppb) in surface water is above the limit for human consumption or watering. In groundwater, the oxidation-reduction potencial and pH conditions that allow Fe to remain in solution could be responsible for the higher concentration of As (850 ppb).

Introduction to the CAMECA IMS 7f-GEO

PAULA PERES, EMANUEL DE CHAMBOST AND MICHEL SCHUHMACHER

CAMECA, 29 quai des Grésillons, 92622 Gennevilliers Cedex, France. (peres@cameca.com)

SIMS is applied to a variety of applications in Geoscience, because it offers sensitivity compatible with very local isotopic and/or elemental analysis of solid samples. Large SIMS instrument like the CAMECA IMS 1280 offers outstanding performance for the entire SIMS application range (dating experiments, stable isotopes, REE analysis) thanks to its very high transmission mass spectrometer combined to a versatile multi-collection system. However, sometimes this tool can be seen as oversized for a laboratory with a limited application range. Therefore CAMECA has introduced the IMS 7f-GEO, a compact SIMS model with new features targeted to improve performance for isotopes and trace element analysis:

- Quasi-continuous record of the primary ion current during analysis.
- Magnetic sector with a very fast peak switching capability over the full mass range (magnetic and electrostatic peak switching combination).
- Secondary ion detection equipped with an EM and a pair of Faraday cups. Double FCs configuration makes possible to run an analysis in a pseudo-bicollection mode well-suited for stable isotope analysis.
- High precision Faraday Cup electrometer.

Typical analytical performance of the IMS 7f-GEO for stable isotope analysis (18O/16O): for an analysis area of 10x10µm², a single analysis internal error of less of 0.3 per mil is reached for a total integration time < 60sec. Detailed instrumental features and experimental data will be presented.
Heavy metals content in Belgrade soils

S. PEROVIC1, V. JOVIC2 AND I. BRCESKI3

1BMDBAU doo, Dr Zore Ilic Obradovic 8/3, Belgrade, Serbia (slobodan.perovic@gmail.com)
2Faculty of Mining and Geology, University of Belgrade, Dijasna 7, Belgrade, Serbia (jvidojko@eunet.yu)
3Faculty of Chemistry, University of Belgrade, Studentski trg 12-16, Belgrade, Serbia (ibrceski@chem.bg.ac.yu)

The main goal of the paper is to present results of researches held from 2004 to 2006 regarding heavy elements content in the Belgrade city soils. Lot of 153 soil samples from 24 different locations were taken and analyzed from 2004 to 2006 in laboratory "MOL" (Belgrade).

Methods

Samples were taken from exact localities, from the topsoil (surface soil) – 0-15 or 0-20 cm of depth. Each sample was prepared as a composite of few sub-samples using standard techniques (EPA method 3040).

Different instrumental methods were used to determine concentrations of desired elements: (EPA 213.2), (EPA 239.1), (EPA 206.2), (EPA 249.1), (EPA 220.1), (EPA 218.1), (EPA 289.1) and (EPA 245.1); spectrophotometric technique was used for determining chromium concentrations.

Discussion of results

On the most of the localities (21 out of 24) certain excess of concentration of elements, which are important for soil pollution assessment, is determined. Only in one case exceeding concentration of chromium was related to geological factors; in other 152 out of 153 cases – human activities were only source of pollution.

Nickel concentration in soil samples from Belgrade area exceeds MAC of 50 ppm in 20 of 24 samples. Concentration reaches up to 228 ppm in soils from New Belgrade.

On the localities of Ada Ciganlija excess in concentrations for six elements and in New Belgrade of four elements were determined. Samples of river mud from Ada Ciganlija lakeshore showed very high level of contamination with lead, nickel, copper and especially zinc.

Low water contents in minerals from Gakkel ridge abyssal peridotites, Arctic Ocean

A.H. PESLIER1, J.E. SNOW2, E. HELLEBRAND3 AND A. VON DER HANDT4

1TeSUH, University of Houston, Houston, TX 77204, USA (apeslier@mail.uh.edu)
2Department of Geosciences, University of Houston, Houston, TX 77204, USA (jesnow@uh.edu)
3SOEST, University of Hawaii, Honolulu, HI 96822, USA
4Max-Planck Institute für Chemie, 55020 Mainz, Germany

We report the first water contents ever measured in abyssal peridotite minerals. The analyses are made possible by the exceptionally fresh state of a few Gakkel Ridge peridotites that show almost no serpentinization. Gakkel ridge is the slowest spreading ridge on Earth (Michael et al., 2003). The three preliminary samples analyzed so far come from dredge haul PS66-238 (Snow et al., 2007) from an amagmatic region where no basalts were found, and the extent of melting is low to non-existent. FTIR spectra of olivines and pyroxenes resemble previously published ones (e.g., Miller et al., 1987, Skogby et al., 1990). Water contents in one peridotite correlate with grain size in olivines and are variable in orthopyroxenes, whereas those of the other two samples are homogeneous. No water variations are observed within individual grains.

Calculated water concentrations in H2O ppm are <1-5 for forsteritles, 25-60 for enstatites, and 130-200 for diopsides. These water contents are 2 to 3 times lower than typically found in continental spinel and garnet peridotites (e.g., Peslier et al., 2002; Peslier and Woodland, 2006). Recalculated whole-rock water contents of the abyssal peridotites are at most, 50 ppm, about half the amount calculated from MORB-glass analyses for the depleted-MORB mantle (DMM) (e.g., Dixon et al., 2002). The low water contents of the abyssal peridotites also contrast with water contents measured in MORB glasses from Gakkel Ridge which are higher than those of MORB globally (Michael et al., 2006). If the low water content of Gakkel ridge abyssal peridotites is representative of that of the Earth’s oceanic mantle, models for extents of melting, major and trace element trends and crustal thickness at mid-oceanic ridges (e.g., Asimow and Langmuir, 2003) need reassessment.

The chemistry of diffuse-flow vent fluids on the Galapagos Rift (86°W): Temporal variability and subseafloor phase equilibria controls

N.J. PESTER1, D.A. BUTTERFIELD2, D.I. FOUSTOUKOS3, K.K. ROE2, K. DING1, T.M. SHANK4 and W.E. SEYFRIED, Jr.1

1Department of Geology and Geophysics, University of Minnesota, Minneapolis, MN 55455, USA

3Carnegie Institute Geophysical Laboratory, Washington, DC 20015, USA
4Biology Department, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts, 02543, USA

Recent (2002, 2005) expeditions to the Galapagos Rift, 86°W have conducted integrated experiments to assess temporal/spatial changes in both the chemistry and associated biology of diffuse-flow hydrothermal vents. The chemical data adds significantly to time series observations of hydrothermal processes at the Galapagos Spreading Center (GSC), where seafloor venting was first discovered in 1977. Assuming quartz-fluid equilibria (0.55 NaCl solution), end-member values for dissolved silica in 2002/2005 indicate temperatures ~50-100°C lower than in 1977. The higher predicted temperature in 1977 is consistent with observed chloride depletion in fluids issuing from Oyster Beds vent, indicating fluid phase separation, whereas all fluid samples from 2002/2005 are at or above seawater concentration. Respective values of dissolved Mn further suggest a lower temperature hydrothermal reaction zone at 86°W relative to three decades ago. The slope of Li-Si data from 1977, however, does not depart significantly from the 2002/2005 data, suggesting temperature change has little effect on dissolved Li in the hydrothermal endmember. At some point between 1990 and 2002 a volcanic eruption covered the historical Rose Garden vent-field, ending years of biological observations. Although the precise age of the lava flow is uncertain, the lack of chloride depletion and low H2S/heat ratios of the 2002/2005 vent fluids suggest the 2002 expedition arrived well after the eruption based on observations from other diffuse-flow systems perturbed by volcanic activity. Lower dissolved silica, Mn and H2S in the 2005 vent fluids relative to 2002, however, may indicate continued cooling in the aftermath of the recent eruption. Results of geochemical modeling for evolved seawater in equilibrium with a moderately oxidizing mineral assemblage are consistent with chemistry of recent GSC fluid samples, predicting H2S/Fe > 1, with little Fe in fluids diluted to the extent typical of 86°W vents. Results from in-situ chemical sensor measurements reveal non-conservative behavior of dissolved H2S, especially at temperatures below 10°C, which may be due to microbial metabolism.

Quantification of sulphur cycling at the Mid-Atlantic Ridge

M. PETERS1, C. OCKERT1, J. FARQUHAR2, A. MASTERSO2 AND H. STRAUSS1

1Geologisch-Paläontologisches Institut, Westfälische Wilhelms-Universität Münster, Germany
2Department of Geology, University of Maryland, U.S.A.

Mid-ocean ridges and associated hydrothermal vent systems represent a unique scenario in which the interaction of hydrosphere, lithosphere and biosphere and the related element cycling can be studied. Here, we present concentration and isotope data (S, O, H, C) for hydrothermal fluids and their dissolved constituents as well as from mineral precipitates collected at the Logatchev hydrothermal field (14°45′N) and different sites at the southern MAR (4° – 11°S).

δ34S values for dissolved sulphide and metal sulphides from the emanating hot fluid itself or pieces from black smokers between +1.9 and +8.8‰ (V-CDT) suggest that sulfur represents a mixture between mantle sulfur and reduced seawater sulphate. More detailed quantifications are based on the rare sulfur isotopes (33S and 36S) suggesting a contribution from recycled seawater sulphate between 20 and 30%.

Dissolved inorganic carbon in hydrothermal fluids from both hydrothermal areas show characteristic δ13C values around -3.9‰ (V-PDB, end member corrected).

Isotope values of Δ13O = 2.2‰ and Δ2H = 6.6‰ for the hydrothermal fluids at Logatchev and southern MAR sites clearly point to intense interaction between fluid and host rock. Very high sulphide concentrations up to 8.2mmol/L (calculated end member) measured for fluids from the Turtle Pits site (5°S) indicate an early stage of hydrothermal activity and are consistent with young volcanism. This indication is supported by very high fluid temperatures up to 407°C for the black smoker “Two Boats”.

Strongly negative sulphur isotope values as low as -24.0‰ for sulphidic sediments at the Logatchev HF are clear indicators for bacterial activity and, thus, point to the participation of microbial communities in sulfur cycling at the Mid-Atlantic Ridge.

The results, so far, provide a deeper insight into element cycling at the Mid-Atlantic Ridge, including apparent differences to fast-spreading ridge systems, such as the East-Pacific Rise (EPR).

Sequential extraction of radioactive metals in soils from Crucea uranium mine (Romania)

L. PETRESCU\(^1\) AND E. BILAL\(^2\)

\(^1\)University of Bucharest, Department of Mineralogy, 1 N.Balcescu Blvd., Ro-010041 Bucharest 1, Romania (lucpet@geo.edu.ro)
\(^2\)Ecole Nationale Supérieure des Mines, Département GENERIC, 158 Cours Fauriel – 42023 Saint Étienne CEDEX 2, France (bilal@emse.fr)

ICP and XRF Spectroscopy methods were used to evaluate the metals (ppm) from soils for the mining dumps of Crucea-Botusana uranium deposit (Bistrita Mountains, Romania).

The sequential extraction has emphasized the fact that U is associated with all the mineral fractions present in the soil samples. A great percentage of U can be found in the carbonate, organic and oxides fractions. The percentage of U detected in the exchangeable fraction is rather small. The fact that 21.77\% of the total U can be found in the specifically absorbed and carbonate bound fraction, indicated the important role played by the carbonates in the retention of U; one the other hand this fraction is liable to release U if the pH should happen to change.

Th appear in high-enough concentration in the soil is scarcely available because 70.29\% is present in residual fraction, and about 21.78\% in the organic and oxides fractions. This is certainly due to the fact that this naturally occurring radionuclide can be associated with relatively insoluble mineral phases like alumino-silicates and refractory oxides. Its association with the organic matter suggests that it can form soluble organic complexes that can facilitate its removal by the stream waters.

In the case of Sr, the sequential extraction shows that it is very strongly fixed because the residual fraction concentrates the great amount of this element. What is interesting is the percentage of 2.65 \% of Sr from the exchangeable fraction because it can be easily released and transported to the surrounding environment.

Pb it is present in various relatively soluble pools (17.81\% in carbonate boud and 34.85\% in organically bound), which appears to be an efficient sink for this element. This fact may indicate a possible link between the biological activity and the Pb cycling into the soil. In addition, only 17.78\% is present in the insoluble residual fraction.

Although from our research it resulted that the radioactive metals does not concentrate in the exchangeable fraction (Th) or it concentrates very little in it (U and Sr), the isolation of the mineral fraction of soil rich in U, Th and Sr helps us in the future identification of the connections which control the cycle of the radioactive metals.

These results have important implications for remediation strategies. The thorium and uranium from Crucea mining area are in labile, not strongly retained, fractions, thus making them amendable for remediation by phytoremediation.

Phase decomposition in non-isotropic multi-component systems: The alkali feldspar example

E. PETRISHCHEVA AND R. ABART

Institute of Geological Sciences, Free University Berlin (eptris@zedat.fu-berlin.de, abart@zedat.fu-berlin.de)

Phase decomposition in a multicomponent system is considered theoretically. The approach of non-linear diffusion is used and the corresponding system of Cahn-Hilliard equations is systematically derived from the expansion of the free energy. In contrast to the standard Cahn-Hilliard model the possible anisotropy of the system is taken into account. The final equations set is solved numerically using a finite element approach. Realistic approximations for the free energy are used. The numerical solutions are finally compared to observations made on naturally exsolved feldspar. Good qualitative agreement is found. The morphology of exsolution phases depends on the composition of the homogeneous precursor feldspar and on the degree of anisotropy. Host-inclusion arrangements are obtained, when the bulk composition is close to one of the spinodal points and a co-continuous morphology is obtained, if the bulk composition is half way between the respective binodal compositions. For feldspar compositions that lie close to the albite-K-feldspar binary, the anorthite component is preferentially fractionated into the albite-rich exsolutions.
Isotope-geochemical criterion in search for the Noril'sk-type massive PGE-Cu-Ni sulphide ores: Constraints from Pb, Nd and Sr isotope data

O.V. PETROV, K.N. MALITCH, YU.D. PUSHKAREV AND E.S. BOGOMOLOV

All-Russia Geological Research Institute, Sredny pr. 74, St. Petersburg, Russia (Kreshimir_Malich@vsegei.ru)

Our study aims on isotope-geochemical speciation of main types of intrusive bodies at Noril’sk district (northern Siberia), with particular focus on isotope-geochemical estimation for the unique metallogenic potential of the Noril’sk-type intrusions that range in thickness to 360 m and length to 25 km.

This study presents the first results of a multi-technique approach, which utilized isotope systematics of Nd, Sr and Pb for rock-forming minerals (i.e. pyroxene, plagioclase and olivine) and associated sulphide minerals (disseminated ores) derived from main lithological units of various ultramafic-mafic intrusions (namely economic Noril’sk-1, Talnakh and Kharanakh, subeconomic Zub-Marksheider and Vologochan, prospective Mikchangda and none-economic Nizhny Talnakh). Initial Sr and Pb isotope ratios have been also determined in massive sulphide ore samples at Talnakh and Kharanakh.

Initial lead isotope compositions of plagioclase and sulphide (67 analyses) significantly differ from each other indicating their isotope heterogeneity. Similarly, contrasting difference in the Sr isotope composition has been observed for the rock-forming silicate minerals and sulphide ores. At Talnakh and Kharanakh, concentration of Sr in massive sulphide ore varies from 4 to 30 ppm; (87Sr/86Sr)$_i$ varies in the range 0.7085-0.7111, whereas in plagioclase and pyroxene (87Sr/86Sr)$_i$ usually not exceeds 0.7076. This implies that sulphide ore melt appeared in its location site as isotopically heterogeneous mechanical admixture, marked by specific isotopic compositions of Pb and Sr, different from that of rock-forming minerals. It is noteworthy that sulphide ores, in comparison with silicate minerals, were essentially enriched by radiogenic Sr component at time of intrusion.

In Sr-Nd isotope systematics silicate matter from economic ore-bearing intrusions (about 60 bulk rock samples, plagioclase and pyroxene extracted from the bulk rocks) in comparison with silicates from none-economic weakly mineralised intrusions (81 sample) manifest clear contamination by the component, which along with relatively constant the Nd isotope composition (epsilon Nd about +1±0.5) is enriched with the radiogenic Sr. This feature can be employed as a prospective sign for the presence of significant quantities of the ore contaminant, which has isotope signatures close to that of massive sulphide ores.

Quantifying mineral aerosol inputs and the mobility of “immobile” elements in weathering studies

JULIE C. PETT-RIDGE$^1$, LOUIS A. DERRY$^1$ AND ANDREW C. KURTZ$^2$

$^1$Cornell University, Ithaca, NY (jcp38@cornell.edu)
$^2$Boston University, Boston, MA

Calculations of chemical weathering fluxes rely on a complete characterization of the mass balance for a given system. This study addresses two issues that may play an important role in these calculations. The first issue is that of mineral aerosol inputs, which can be a significant contribution to the overall atmospheric flux. Appropriate spatially and temporally averaged values for mineral aerosol fluxes are not easily established. The second issue is the use of “immobile” index elements such as Ti and Zr in the calculation of weathering losses of other elements. This study focuses on an analysis of mineral aerosol inputs and mobility of a wide variety of trace elements from the Rio Icacos watershed in the Luquillo Mountains of Puerto Rico. Additionally, this study puts the findings from the Rio Icacos in a global context based on literature review.

Results of our analyses in the Rio Icacos illustrate that Sr isotopes may be used to calculate watershed-scale average mineral aerosol deposition fluxes given a situation of a monolithologic catchment, a difference in the $^{87}$Sr/$^{86}$Sr ratio between the bedrock and the mineral aerosol inputs, and Sr-bearing primary minerals weathering to completion in the regolith. Nd isotopes are used to demonstrate that mineral aerosol inputs are incorporated to a depth of >3 meters in the regolith.

Trace element and rare earth element data were analyzed in order to assess patterns on elemental mobility within Rio Icacos regolith. Of all elements, Zr indicates the least mobility in this system, yet Zr data indicate leaching losses of ~50%. Alternatively, the saprolite has expanded by a factor of 2x during formation, but volume expansion is considered highly unlikely based on textural evidence. Calculations of mass losses during chemical weathering based on normalization to trace elements therefore require careful consideration in the case of intense weathering environments.
Interaction of the hydrologic cycle with the continental crust exerts a strong influence on the chemical composition of the ocean and atmosphere. Advanced models of long-term ocean/atmosphere evolution therefore critically depend on reconstructions of the hydrologic cycle and bedrock geology in the geologic past.

Here, I argue that important aspects of past surface geology can be reconstructed from radiogenic isotope records of seawater. These reconstructions rely on linear correlations between bedrock age and lithology with the isotope composition of continental runoff (Peucker-Ehrenbrink, submitted). Global and regional bedrock lithology and ages are quantified using GIS technology and digital geologic maps at resolutions of 100 to 10,000 square kilometers per polygon, whereas chemical characterization of runoff relies on literature compilations. Inverting the marine Sr isotope record in this fashion yields average bedrock ages of the continental drainage in the geologic past. This new paleo-age record indicates older mean bedrock ages in the early Paleozoic, bedrock rejuvenation from the Paleozoic into the Mesozoic and an aging trend that started in the Cenozoic. In general, aging corresponds to greater exposure of igneous and metamorphic rocks whereas rejuvenation is driven by greater exposures of sedimentary and/or volcanic rocks.

The general validity of this bedrock-age record can be independently tested with paleo-geologic reconstructions by Ronov and coworkers (as quantified by Bluth & Kump, 1991), as well as the Nd isotope evolution of sedimentary rocks from large-scale continental drainage regions (e.g. Patchett et al., 1999). Both are suggestive of a trend towards younger bedrock from early to late Paleozoic, broadly similar to the paleo-bedrock record.

The application of this concept to the marine Os and Hf isotope records requires investigating the relationships between river isotope chemistry and drainage basin geology (Peucker-Ehrenbrink & Miller, in press). Marine paleo-records for Nd need to be spatially averaged due to the short residence time of Nd in seawater and the large isotope variability in continental Nd sources (e.g., Jeandel et al., 2007); alternatively, they may yield insights into regional changes in continental drainage geology in the geologic past.

High-field strength elements (Nb, Ta, Zr, Hf) in continental basalts from the CEVP – Implications for the HFSE budget of the lithospheric mantle and the global Nb budget

J.A. PFÄNDER1,2, S. JUNG1, C. MÜNKER1 AND K. MEZGER1

1Institut für Mineralogie, Universität Münster, Germany
2Institut für Geologie, TU Freiberg, Germany
(pfaender@tu-freiberg.de)

Nb/Ta ratios in continental basalts from the Central European Volcanic Province (CEVP) are among the highest values measured so far in terrestrial rocks by high-precision methods. In volcanic rocks from the Rhön, Vogelsberg and Eifel regions, Nb/Ta ratios are subchondritic (<19.9) with values between 15.0 and 19.1 and on average higher than in ocean island basalts at comparable Zr/Hf ratios (see figure). This observation is investigated within the context of a potentially Nb enriched lithospheric mantle that may play a role in balancing the global Nb budget.

Crustal contamination of most samples is displayed by elevated 187Os/188Os ratios (>~0.150), but samples having low (i.e. mantle like) 187Os/188Os (~0.129-0.150) have the highest Nb/Ta ratios, indicating that the elevated Nb/Ta ratios are not imprinted by crustal assimilation.

Nb/Ta ratios are positively correlated with Lu/Hf ratios in all but the Vogelsberg tholeiites, a feature that cannot be explained by partial melting of either spinel or garnet peridotite sources, but by the mixing of asthenospheric melts from a garnet bearing source with melts produced from amphibolitic veins. High HFSE concentrations and elevated Nb/Ta ratios (~17) with respect to the asthenospheric mantle (~14) require only low amounts of such melts in the order of a few percent. Therefore, elevated Nb/Ta ratios within some of the volcanic rocks of the CEVP do not mirror elevated Nb/Ta ratios within the subcontinental lithosphere itself, but reflect the presence of HFSE enriched, amphibole rich domains from which high Nb/Ta melts are produced during magma ascent and remelting.

The reconstruction of changes in the seep activity of a pockmark site using Mg/Ca and Sr/Ca ratios in the sediments of the lower Congo Fan

K. PFEIFER1 AND S. KASTEN2

1Alfred Wegener Institute for Polar and Marine Research, Am Handelsfahren 12, 27570 Bremerhaven, Germany (Kerstin.Pfeifer@awi.de)
2Alfred Wegener Institute for Polar and Marine Research, Am Handelsfahren 12, 27570 Bremerhaven, Germany (Sabine.Kasten@awi.de)

Pockmark structures of the Northern Congo Fan at a water depth of 3100 m were investigated during RV Meteor cruise M56 in November and December 2002. The data presented here were obtained by geochemical sediment and pore water sampling in a pockmark called Black Hole. No direct evidence for active fluid/gas discharge into the water column was detectable in this pockmark; however, gas hydrates were found close to the sediment surface. The depression was covered by fauna characteristic for areas of fluid/gas seepage such as vesicomyid clams and vestimentiferan tubeworms. Additionally, the sediments contain huge amounts of authigenic carbonates. In the sediments, authigenic carbonate formation occurred in the form of finely disseminated precipitates and also as massive carbonate concretions. Major and minor element contents were analysed for both, the bulk sediment and the concretions, and also in the pore water. Sr/Ca and Mg/Ca ratios determined in the concretions and in the surrounding sediment showed characteristic values which were used to distinguish between authigenic high Mg-calcite and aragonite precipitations (Bayon et al., 2007). High Mg-calcite was found at different depths in the sediment, whereas aragonite was only present close to the sediment surface. Changes in the Sr/Ca and Mg/Ca ratios determined in the pore water are characteristic for the carbonate mineral which currently precipitates from the solution. Pore water-ratios indicative for high Mg-calcite precipitation were found in the recent zone of anaerobic oxidation of methane, whereas ratios indicative for aragonite formation were only found in the surface sediment where sulphate concentrations are at seawater level. The combination of pore water and solid phase Sr/Ca and Mg/Ca ratios enables a distinction between recent carbonate mineral formation and carbonate precipitation in the past. Based on the elemental composition of the bulk sediment, we created a model for the history of past methane fluxes and seep activity for the investigated region of the pockmark.

Studies for the sorption of metals from lake water using limestone and rice bran

M. PHANIHOMESHWARI, N.N. MURTHY AND A.K. KRISHNA
National Geophysical Research Institute, Hyderabad, India

Environmental research studies were carried on Noor Mohamed Lake in Katedan Industrial Development Area, Hyderabad, India. The study reveals that the lake was highly contaminated with industrial effluents. Contamination of lake water was due to release of industrial effluent containing organic and inorganic chemicals. A sorption experiment using laboratory columns was carried on lake water to reduce the concentration of heavy metals to limited extent, in this study an agricultural by-product rice bran (30%) and a geological media limestone (70%) has been successfully used for reducing the concentration of metals in lake water. The Medias are efficient in reducing metal concentration by Sorption, adsorption, precipitation, oxidation and reduction reactions involved in process which depends on the factors like pH, surface areas of reactive media and porosity.

Vertical columns open at both the ends made of polyvinyl chloride of length 50 cm / 10 cm diameter was packed with two different medias in 3:7 ratio covered with a filter paper and closed with Teflon lids fitted with Silicon tubes of 3 mm size and effluent was passed using a peristaltic pump with speed of 55 rpm / 10 ml per minute. The experiment was carried for one week and the sample was collected from outlet, analysed for pH, E.C, TDS and metals like Zn, Cu, Cr, Pb, Ni by inductively coupled plasma optical emission spectrometry (ICP-OES).

The results shows that there was no change in pH but a slight increase in total dissolvable solids from 1026 ppm to 1857 ppm, this was due to the release of dissolvable solids from the medias, concentration of metals for Cr-43.52ppb (Cr-68% removal), Zn - 98.25ppb (Zn-88% removal), Cu–30.43ppb (Cu-41% removal), Ni–27.44ppb (Ni51% removal), Pb–15.62 ppb (Pb-84% removal) with limestone and rice bran.

Contribution of two main smelters on urban soils pollution in northern France investigated by lead isotopes

S. PHILIPPE1, L. COURCOT1, F. DOUAY2, C. WATERLOT2, C. PRUVOT2, J. CAILLAUD1 AND W. DÖRR3
1FRE 2816, MREN, 32 Avenue Foch, ULCO, F-62930 Wimereux, France (sylvie.philippe@univ-littoral.fr)
2ISA, Laboratoire Sols et Environnement, 41 rue du Port, F-59046 Lille cedex, France (f.douay@isa-lille.fr)
3Institut für Geowissenschaften, JWG-Universität, Altenhöferallee 1, D-60438 Frankfurt/Main, Germany

Introduction and objectives
The studied urban zones are located in northern France at the vicinity of two base metal smelters which are 3.5 km distant from each other. Historical Pb, Cd and Zn contamination through atmospheric emissions from both plants has been demonstrated by different authors (Frangi et al., (1997) or Sterckeman et al., (2002) on cultivated soils).

Urban (kitchen garden and lawn) soils in the studied zones present varying and sometimes higher Pb contents than the neighbouring cultivated soils (Pruvot et al., 2006). Pb isotopes have then been used to better constrain the contribution of each emitter to the observed pollution. A second aim was to look for other possible sources of contamination (manures with ashes or slag, other atmospheric inputs…) to explain the anomalous contents.

Analyses have been performed on homogenised samples from the upper 25 cm of the garden soils. Pb isotopic compositions were analysed by TIMS on a MAT-261. Pb, Cd and Zn concentrations were obtained by GFAAS.

Isotopic results and discussion
Garden soils with different lead contents and supposedly various cultural practices show a distribution into two distinct and homogeneous lead isotopic signatures. Each signature corresponds to soils located in the vicinity of one of the two plants. This supports the hypothesis of a quite exclusively airborne pollution related to one refinery activity. Furthermore, mixing of the two lead types can be observed on one soil located in between the two refineries, which displays an intermediate isotopic composition. Additionally, whatever its chemical speciation, lead obtained by single chemical extractions performed on some garden soils shows isotopic homogeneity within a specific soil, suggesting that pollution has affected all soil compartments.

⁴Geological Survey of Western Australia, 100 Plain St., Perth, WA 6004, Australia (martin.vankranendonk@doir.wa.gov.au)

We report multiple-isotope sulfur analyses (³²S, ³³S, ³⁴S) of sulfides and sulfates from a unique collection of pristine drill core samples (Pilbara Drilling Project; Van Kranendonk et al., 2006) from the 3,490 Myr old Dresser Formation at North Pole, Western Australia. We show that the strongly ³⁴S-depleted microscopic sulfides preserved in barite crystals that have been interpreted as evidence for sulfate-reducing organisms during the early Archean (Shen et al., 2001; Shen and Buick, 2004) have mass independently-fractionated sulfur isotopic anomalies (Δ³³S) different from their host barite and therefore that they cannot have been produced by sulfate reducing microbes. Instead, we interpret the combined negative δ³⁴S and positive Δ³³S signature of these microscopic sulfides as evidence for the early existence of organisms or consortia that reduce or disproportionate elemental sulfur. These results support the prediction arising from phylogenetic reconstruction that elemental sulfur reduction is among most deeply-rooted metabolic pathway in both of the prokaryotic Domains.

Large-scale magmatism is often linked to the breakup of a supercontinent, but it is not established whether it is caused by a plume head or a global temperature increase of the mantle. On the basis of convection modeling in an internally heated mantle, we have shown that continental aggregation promotes large-scale melting without requiring the involvement of plumes (Coltice et al., 2007). When only internal heat sources in the mantle are considered, the formation of a supercontinent causes the enlargement of the wavelength of the flow and subcontinental warming as large as 100 °C. We will show how plumes interact with supercontinental warming in order to better understand the evolution of melting during the opening of Pangea.

We will also describe the importance of the supercontinental warming model over the course of the evolution of the Earth’s mantle and the growth of the continental crust.
CRONUS-Earth: Half-way to the destination

FRED M. PHILLIPS
Earth & Environmental Science Department, New Mexico Tech, Socorro NM 87801 (phillips@nmt.edu)

In-situ cosmogenic nuclides are widely and increasingly used for to study earth-surface processes and its recent history, but these goals have been impared by inconsistencies in the understanding of the production systematics. The CRONUS-Earth Project was funded by the U.S. National Science Foundation with the objective of reconciling these discrepancies and providing a generally accepted basis for interpreting cosmogenic nuclide data. The Project is approximately half-way through its five-year duration and has achieved significant progress toward these goals. Areas of considerable uncertainty that have seen major advances include samples for $^{36}$Cl production-rate calibration and spatial/temporal scaling of production. New paleomagnetic reconstructions have become available to complement improved scaling theory, resulting in testable predictions of global production patterns. The relation between geologically-based and neutron-monitor based scaling has been elucidated through monitoring of neutron-monitor-response physics. Calibration samples have been collected in a rigorous fashion from sites associated with the shoreline of Lake Bonneville, Younger Dryas glacial sites in Scotland, and LGM glacial sites in the Puget Lowland of Washington State, a locality of particular importance for resolving discrepancies in $^{36}$Cl production. Essential data and tools include improved production cross sections from neutron beam experiments and the release of a web-based cosmogenic calculator for the community.

Extraction of biosignatures from weathered basalts

S.J.M. PHILLIPS AND J. PARNELL
Department of Geology and Petroleum Geology, University of Aberdeen, Aberdeen, AB24 3UE, UK (s.j.phillips@abdn.ac.uk)

There is a growing interest in the bio-load in weathered volcanic rocks. The relevance extends to Mars, where there are extensive regions of weathered basalt. Any bio-load in such rocks is likely to be very low, so it is essential to maximize the extraction efficiency for analysis. Analysis of suites of regolithic Tertiary (~60 Ma) basalt from Skye, Scotland, show the importance of particle size for optimal organic recovery.

Basalt from two localities was divided into fine (<500µm)- and coarse (>1cm)-grained fractions and surface contamination removed using acetone. They were then crushed and sieved into five different grain size fractions and subsequently soxhlet-extracted for 48 hours with 93:7 DCM/methanol.

The data show that a reduction in grain size results in a higher yield of extractable organic material (EOM) (Table 1). The n-alkane odd-over-even preference (OEP) exhibited by the GC-MS trace (Fig. 1) indicates that the extract is thermally immature, consistent with a recent biological (microbial) signature.

Figure 1: GC-MS trace of the saturate fraction m/z 85 ion from the Quiraing basalt. Note marked OEP of n-alkane peaks.

The data emphasise the importance of analysing a fine grain size during processing of samples, including future Mars missions, where volcanic rocks may be targeted.
Role of bacteria on uranium migration in a calcareous peatland

V. PHROMMAVANH1, J. KLEIN1, M. DESCOSTES1, C. BEAUAIRE1, J.P. GAUDET2, E. PRESTEL3, M. DUBOW3 AND E. LAPIERRE1

1CEA Saclay, DEN-DANS-DPC-SECRL3MR, F-91191 Gif-Sur-Yvette (vannapha.phrommavanh@cea.fr)

3Université Paris-Sud 11, CNRS UMR 8621 Institut de Génétique et Microbiologie, Orsay

The assessment of a polluted site is usually undertaken through its hydrogeochemical characterization and the impact of the implied conditions on pollution migration. However, in specific natural environments, such as peatlands, microbial activity can also affect, directly or indirectly, this migration.

A calcareous peatland polluted with uranium particles (about 3.5 ppb) contained high concentrations of total dissolved uranium from the surface to 0.8 m deep (up to 7.10^-6 mol.L^-1). This can be explained by the formation of the major complex Ca2UO2(CO3)3. Even though uranium particles have also been found between 0.8 and 2 m, total dissolved uranium concentrations are very low (1.10^-10 mol.L^-1). At these latter depths, where the peat remains humid (water – table from 0.25 to 0.8 m), uranium solubility can decrease due to reducing conditions. The increasing occurrences of framboidal pyrite particles at depths lower than 0.8 m suggest reducing conditions related to sulfate – reducing bacteria.

In order to study the impact of these bacteria on the physico – chemical conditions of the peat soil, batch experiments were performed. Using various types of carbon sources (ethanol, oxalate) and doping with sulfate, trimethylphosphate and uranium, at 25 °C and 5 °C, the total dissolved uranium content was followed throughout the incubation. The ethanol – doped batch incubated at 25 °C shows a significant decrease of uranium from 1.95.10^-5 to 3.93.10^-8 mol.L^-1 in 200 hours. Other parameters (pH, Eh, dissolved oxygen, [SO4^2-], [HS^-], etc.) are also followed and compared to the equation of microbially – mediated sulfate reduction:

\[ 2\text{CH}_2\text{O} + \text{SO}_4^{2-} \leftrightarrow 2\text{HCO}_3^- + \text{H}_2\text{S} \]

These batch experiments and the identification of the bacterial populations (via 16S rDNA sequence) show that sulfate – reducers in peatlands produce reducing conditions that can immobilize uranium and possibly other trace metals.

The role of solvent in the kinetics of barite nucleation

S. PIANA, F. JONES AND J.D. GALE

Nanochemistry Research Institute. Curtin University of Technology. GPO Box U1987 Perth, 6845 Western Australia. Australia

Crystallization from a supersaturated solution is one of the fundamental geochemical processes. Although several very successful models that provide a qualitative understanding of the crystal growth process exist, in most cases the atomistic detail of crystal growth is not fully understood. Here it is shown how the combined use of computer simulations and experiments can help in understanding the kinetics of nucleation and crystal growth of barite. It is found that the solvent plays a prominent role in determining the rates of both two and three-dimensional nucleation in solution. The results of this study are expected to be valid also for other divalent ion salts, as their crystallization kinetics are often remarkably similar.

Seismic anti-correlation in the mantle: Is hot blue and cold invisible?
A.S. PIAZZONI1, G. STEINLE-NEUMANN2 AND H.-P. BUNGÉ3

1Department for Geosciences, University of Munich, Germany (antonio.piazzoni@geophysik.uni-muenchen.de)
2Bayerisches Geoinstitut, University of Bayreuth, Germany (g.steinle-neumann@uni-bayreuth.de)
3Department for Geosciences, University of Munich, Germany (bunge@geophysik.uni-muenchen.de)

Low levels of bulk sound velocity ($V\Phi$) variations below 2000 km depth in the mantle and a prominent anti-correlation of $V\Phi$ to shear seismic wave velocity ($VS$) near the core mantle boundary are typically used to infer the presence of compositional deep mantle heterogeneity. Using a thermodynamically self-consistent mantle mineralogy model based on Gibbs free energy minimization we show that these effects can arise from differences in the isothermal and adiabatic bulk modulus at high pressure and temperature of the Earth’s lower mantle, and that it is possible to reproduce the observed VS/$V\Phi$ anti-correlation in a chemically uniform mantle. The mineralogy model provides us with elastic constants and density for any given P,T condition.

We take this density to compute convective buoyancy forces in a simple (2-D purely bottom heated isoviscous and isochemical) compressible mantle convection model. Our approach allows us to predict a number of seismic observables from the convection model, all of which agree remarkably well with observations from a tomographic study. Our results are fully compatible with other published mantle mineralogy models, which similar to our finding predict an increase of $\partial V\Phi/\partial T$ with temperature and pressure, and a pronounced VS/$V\Phi$ anti-correlation in the lowermost mantle.

Contracting KREEP magmatism in the early evolution of the Moon

Ages of zircons from lunar Breccias

Previous (SHRIMP) age studies of zircons from lunar granophyres and other rocks (Meyer et al. 1996) showed that zircon-forming magmatism in the lunar highlands was continuous from 4.3Ga until at least 3.88Ga. We have further investigated the distribution of lunar zircon ages by undertaking SIMS U-Pb isotopic analyses (SHRIMP II at Curtin University and CAMECA 1270 at the Swedish Museum) of zircons from breccias from the Apollo 14 and Apollo 17 landing sites.

U-Pb results
Analytical results, presented on concordia plots on Figure 1, show that Apollo 14 and 17 zircons have essentially identical age patterns in the range 4.35 to 4.20Ga, but, whereas Apollo 14 zircons have ages in the range 4.20 to 3.9 Ga, zircons from Apollo 17 samples have no ages younger than 4.20Ga.

Interpretation
Our results show that lunar zircon-forming magmatism was not continuous from 4.35 to 3.88Ga everywhere on the Moon, but has a marked regional asymmetry. We explain this by proposing that between about 4.35 and about 4.20Ga the source reservoir for zircon-forming KREEP magmatism contracted to only just include the area of the Serenitatus impact (Apollo 17) and after about 4.20Ga no zircon-forming magmatism occurred at this site. Magmatism continued at a reducing rate at the Apollo 14 site until about 3.90Ga, when it also ceased.

Chemical and isotopic variations of surface waters at a small catchment scale, lithological vs biological controls (the Strengbach case).

M.C. Pierret, F. Chabaux, P. Stille, J. Prunier, D. Viville and D. Lemarchant

Centre de Géochimie de la Surface, CNRS—ULP, 1 rue Blessig, 67084 Strasbourg cedex, France
(pierret@illite.u-strasbg.fr)

The accurate determination of parameters controlling the chemical composition of surface waters is important for a correct modelling of the future evolution of the ecosystems in response to external forcing such as climate and human activities. Among these parameters, vegetation plays an important role in affecting movement, cycling and fractionation of elements.

In this general framework, a detailed study of the geochemical variability of the surface waters of the Strengbach catchment was carried out. The catchment is a small-forested watershed, about 80ha in surface area, in the Vosges Mountain, France (Observatoire Hydro-Géochimique de l'Environnement; http://ohge.u-strasbg.fr). It is located on a Hercynian granite, which was more or less hydrothermally altered.

During two hydrologic cycles (2004-2006), the stream at the outlet of the watershed, as well as all springs welling up located at different altitudes from various hillsides, were regularly sampled. Major and trace element (Sr, Rb, Ba, U) concentrations and Sr isotope ratios on the dissolved load of the water samples were determined.

The data highlight the large spatial variability of the chemical and isotopic composition of the surface waters of the Strengbach watershed. The variations of the mineralogical characteristics of bedrocks and soils, which are especially related to the more or less hydrothermalized character of the bedrock, can account for the spatial geochemical variations observed among the different springs of the watershed.

The data also outline an important time variation of the chemical and isotopic composition of water samples within each spring. It can be shown by using mixing diagrams, such as 87Sr/86Sr vs. Ca/Sr, that rain contribution is not a important parameter explaining the time variation. In addition, a simple binary mixing model between two water end-members, even with variable contribution versus time, cannot account for the observed geochemical variations. The latter imply the occurrence of specific chemical fractionations unrelated to lithological parameters, but probably induced by chemical recycling through the vegetation.

The results of our spatial and time variability study of surface waters at a small watershed scale point out how such a geochemical approach can help understanding the quantification of vegetation impact on the geochemical budget.

Processes and sources during late Variscan dioritic-tonalitic magmatism (Gęsiniec Intrusion, Bohemian Massif)

A. Pietranik1 and T. Waight2

1Institute of Geological Sciences, University of Wroclaw, 50-205 Wroclaw, Poland (apie@ing.uni.wroc.pl)
2Institute for Geography and Geology, University of Copenhagen, 1350 Copenhagen K, Denmark

Tonalitic–dioritic intrusions are common in orogenic settings. Two groups occur, emplaced at different stages of orogenic development: syn-collisional, pre-dating the main granite emplacement stage and post-collisional, contemporaneous with or post dating granite magmatism. Diorites and tonalites together with basaltic–andesitic volcanics are often the most mafic rocks present in orogenic and are often taken as end members that interacted with crust to produce a range of more felsic magmas and/or as the heat source for melting of the crust. However, dioritic–tonalitic intrusions are often characterised by variable isotopic and trace element compositions suggesting that they themselves underwent differentiation and contamination.

The Gęsiniec Intrusion (GI, 294-307 Ma, Bohemian Massif) represents a post collisional Variscan dioritic-tonalitic intrusion, generated during lower crust and lithospheric mantle delamination. Similar incompatible element ratios suggest a common source for the tonalite – dioritic rocks in the GI, this source is distinct from that of earlier Variscan diorite-tonalite magmatism (syn-collisional, 340-350 Ma) in the Bohemian Massif. The parental magmas for the post-collisional GI were probably tholeitic, water-undersaturated basalts derived from unmetasomatised mantle that interacted with crust. Parental magmas for 340-350 Ma dioritic-tonalitic magmatism were basalts derived from subduction-modified mantle (e.g. Janousek et al. 2000).

In situ Sr isotope and trace element analyses of the GI plagioclase yield a range of 0.7069-0.7091, greater than that of whole rocks (0.7069-0.7084). Trace element and isotopic compositions of plagioclase suggest that different samples represent different processes of magma evolution from assimilation of wall rock by crystal mush at the magma chamber boundary, to interaction with water-rich magmas. The main differentiation recorded in plagioclase is thought to have occurred in the lower crust, below the level of emplacement of the GI and was followed by decompression and extensive resorption of plagioclase. The GI represents therefore an assembly of magmas derived from similar sources, but having undergone separate differentiation processes before final emplacement.

PAHs in sediment cores from an estuary in south of Brazil

R. PIETZSCH1, S.R. PATCHINEELAM2 AND J.P.M. TORRES3

1Departamento de Geoquímica, Universidade Federal Fluminense, Niterói, Brazil (pietzsch@petrobras.com.br)
2Departamento de Geoquímica, Universidade Federal Fluminense, Niterói, Brazil (geosam@vm.uff.br)
3Instituto de Biofísica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil (jptorres@biof.uff.br)

The temporal and spatial distribution of 14 selected PAHs, amongst the 16 priority pollutants have been analysed in the estuarine system of Guaratuba Bay, Paraná State, in the south region of Brazil. Two dated sediment cores of approximately 40 cm each were collected on the inner sector and close to the mouth to the sea of the estuary, which is approximately 15 km long. The sedimentation rate is estimated to be 6.1 mm/year and 5.2 mm/year accordingly to 209Pb and 137Cs geochronologies, respectively (Sanders et al., 2006). The surrounding region is not highly industrialised, with agriculture of banana and rice being the main economic activities, followed by fishery, aquaculture and tourism, the latter suffering a rapid increase in the past years due to the scenic landscape of the region. A moderate drainage basin encompasses the estuary, consisting of 1,724 km² and two main rivers alone, Cubatão and SãO João, introduce as much as 80 m³/s of freshwater into the bay. Despite of that, it is well known that PAHs are ubiquitous contaminants in the environment and the use of marine sediments to reveal levels of environmental quality have been extensively reported in the literature, as they are a sink for such hydrophobic compounds. In order to quantify the distribution of PAHs along the sedimentary record, the following individual compounds were analysed in 21 sections of the cores: naphthalene, acenaphthylene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzo[a]anthracene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, dibenz[a]anthracene, benzo[g,h,i]perylen e and indeno-[1,2,3cd]pyrene. The analyses were carried out using a HPLC coupled with a fluorescence detector. The total PAH concentration ranged from 1.5 to 3,126.8 ng/g (mean 494.9) of dry weight, and the PAHs up to four rings were the most abundant. Among these, phenanthrene and fluoranthene showed the highest concentrations. Apparently, diagenetic processes, rather than petrogenic or pyrogenic inputs, play an important role in the distribution of phenanthrene along the sedimentary column, as proposed by Wakeham et al. (1980).

3The National Museum of Ireland, Collins Barracks, Benburb St. Dublin 7, Ireland
4The School of Earth Environment, The University, Leeds, LS2 9JT, UK

The Bronze Age is seen to represent a critical stage in European prehistory because of the widespread deployment of a range of distinctive materials (e.g. amber, jet, gold) in the construction of different social identities including strategies of status differentiation. Understanding the control of access to these materials and their trade and exchange is key to understanding the new social structures that arise. In Ireland, the deposition in lakes and bogs of large gold artefacts such as lunulae and torcs is one of the most striking features of the Bronze Age. But many of these artefacts are without context, having been found by turf cutters, or lack any associated archaeology. While it is clear gold is an important and special material, it is difficult to integrate the artefactual evidence with what is known of the archaeology and social structure of the Bronze Age.

Here we present the preliminary results of a lead isotope study of Irish Bronze Age gold artefacts using the novel technique of laser ablation ICP-MS. We show that the lead isotope variation in Ireland is sufficient to differentiate sources of gold, and that the required precision of lead isotope measurements can be attained for the necessarily small samples from artefacts using laser ablation. In Late Bronze Age artefacts, where the gold has been alloyed with copper, lead mixing lines can be obtained, which may allow the sourcing of both the copper and the gold.

These and future results will complement existing microchemical studies that have suggested changing access to gold resources through the Irish Bronze Age, and will provide the basis for models of gold procurement, trade and exchange.
Experimental constraints on the origin of alkaline basalt: Evidence for a metasomatized lithospheric source

S. PILET, M.B. BAKER AND E.M. STOLPER
California Institute of Technology, Pasadena, USA
(pilet@gps.caltech.edu; mikeb@gps.caltech.edu; ems@gps.caltech.edu)

Due to the difficulty of explaining the high trace element and isotopic compositions of alkaline magmas from oceanic islands and alkaline massifs by simple peridotite melting, a recycled oceanic crust component is often assumed to be present in the source of these rocks. Alternatively, this component may be recycled oceanic or continental lithosphere that contains metasomatic veins. Coupled major and trace element models for the formation of alkaline lavas can provide important constraints on this debate. At present, no experimental studies have successfully reproduced the range of alkaline basalts found in ocean islands or continental massifs.

We present the results of melting experiments on natural clinopyroxene hornblendite and hornblendite lithologies from the French Pyrenees conducted at 1.5 GPa and 1150-1350°C, and explore the alternative hypothesis that OIBs result from partial melting of recycled metasomatized lithosphere. The compositions of low-degree melts in experiments on both amphibole-bearing lithologies are controlled by kaersutite breakdown and are strongly ne-normative and silica-poor. K2O/Na2O, Al2O3/TiO2 and CaO/Al2O3 ratios in the experimental partial melts are similar to silica-poor basanites found in oceanic islands and continental alkaline massifs. Moreover, the incompatible trace element patterns of the glasses overlap those of silica-poor lavas in both tectonic settings. A second set of experiments was done using a layer of hornblendite sandwiched between layers of moderately depleted peridotite (DMM1) at 1.5 GPa and 1225-1325°C, and demonstrates that the reaction of partial melts of amphibole-rich veins with surrounding peridotite can explain the observed compositional transition between basanite and alkali basalt. The higher SiO2 content (4-5 wt%) observed in melts from the sandwich experiments relative to those containing just the amphibole lithologies reflects the dissolution of orthopyroxene in the peridotite layers in the sandwich runs.

Our results support the hypothesis that partial melting of metasomatized lithosphere (i.e., peridotite-amphibole-bearing veins) generates alkaline basalts in continental settings [1] and that recycling and partial melting of such veined lithosphere can also contribute to the compositional characteristics of oceanic alkaline lavas. Further, the isotopic characteristics of both HIMU and EM-type OIBs are consistent with plausible models of amphibole-bearing vein formation and the resulting element fractionations [2]. Thus, recycling of metasomatized lithosphere should be considered as a viable, testable alternative to widely accepted models of OIB formation that invoke recycling of oceanic crust ± sediments.

AFM observations of dissolution and growth on anhydrite (100), (010) and (001) cleavage faces

C.M. PINA AND L. FERNÁNDEZ-DÍAZ
Dpto. Cristalografía y Mineralogía. Universidad Complutense. 28040 Madrid. Spain. (cmpina@geo.ucm.es; lfdiaz@geo.ucm.es)

Anhydrite is a common calcium sulphate mineral which can coexist with gypsum in evaporitic and diagenetic rocks. Textural relationships between both minerals often indicate that gypsum crystals form after previously crystallised anhydrite, through a process that involves the coupling between dissolution and crystal growth reactions. In this work, we present in situ Atomic Force Microscopy observations of the interaction of anhydrite (100), (010), (001) cleavage surfaces with deionised water and CaSO4 aqueous solutions. In water, anhydrite faces dissolve at different rates and exhibit specific nanotopographic features (e.g. etch pit shapes, retreating and stabilisation of certain step directions, etc.) that can be justified on the basis of the Hartman-Perdok Theory. In contact with CaSO4 solutions, the growth of metastable monolayers (~3.5Å in height) is promoted on both anhydrite (010) and (100) faces (the growth on anhydrite (001) faces was not observed). The monolayer develops jagged edges that form defined angles with the original steps on anhydrite surfaces. Moreover, as occurs in the case of dissolution, the growth of monolayers over anhydrite (010) and (100) surfaces is highly anisotropic, revealing a strong crystallographic control. The nature of such monolayer is discussed on the basis of both crystallographic and thermodynamic arguments.
Oriented overgrowth of brushite 
(CaHPO₄·2H₂O) on gypsum 
(CaSO₄·2H₂O)

ANDRÉ JORGE PINTO, AMALIA JIMÉNEZ AND 
MANUEL PRIETO

Departamento de Geología, Universidad de Oviedo, Jesús Arias de Velasco, s/n. 33005 Oviedo, Spain
(apinto@geol.uniovi.es)

At slightly acidic conditions and 25º C, the interaction between aqueous solutions containing dissolved P(V) and gypsum results in surface precipitation of brushite (CaHPO₄·2H₂O) crystals. These crystals grow oriented onto gypsum’s surface, forming an epitaxy. Using an A-centered unit-cell setting for both brushite (Aa) and gypsum (A₂/a), the determined epitaxial relation is (010)₆ || (010)₄, [001]₆ || [001]₄, and [100]₆ || [100]₄. In the performed experiments, the obtained morphologies of brushite consist of thin crystals elongated in the [101] direction with {010}, {111} and {111} as major forms. In the present work, both crystal morphology and epitaxial orientation are approached on the basis of the bond arrangement within the structure of both mineral phases.

Figure 1: SEM image of thin brushite crystals oriented onto gypsum’s (010) face, along [101] direction.

Sequential Metal Extraction procedure as applied to sediments in Acid Mine Drainage environments (Aljustrel, Portugal)

C. PINTO¹, M.A. GONÇALVES¹ AND N. NENG²

¹Dep. Geología and CREMINER, Ed C6, Piso 4, 1749-016 Lisboa, Portugal (geoecilvia@sapo.pt; mgoncalves@fc.ul.pt)
²Dep. Química e Bioquímica, Ed C8, Piso 2, Campo Grande, 1749-016 Lisboa, Portugal (ndneng@fc.ul.pt)

Acid Mine Drainage (AMD) is a serious environmental concern caused by mining activities and presents severe consequences to surface and underground water systems. In this work we have studied the partitioning of trace metals in sediments from AMD systems in the area surrounding the Aljustrel Mines (Iberian Pyrite Belt), using a modified Sequential Metal Extraction (SME) procedure.

Authors acknowledge that SME methods are useful to study metal partitioning in sediments. However, there are several problems with these methods, including the one of Tessier et al. (1979). Among these are: trace element redistribution among phases, nonselectivity of extractants, and sulphide dissolution during organic matter oxidation steps. In order to overcome these difficulties the proposed method combines modifications from Hirner (1996) and Breward et al. (1996). The oxidation of organic matter is performed separately by first extracting it from the sediment. The six-step sequential extraction procedure was performed on streambed sediments of Ribeira de Água Forte (Aljustrel). The extractant solutions were analysed by AAS for selected trace metals (Cu, Zn, Pb, Ni, Cd, and Co).

Cu, Pb, and Zn have the highest averaged relative concentrations in the sediments (51%, 27%, and 14%, respectively). Ni, Cd and Co exhibit low values (< 4%). In contrast to these results in the sediments, water analyses show higher Zn concentrations in relation to Cu, suggesting a preferential sediment-water partitioning for Cu. Also shown is the anomalous character of an iron-rich sample in relation to the correspondent water, where a peak in all elements is observed. This sample is also exceedingly anomalous in Cu for reasons currently unknown to us. In relation to the different phases, organic matter has no important role in the adsorption processes (1.7%). Trace metals occur preferentially bound to iron oxide phases (70%), followed by non-specific adsorption (25%).

The Vale de Abrutiga U-mine consists of quartz veins containing wolframite, sulphides and secondary saléeite and metasaléeite.

One hundred thirty seven chemical analyses of zircon were obtained by electron-microprobe from unaltered and altered biotite granite, mineralized quartz veins, phyllite and quartzite of regional metamorphism and phyllite adjacent to mineralized quartz veins from the Vale de Abrutiga U-mine area, central Portugal. Chemical composition of zircon is highly variable. Zircon from altered granite is the richest in P, Y and Fe³⁺ and contains on average 0.22 wt. % UO₂, but values up to 0.50 wt. % UO₂ were found in the analyses with low totals (~84.69 wt. %). Distribution of U in some of these individual altered grains shows a chemical zonation expressed in the rim containing more U than the core. The core has a chemical composition similar to that of zircon from unaltered granite. Zircon from quartzite has the highest content in Zr and the lowest of Fe³⁺. Zircon from phyllite adjacent to quartz veins has higher U content than zircon from phyllite of regional metamorphism, which does not contain U. Zircon from mineralized quartz veins is dissolved and vacuolated. The grains have cores chemically close to the endmember [(Hf,Zr)SiO₄], but rims are hydrated, have very low totals (~82 wt.%), low SiO₂ (~14 wt.%) and ZrO₂ (~40 wt.%) contents and very high Fe₂O₃ (~8 wt.%) and UO₂ (~18 wt.%) contents. The anomalous zircon rims were lately formed from U-rich supergenic solutions. Enrichment in U is a characteristic of altered zircon from the mineralized quartz veins and from altered Variscan granite. The high U contents found in rims of the altered zircon from altered granite and mineralized quartz veins are associated to high Fe contents. It is well known that uranium sorption on Fe oxyhydroxides is an important process. Therefore the very high U-enrichment found in rims of altered zircon grains can be due to the presence of these Fe oxyhydroxides.

The Vale de Abrutiga U-mine was formed in lithological and structural traps by U-rich solutions derived from meteoric water, warmed by deep circulation, and enriched in U by the solubilisation of U-minerals from granites (uraninite, monazite). Uranium from U-rich solutions percolating through the quartz veins was later adsorbed by the most altered zircon or by Fe oxyhydroxides which formed in the most altered rims of zircon crystals.

3-D modeling of iron ore deposit in Chadormalu area in the Central Iran

MORTAZA PIROUZ¹, NEDA GHAZIPOUR², REZA MONSEF³ AND MOHAMAD HASHEM EMAMI⁴

¹School of Geology, Faculty of Earth Science, Tehran University (mortaza_pirouz@khayam.ut.ac.ir)

⁴Geological Survey of Iran

Chadormalu iron ore deposit is one of the biggest iron ore in Iran. That is located in the Central Iran and excavates iron ore in this area. Chamomile reverse fault and Kankani right lateral strike slip fault shear and deform ore deposit. Asymmetric ore deposit shape and faulting are some reasons that excavators have problems for exploration. Expansion of iron ore, distribution of contaminated ore (for example apatite) and recognized of blind faults concludes with use chemical analysis and logging boreholes data in deferent topographic levels. Deferent topographic levels data merge and design under ground 3-D models iron ore. Iron ore deposit is flattening and its strike is northwest - southeast. Iron ore massive dip is high angle and its dip direction is southwest. Stratigraphic iron ore boundaries are faulted and high angle. A lot of many strike slip fault distinguish with north - south strike into ore body. Designed 3-D models can be show best location for start of excavation. Therefore, we can subdivide ore deposit to several quality parts.
Radiogenic $^{26}$Al chronometry of evaporites

C. PLACZEK, D.E. GRANGER AND M. CAFFEY

Purdue Rare Isotope Measurement Laboratory and
Department of Earth and Atmospheric Sciences, Purdue
University, West Lafayette, IN, USA
(cplaczek@purdue.edu; dgranger@purdue.edu;
mcaffee@physics.purdue.edu)

Radiogenic production of $^{26}$Al in Na rich evaporites can potentially be used for chronometry over several million years. This can be a tool for dating paleoclimate conditions in arid environments. Measurable quantities of $^{26}$Al are present in material with either high concentrations of alpha emitters (principally U and Th) or high concentrations of target nuclei. Significant quantities of $^{26}$Al are recorded in U and Th ores, and the primary mechanism of this production is the $^{23}$Na($\alpha$, n)$^{26}$Al reaction (Sharma and Middleton, 1989). Measurable quantities of $^{26}$Al should, therefore, also be present in material with modest concentrations of U and Th, but high concentrations of Na. To test this potential geochronometer, a review of the available cross-sectional data for this reaction, as well as the U, Th, and Na composition of various evaporites was done. We will present preliminary data testing the feasibility of this method.

The $^{238}$U and $^{232}$Th decay chains are the dominant natural alpha sources, with a total of 8 alpha particles emitted in the $^{238}$U decay chain and 6 from $^{232}$Th decay. The range of alpha particles in rocks is generally less than a few tens of microns, and the alpha-emitters contained within the evaporite minerals themselves are the principal mechanism of radiogenic $^{26}$Al production. Since U is soluble in water, and Th is largely insoluble, many evaporite deposits have high U/Th. Disequilibrium in the U-series decay chain occurs in subaqueous deposits over the time range of this potential chronometer, and excess of $^{234}$U over $^{238}$U in evaporites will result in higher $^{26}$Al production.

Saline minerals, which are common in marine, lacustrine, hydrothermal, and soil deposits are high in Na and low in Al. Calculated $^{26}$Al production rates for U in secular equilibrium is ~10 atoms/gram Na/ppm U, and minerals such as halite, glauberite, and trona are 30 to 40 weight percent Na. The range of measured and previously reported U concentration in salts varies from a few ppt to several ppm. Exceptionally pure salts incorporates less U, but also contain less stable Al. Al concentrations in salts range from 1.5-150 ppm. At these concentrations, production rates are comparable to cosmogenic $^{26}$Al at the surface. A salt with 10 ppm Al and 1 ppm U should contain detectable $^{26}$Al in less than a century.

Importance of thioarsenates for arsenic redox processes along geothermal drainages, Yellowstone National Park

B. PLANER-FRIEDRICH1, J. LONDON1, R.B. MCCLESKEY2, D.K. NORDSTROM2 AND D. WALLSGLÄGER1

1Trent University, Peterborough, Canada
(brittapaner@trentu.ca, dwallsch@trentu.ca,
Jacquelinlondon@trentu.ca)
2U.S. Geological Survey, Boulder, USA (dkn@usgs.gov,
rmbccles@usgs.gov)

Thioarsenates were found to play an important role in arsenic speciation and the mechanism of arsenic oxidation in sulfidic hot spring discharges in Yellowstone National Park. Previous studies, using hydride-generation atomic absorption spectrometry (HG-AAS) [1], reported arsenite predominance at the geothermal source, followed by rapid oxidation to arsenate in the discharge channels, however, HG-AAS is not designed to measure thioarsenates. We used anion-exchange chromatography inductively-coupled plasma-mass-spectrometry to study arsenic speciation along the drainage channel of the sulfidic Ojo Caliente hot spring (pH 8) and a near-by geyser (pH 9.1).

At the geothermal sources, we detected thioarsenates, not arsenite, as the predominant species. Its formation is presumably caused by the presence of S0-donors such as polysulfides or thiosulfate (0.6 mg/L at the source of Ojo Caliente). Along Ojo Caliente drainage channel the major initial product of thioarsenate conversion was arsenite. Arsenate only formed from arsenite as a secondary product once all thioarsenates disappeared. Compared to Ojo Caliente, the discharge at the geyser was more vigorous, the drainage channel steeper and the flow faster. Under these conditions, thioarsenate was found to transform to di- and monothioarsenate with arsenate as final end product. Arsenite concentrations did not increase significantly.

Preliminary laboratory studies show that thioarsenate converts to arsenite without significant increase of arsenate, mono- or dithioarsenate if the solution is purged with nitrogen or air and sulfide is volatilized from solution or partially oxidized to thiosulfate but the oxidation rate is too low for complete oxidation to sulfate. By adding H$_2$O$_2$, thiosulfate is oxidized to sulfate and thioarsenate undergoes ligand exchange to thioarsenate species with a successively lower number of SH-groups to finally yield arsenate without formation of significant amounts of arsenite.

Oscillatory zoning fahlores from Au-Ag epithermal deposits

O.Y. PLOTINSKAYA¹, V.L. RUSINOV¹ AND R. SELTMANN²

¹IGEM RAS, Moscow, Russia (plotin@igem.ru)
²Natural History Museum, London, UK (rs@nhm.ac.uk)

Results

Oscillatory zoning was found in tellurian fahlores (goldfieldites) \([ (Cu,Ag)_{10} (Fe,Zn)_{2} (Te,Sb,As)_{3} (S,Se)_{13} ] \) from three epithermal Au-Ag deposits: Prasolovskoe, Ozernovskoe (Kamchatka-Kuril arc, Russia), and Elshitsa (Sredna Gora zone, Bulgaria). Two types of oscillatory zoning were revealed.

(1) Multiphase (or heterophase) with successive deposition of different minerals or mineral assemblages e.g. Elshitsa where there is regular alternation of goldfieldite bands (Te 2 to 3.2 apfu) with bands (1-2 to 50-100 µm) of tellurian-tennantite (Te 1.5 to 2 apfu) with abundant inclusions of native tellurium. At Prasolovskoe there are “chains” of hessite grains that occur within goldfieldite with a period of 10-20 µm.

(2) Monophase oscillatory zoning reflects element fluctuations in the chemical composition of a mineral. At Elshitsa it is represented by variations of Te from 2.3 to 3.2 apfu and As from 1.8 to 0.7 apfu with a period of 2-3 to 10 µm. At the Ozernovskoe deposit Te ranges from 1.25 to 2.5 apfu, and Sb from 0.86 to 1.33 with a period of up to 20 µm while As increases from 0.75 to 1.63 apfu.

Discussion

The number of such zones in grains with multiphase zoning is usually the same for all crystals in the sample which means that multiphase zoning was caused by an external factor, e.g. due to fluctuation of H₂S and O₂ activities in the solution, and can be described by the equation:

\[
Cu_{12}As_{2}Te_{2}S_{13} + 2.8Te^2 + 2.6H_{2}S + 0.4H_{2}O + 2.8O_{2} = 1.2Cu_{10}Te_{4}S_{13} + 2As(OH)_{3}\]

Monophase zoning is caused by an internal factor, e.g. by the difference between velocities of absorption of any component and its diffusion in the growing zone of the crystal. Since such a zoning occurs only in non-stirred solutions and can indicate local stagnation of the fluid.

Conclusions

Oscillatory zoning can be caused by both external and internal mechanisms and contain important information on mineral forming conditions.

Terrestrial atmospheric nitrogen in lunar soils?

F.A. PODOSEK1, B. MARTY2, L. ZIMMERMAN2, R. KOROTEV1 AND M. OZIMA3

1EPSC, Washington Univ., St. Louis, MO 63130, USA
2CRPG/CNRS, BP 20, 54501, Nancy, France
3University of Tokyo, Tokyo 113-0033, Japan

Surface-correlated N in lunar soils and breccias exhibits an obvious but mysterious effect that was evident essentially from the first analyses of samples returned by the Apollo missions: The isotopic ratio $^{15}\text{N}/^{14}\text{N}$ is variable, by up to 30%. For some time this was interpreted in terms of variation in the solar wind isotopic composition, perhaps reflecting solar nuclear processes and perhaps even reflecting a secular trend (e.g. Kerridge, 1993). This would be very difficult to understand (Geiss and Bochsler, 1982) in terms of the standard model of the Sun, however, and more recently Hashizume et al. (2000), among others, have championed an alternative interpretation that the isotopic variations reflect N in extralunar, extrasolar particle infall mixing with the solar wind N.

Most recently, Ozima et al. (2005) have suggested another interpretation: That the isotopic variations in lunar soil N reflect admixture of solar wind N with an "Earth wind" flux of atmospheric N. An Earth wind flux is quantitatively insufficient under present circumstances, but might have been quantitatively effective very early in the history of the Earth-Moon system, before the development of the global geomagnetic field. Although viable this seems a quite unlikely hypothesis, but one laden with important consequences if valid.

The Ozima et al. (2005) hypothesis is also subject to simple test: If the isotopic variations are due to a contribution of Earth wind they should be essentially absent in lunar farside samples, since the Moon is thought to have been spin-locked essentially throughout the history of the Earth-Moon system, and an Earth wind would not reach the farside. The purpose of this work is to apply this test.

There are no samples returned from documented farside locations, but there are numerous lunar meteorites, half of them presumed to originate on the farside. We analyzed N in nearly all eleven soil and fragmental breccias known among Antarctic lunar meteorites. By the Earth-wind hypothesis, half should display essentially constant isotopic composition of N, at the solar wind value. This expectation is not realized in our observations, so we conclude that the Earth-wind hypothesis for the origin of N isotopic complexity in lunar soils is not tenable.

The rim structure of simple craters as an indicator for an impact vector

M. POELCHAU1, T KENKMANN1 AND D. KRING2

1Museum für Naturkunde, Berlin, Germany
(michael.poelchau@museum.hu-berlin.de; thomas.kenkmann@museum.hu-berlin.de)
2Center for Advanced Space Studies, LPI, Houston, Texas (kring@lpi.usra.edu)

The rims of two simple impact craters, Wolfe Creek, Australia, and Meteor Crater, AZ, USA, were examined. New methods of analysis were devised to display structural features that may be indicative of oblique impacts. Data from the two craters are compared.

Although the majority of craters are formed by oblique impacts, crater shapes remain circular for impact angles >30° and thus normally do not give any implications for the direction of impact. However, the ejecta blanket is the most sensitive indicator for impact angle and direction, and can show a “forbidden zone” on other terrestrial bodies.

The ejecta trajectories forming asymmetric or bilaterally symmetric ejecta blankets of oblique impacts may deviate from a radial orientation with respect to the final crater center and could probably be traced at the rim and overturned flaps of simple craters, which represent the most proximal part of the ejecta. We therefore systematically analyzed strike and dip of strata in the crater rims of two young, simple impact craters, Wolfe Creek Crater and Meteor Crater.

Wolfe Creek Crater is located in Western Australia, was formed 300 ka ago and has an average diameter of 880 m. It was formed in sub-horizontal Devonian sandstones that are over lain by a layer of Miocene laterites. Meteor Crater in Arizona is 50 ka old and 1200 m in diameter. Pre-impact target rocks are sub-horizontal Permo-Triassic sandstones and limestones.

The strike data collected in both craters is translated from a geographic to an azimuthal reference scheme with the point of origin situated in the crater center. The strike of rock layers in the rim is examined for deviations from a hypothetical concentric orientation with regards to the crater center. The deviation can be expressed as an angular value for each measurement.

Results: When displayed in a polar plot, which gives a better sense of the spatial relationship, the values reveal a bilaterally symmetric orientation of the bedding and potential “forbidden zones”. These preliminary results contradict earlier propositions for an impact vector in both Wolfe Creek Crater (Shoemaker et al., 2005) and Meteor Crater (Roddy & Shoemaker 1995). We intend to compare these results with other information, e.g. distribution of dip data, stereo plots and spatial relationships of bedding in three dimensions.

Acknowledgements: We would like to thank DFG for funding this project (KE 732-11/1).

The influence of weathering processes on riverine Mg and Li isotopes in rivers draining basaltic terrain

P.A.E. Pogge Von Strandmann1,2, K.W. Burton1,3, R.H. James1, P. Van Calsteren3 and S.R. Gislason4

1Department of Earth Sciences, The Open University, UK
2Department of Earth Sciences, Bristol University, UK
(P.PoggeVonStrandmann@bristol.ac.uk)
3LMTG, Universite de Toulouse, 14 Av. E. Belin, 31400, Toulouse, France
4Institute of Earth Sciences, University of Iceland, Iceland

Chemical weathering of continental Ca-Mg silicates is a long-term sink of atmospheric CO2, and therefore exerts a major control on climate. However, tracing change in weathering processes through time is difficult because many traditional radiogenic isotope tracers yield ambiguous signals. The transfer of Mg from the continents to the oceans, and its subsequent removal from the oceans, plays a major role in the global carbon cycle, and has also been invoked as a dominant control on oceanic carbonate chemistry. However, the relative importance of these processes, as well as those which fractionate Mg isotopes during weathering, are not well understood. Distinguishing Mg isotope variations which arise from differences in lithology from those caused by weathering processes is difficult, because the range of δ26Mg observed in different rock types is large. However, the study of monolithological terrains offers one way of circumventing the effects from different rock types.

This study presents Li and Mg isotope data for bedload, suspended and dissolved load of rivers from basaltic catchments in Iceland. In addition, primary basaltic mineral phases and soils have also been analysed to determine the possible effects of weathering of primary minerals and the formation of secondary phases.

Li isotope (δ7Li), variations are generally thought to reflect the balance between dissolution of primary minerals and secondary mineral formation; the light isotope, 6Li, is preferentially taken up by secondary minerals. The δ7Li of the dissolved phase varies between +17 and +44‰, and generally decreases downstream.

δ26Mg values of the river sediments range from -0.83 to +0.83‰ relative to DSM-3. Basaltic soils have variable δ26Mg; those with a higher secondary mineral content are isotopically lighter. Co-variations of riverine δ26Mg with suspended load δ26Mg, as well as with pH and the fraction of Mg lost to clays appear to indicate that the isotope composition of the dissolved load is dominantly controlled by preferential uptake of 24Mg into clays, leaving the residual dissolved load isotopically heavy.

These data suggest that Mg isotopes in basaltic rivers are dominantly controlled by secondary mineral formation, and thus the degree of chemical weathering.

Carbon isotope evidence (13C and 14C) for fossil methane-derived dissolved organic carbon from gas hydrate bearing cold seeps

J.W. Pohman1, J.E. Bauer2, C.L. Osburn3 and R.B. Coffin3

1U.S. Geological Survey, Woods Hole Science Center, Woods Hole MA, USA (jpohman@usgs.gov)
2Virginia Institute of Marine Science, College of Wm. & Mary, Gloucester Point VA, USA (bauer@vims.edu)
3Naval Research Lab, Marine Biogeochemistry, Washington D.C., USA (osburn@nrl.navy.mil, coffin@nrl.navy.mil)

Vast reservoirs of gas hydrate in continental margin sediments have the potential to influence the properties of organic matter in both sediments and the overlying water column. Natural radiocarbon and stable carbon isotopes were utilized to determine if fossil methane-derived carbon associated with gas hydrate-bearing sediments was incorporated into the dissolved organic carbon (DOC) of both sediment pore waters and overlying near-bottom waters from northern Cascadia margin cold seeps. Pore water DOC from the sulfate-methane transition (SMT) had a δ13C of -60‰ at a site with a microbial methane source and -45‰ at a site with a thermogenic methane source. In both cases, methane-derived carbon was the predominant carbon source (80-100%) for DOC associated with the SMT. Furthermore, 14C- and 13C-depleted bottom water DOC from the thermogenic gas hydrate site indicates that methane carbon constituted 30-50% of the bottom water DOC. Our results indicate that fossil-derived sources of carbon were a significant component of DOC in the cold seep systems we investigated, and suggest that fossil methane-derived DOC fluxes from cold seep sediments may contribute to the aged DOC pools of the deep open ocean.
Neon and plume – MORB mixing along the Galapagos Spreading Center

VIRGINIE POIRIER¹, PETE BURNARD¹, DAVID W. GRAHAM² AND YVES MARROCHI¹

¹Centre de Recherches Pétrographiques et Géochimiques, BP 20, 54501 Vandoeuvre-lès-Nancy, France (Virginie.Poirier@etudiant.ensg.inpl-nancy.fr)
²Oregon State University, College of Oceanic and Atmospheric Sciences, Corvallis, OR 97331, United States.

Characterizing noble gas composition variations along plume-influenced ridges can help reveal mantle processes such as mantle flow, source mixing, degassing, fractionation and mantle heterogeneities. Lava s from Western and Southern Galapagos islands have very high $^{3}\text{He}/^{4}\text{He}$, up to 30 Ra, but the Northern Galapagos islands and Wolf-Darwin lineament have relatively low $^{3}\text{He}/^{4}\text{He}$, between ~6 and 8 Ra. Along the Galapagos Spreading Center (GSC), $^{3}\text{He}/^{4}\text{He}$ ratios are from 5.9 to 8.5. No high $^{3}\text{He}/^{4}\text{He}$ ratios resembling those of Western and Southern islands are observed along the GSC, despite many indicators of the involvement of plume-derived material [1]. Here, we use Ne isotopes to detect plume involvement in the generation of GSC basalts.

New basaltic glasses were sampled in the ridge axis of GSC between 86 and 98°W. The samples were analysed by crushing of one fragment of sample in order to release volatiles trapped in vesicules. The abundance of CO₂ was measured with a capacitance manometer and the isotopes of Ne were analysed on a Helix MC noble gas multi-collection mass spectrometer.

Preliminary results from two samples so far analysed have very low abundances of mantle Ne, with $^{4}\text{He}/^{21}\text{Ne*}$ (where * denotes corrected for atmospheric contamination) significantly higher than the mantle production ratio. Fractionation of He from Ne may result from late stage degassing (during emplacement of the lavas, for example) or could be due to contamination of the plume-derived melts by asthenospheric He (but no Ne). Analysis of more samples, as well as analysis of Ar isotopes and abundances, will allow two cases to be distinguished.

Significance of the mantle Fe isotope variations

F. POITRASSON¹, G. DELPECH², M. GRÉGOIRE³ AND B.N. MOINE⁴

¹LMTG-CNRS, 14, av. E. Belin, 31400, Toulouse, France. (Franck.Poitrasson@lmtg.obs-mip.fr), ²Univ. Paris-Sud, Orsay, France, ³DTP-CNRS, Toulouse, France, ⁴Univ. St Etienne, France.

The Fe isotopic variability found among mantle xenoliths [1] is in sharp contrast with the homogeneous isotopic composition of mantle-derived rocks [2,3]. To address this issue, we have undertaken a comprehensive petrological and geochemical study of different suites of mantle xenoliths. They sample continental and oceanic lithospheric mantles of different ages, in the spinel facies and the garnet facies.

The $\delta^{57}\text{Fe}_{\text{IRMM14}}$ range measured at the bulk rock scale (0.99‰) is even larger than previously found. None of the xenolith suites studied display a homogeneous isotopic composition. Bulk-rock Fe isotope signatures were compared to bulk-rock and mineral major and trace element contents. In some cases, the observed correlations can be interpreted as resulting from the effect of different types of metasomatism whereas for other examples, they seem to reflect melt extraction. Although both of these processes affected the bulk-rock Mg#, it was possible for three of the studied xenolith suites to infer the “starting” isotopic composition of the mantle area studied. Two intracontinental suites (Cameroon and South Africa) yielded a $\delta^{57}\text{Fe}_{\text{IRMM14}}$ of 0.1‰, whereas one intraoceanic suite (Kerguelen) led to a value of 0‰ for a highly melt-depleted mantle.

These results point to an “initial” lithospheric mantle, prior to multiple episodes of metasomatism and melt extraction, having a mean $\delta^{57}\text{Fe}_{\text{IRMM14}}$ indistinguishable from that of mantle-derived basalt. This inference is consistent with [4].

These findings also illustrate that Fe isotopes are a sensitive tracer of mantle metasomatic processes despite the high temperatures involved and the usually small Fe isotopic variations observed in igneous rocks. The mechanisms responsible for this peculiar behaviour of Fe isotopes has yet to be fully understood.

Plagiogranitic ocelli in the pillow lavas of the Eoarchean (3.7-3.8 Ga) Isua greenstone belt, SW Greenland

A. POLAT1, P.W.U. APPEL2 AND R. FREI3

1University of Windsor, Windsor, ON, Canada (polat@u windsor.ca)
2Geol. Survey of Denmark and Greenland, Copenhagen, Denmark (pa@geus.dk)
3University of Copenhagen, Copenhagen, Denmark (robertf@geol.ku.dk)

Pillow basalts in the 3.8-3.7 Ga Isua greenstone belt, West Greenland, contain randomly-distributed white ocelli structures. The ocelli are composed predominantly of polycrystalline Na-plagioclase and quartz, with minor hornblende and biotite. They are devoid of any radial and concentric internal structures and display all stages of coalescence. Compositionally, the ocelli are calc-alkaline dacites, whereas the surrounding matrix is a tholeiitic ferrobasalt, suggesting that ocelli melts were not derived from the melts of basaltic matrix by fractional crystallization. Similarly, transition metal and REE abundances cannot be explained by simple closed-system crystal fractionation of mafic liquids. High concentrations of Ni (120-270 ppm in ocelli; 105-160 ppm in matrix), Cr (395-570 ppm in ocelli, 330-590 ppm in matrix), and Co (25-45 ppm in ocelli, 54-64 ppm in matrix) are consistent with near-primary mantle-derived dacites, whereas the surrounding matrix is a tholeiitic ferrobasalt, suggesting that ocelli melts were not derived from the melts of basaltic matrix by fractional crystallization. Similarly, transition metal and REE abundances cannot be explained by simple closed-system crystal fractionation of mafic liquids. High concentrations of Ni (120-270 ppm in ocelli; 105-160 ppm in matrix), Cr (395-570 ppm in ocelli, 330-590 ppm in matrix), and Co (25-45 ppm in ocelli, 54-64 ppm in matrix) are consistent with near-primary mantle-derived melt compositions. On the basis of chondrite-normalized REE patterns, the ocelli are divided into two groups. Group 1 is characterized by LREE-depleted patterns, whereas Group 2 displays LREE enrichment. The trace element characteristics of the Group 1 ocelli are similar to those of the surrounding matrix. Both the ocelli and matrix are depleted in Nb relative to Th. Geochemically the Isua ocelli and host volcanic rocks closely resemble those of Phanerozoic supra-subduction zone ophiolites. Given the pronounced depletion of Nb, relative to Th and LREE in the Group 2 ocelli and picritic to basaltic host rocks, partial melting of a forearc mantle wedge, fluxed with subduction-derived LREE-rich hydrous fluids or melts, is favoured for the source of the Isua ocelli and host volcanic rocks. The ocelli-bearing island arc picrites are structurally juxtaposed against a boninitic volcanic association [1]. Recently, the presence of a relict sheeted dyke complex has been reported within the picritic to basaltic island arc volcanic association, indicating that the Isua greenstone belt was formed by sea-floor spreading in a supra-subduction zone setting [2]. The presence of plagiogranitic ocelli is also consistent with an ophiolitic origin of the Isua greenstone belt.

Cathodoluminescence behaviour of Mn-rich carbonates

M. POLGÁRI1, B. BAJNÓCZI1, J. GÖTZE2 AND T. VIGH3

1Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary (polgari@geochem.hu)
2Department of Mineralogy, TU Bergakademie, Freiberg, Germany (goetze@mineral.tu-freiberg.de)
3Mangan Ltd, Úrkút, Hungary (manganvigh@vnet.hu)

It is well known that manganese is the most important cathodoluminescence activator in carbonates (Pagel et al., 2000). However, the CL method is rarely applied in the petrological investigation of Mn-carbonate-bearing rocks and mineralizations due to the commonly accepted effect of concentration quenching or self-quenching, which occurs at elevated Mn concentrations. A comprehensive knowledge about the luminescence behaviour of Mn-rich carbonates still does not exist. The purpose of our study was to determine the effect of Mn concentration on self-quenching.

The cathodoluminescence behaviour of Mn-rich carbonates (rhodochrosite, Ca-kutnohorite, Mn-rich calcite) from hydrothermal and volcano-sedimentary systems was preliminarily studied by CL microscopy and spectroscopy. Chemical composition of carbonates was investigated by X-ray diffraction and FTIR spectroscopy methods. Most of the samples showed bright orange-red CL. The brightest CL occurred in the 5 to 14 wt% range of Mn content. A strong decrease of CL intensity was observed between cca. 14 and 18 wt% Mn, but the rhodochrosite samples with 37 to 45 wt% Mn are still dull luminescent. The study by CL spectroscopy indicated a 620 nm maximum peak position for calcite, 640 nm for rhodochrosite and 630 nm for a Ca-kutnohorite with 9 wt% Mn (Fig. 1).

Figure 1. CL spectra of rhodochrosite, Mn-rich calcite and Ca-kutnohorite with 9 wt% Mn

Our results show the existence of cathodoluminescence in carbonates characterized by elevated Mn concentration (5 to 45 wt% Mn). It seems that self-quenching is not complete even in the case of rhodochrosite.

Did hydrothermal fluids contribute to the huge Úrkút Manganese ore body?

M. POLGÁRI1, J.R. HEIN2, M. TÓTH1, T. VIGH3 AND L. BÍRÓ4

1Institute for Geochemical Research, HAS, Budapest, Hungary (polgari@geochem.hu)
2USGS Menlo Park, California, USA (jhein@usgs.gov)
3Mangan Ltd, Úrkút, Hungary (manganvigh@vnet.hu)
4Eötvös Loránd University, Budapest, Hungary (birolori@gmail.com)

Deposition of the black shale-hosted Úrkút Mn carbonate deposit in Hungary occurred in the Early Jurassic. The ore body formed in a structurally controlled marine basin via bacterially mediated, early diagenetic formation of Mn carbonates. It has been proposed that hydrothermal fluids venting into the depositional basin was involved in the mineralization, but this idea is controversial. A hydrothermal origin may be supported by several lines of evidence such as the fractionation of Mn and Fe, the in situ precipitation of celadonite and other clay minerals, and the accumulation of huge amounts of Mn, Fe, Si. However, none of this evidence alone or together for that matter are conclusive and the aim of this study is to look for evidence for a hydrothermal plumbing system by study of the underlying Mn- and Fe-oxide mineralization. Analysis of 12 samples show a wide range of Mn and Fe contents, with mean values of 35.9% Mn and 10.3% Fe. Si (4.9%), Sr (mean 0.6%), P (0.3%), Ba (0.3%) and Co (0.07%) are enriched in the Fe-Mn oxides. The Fe/Mn mineralogy of the samples is cryptomelane, todorokite, manganite, goethite, hematite, goutite. Polished thin sections show signs of bacterial activity and the precipitation of Mn oxides within soft carbonate sediment, sediment that was later partly to completely replaced by a later stage of Mn oxides. Sr and P enrichments reflect input from leaching of carbonates and organic matter. Mn oxide and Mn carbonate mineralization occur above a thick carbonate basement cut by deep fracture zones. Our data suggests that the Fe and Mn oxides were deposited from deep-sourced fluids circulating through basement rocks. Circulation along zones of structural weakness was likely driven by high geothermal gradients. Sr isotopes are being measured on these samples to confirm this idea.

Textural and microstructural analysis of rapidly grown omphacite from eclogite facies pseudotachylites

K. POLLOK1, F. HEIDELBACH2, F. LANGENHORST1 AND T. JOHN3

1Institut für Geowissenschaften, Universität Jena, Burgweg 11, D-07749 Jena, Germany (Kilian.pollok@uni-jena.de; Falko.Langenhorst@uni-jena.de)
2Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (Florian.Heidelbach@Uni-Bayreuth.de)
3PGP, University of Oslo, PO Box, 1048 Blindern, 0316 Oslo, Norway (timm.john@fys.uio.no)

Rapidly grown omphacite (Jd40) has been formed in melt domains of an eclogitized gabbro from central Zambia by frictional melting during pseudotachylyte formation [1]. Omphacite occurs as an extremely fine-grained matrix (grain size of 2-3 µm) and form partly spherulites with diameters ranging from 100 to 300 µm. The textures point to fast mineral growth with local differences in nucleation and growth rate due to heterogeneous cooling. Here, omphacites within melt domains have been studied using electron backscatter diffraction (EBSD) and transmission electron microscopy (TEM) to relate mineral growth texture with deformation (dislocation) microstructure under eclogite facies conditions.

EBSD analyses of a single spherulite show a common b plane for all omphacite grains within the spherulite, while there is no lattice preferred orientation for matrix omphacite. The grains within the spherulite are significantly larger than in the matrix and form radially oriented needles. TEM revealed a strong deformation microstructure with subgrain boundaries, dislocation networks and nodes as well as stacking faults and associated partial dislocations. Grain boundaries of adjacent omphacites are often interlocked and wave-like curved. The spherulitic texture is obviously formed during growth. The distinct dislocation microstructure may have originated from the differential stress developing during rapid growth. Growth related deformation microstructures are barely studied yet and will be discussed in connection with eclogite facies pseudotachylyte formation.

Evaluating magnetic susceptibility as a rapid scoping tool for assessing trace metal contaminated soils

D.A. Polya1, I. Zananiri2, D. Konopoulou3, A. Atzemoglou3, S. Fraser4, P.R. Lythgoe1, J.M. Charnock1,4, J. McBeth1 and A.G. Gault1,5

4CLRC Daresbury, Warrington, UK
5now at Dept. Earth Sciences, University of Ottawa, Canada

The widespread association in many soils of various trace metals with nano- or micro-particulate grains of magnetic Fe-O-H phases has led to the proposal (Bityukova et al., 1999) that the magnetic susceptibility, \(\chi\), of soils might be used as a proxy for trace metal concentrations, particularly concentrations of bioavailable trace metals, in contaminated soils. The utility of such measurements in areas of trace metal contamination has been tested here using field and laboratory magnetic susceptibility measurements and a variety of chemical and mineralogical analyses: ICP-AES, XAS, sequential extraction, EPMA, XRD and XRF. Three contaminated sites, two in Greece (Kozani – a disused power station, Thessaloniki – the site of a tannery) and one in the UK (Potters Hill, Bolton – site of a former chromate works) were selected for study.

Good correlation of Zn and Cu with field-based \(\chi\) data was found, however a very poor correlation was found between Fe and Cr and field-based \(\chi\) data. This suggests that whilst Zn and Cu are predominately associated with phases contributing to \(\chi\), Fe and Cr occur in substantial proportions in phases with contrasting magnetic susceptibilities. EPMA mapping confirmed the existence of all of Fe-rich, Cr-rich and Fe+Cr-phases. XANES and EXAFS data were consistent with the occurrence in the soils of the Cr(III) phases with the following stoichiometries: \(\text{Cr}_2\text{O}_3\), \(\text{Cr(OH)}_2\) and \(\text{FeCr}_2\text{O}_4\).

Whilst field-based \(\chi\) measurements are both cheaper and faster than chemical analysis of bulk soil or soil extracts and thereby have the potential to be a useful scoping tool, the relationship between \(\chi\) and metal concentrations may be critically dependent on the solid phase speciation of the trace metals of interest, necessitating careful consideration of data on a site-by-site basis.

Novel corresponding - states principle approach for calculating the isotopic properties of water under elevated temperatures and pressures

V.B. Polyaakov1, J. Horita2, D.R. Cole3 and A.A. Chialvo4
1Institute of Experimental Mineralogy, RAS, Chernogolovka, Moscow Region, Russia, (polyakov@iem.ac.ru)
2,3Chemical Sciences Division, Oak Ridge National Laboratory, TN 37830-6110 (horitaj@ornl.gov; coledr@ornl.gov; chialvoaa@ornl.gov)

The isotopic properties of geologic fluids under geologic conditions are of geochemical interest. For this reason, we developed a corresponding-state principal (CSP) formulation for expressing the equation of state (EOS) of isotopologues of molecular fluids in terms of the dimensionless three-parameter equation (Polyakov et al., 2007):

\[
Z(\tau, \delta, \omega) = Z_0(\tau, \delta, \omega) + \frac{\partial Z_0(\tau, \delta, \omega)}{\partial \omega} (\omega - \omega_0)
\]

where \(Z\) is the compressibility factor; \(\tau\) and \(\delta\) are dimensionless temperature and pressure, respectively; \(\omega\) is the Pitzer acentric factor; subscript “0” refers to the major isotopologue. Using this CSP formulation for minor isotopologues, we further developed a general EOS-based approach for calculating the reduced isotope partition function ratio (RIPFR) for “real-gas” fluids under elevated temperatures and pressures presented by Polyaakov et al. (2006).

This novel approach was applied to the isotopologues of water (HDO and \(H_2^{18}O\)), using experimental data (e.g. liquid-vapor fractionation and molar volume isotope effects). The RIPFR of water calculated from our approach show contrasting behaviors for HDO and \(H_2^{18}O\). The D/H exhibits an overall decrease of 5‰ with increasing pressure to 1 kb, which is in agreement with experimental results for brucite - water system (Horita et al., 2002). In contrast, the RIPFR for \(H_2^{18}O\) increases by 1% with pressure to 1 kb. The significant pressure effects on the isotopic properties of water obtained from this study have important geochemical implications.

Modelling of contact metamorphism and metasomatism near the Talnakh intrusion: Effect of fluid convection versus conductive heat transfer

O. P. POLYANSKY AND V. V. REVERDATTO
Institute of Geology and Mineralogy, SB RAS, Novosibirsk, Russia (pol@uiggm.nsc.ru)

As was shown for a number of geological and theoretical models, convective heat-and-mass transfer near magmatic bodies is of great importance. The country rocks of intrusions in the Noril’sk ore district at the northwestern margin of the Siberian Craton are one such case. In this communication, mathematical modelling is used to describe the heat redistribution and fluid convection in the volcanosedimentary sequence at the contact with the Talnakh ore-bearing intrusion.

The problem of modeling of heat transfer and convective flows of a two-phase fluid is solved in the 2D setting in the Cartesian coordinate system on the basis of time-dependent equations of nonisothermal hydrodynamics with account of vapor-liquid phase transition (USGS HYDROTHERM code).

Patterns of fluid flow in the hydrothermal system with a permeable vertical zone that crosscuts the intrusion were obtained from the modeling results. The suggested mechanism of mixing of magmatic fluid with formation water may be efficient only at sufficiently high permeability of the rocks (fig. 1).

As the modeling results show, metasomatic zoning may arise at the postmagmatic stage within a zone 150-200 m thick above the intrusion and no more than 30-40 m thick below the lower contact.

This work was supported by grants Sci.Sch.-4922.2006.5 and SB RAS no 116.

Temporal distribution and cyclicity in formation of porphyry Cu-Mo deposits

V. A. PONOMARCHUK, V. I. SOTNIKOV, A. N. M. FEDORIN, V. O. GIMON AND M. N. SHAPORINA
Institute of Geology and Mineralogy, Novosibirsk State University, Novosibirsk, Russia (ponomar@uiggm.nsc.ru)

The recent increased applicability of global paleo-reconstructions, coupled with improved geochronology from most of the world’s investigated Cu–Mo porphyry deposits, allows for an improved understanding of the distribution pattern of orogenic copper and molybdenum in space and time, as well as the relation between the resources of deposits and time of their formation. Geochronological data compiled for about 350 known large to medium (with resources > 0.05 mln. t) porphyry Cu–Mo deposits from all over the world including Asian part of Russia (Sora, Zhirkeen, Schakhtama, Aksug and others) and Mongolia (Khamagtau, Tsagan-Suburga, Erdenetuin-Obo) are represented on the diagram in the time of deposit formation vs resources coordinates (Fig. 1).

Figure 1: Geochronological density of copper resources

1) there is an irregularity in geochronological density of Cu-Mo resources; 2) discreteness in phases of maximum ore-forming activity (28-39; 50-60; 66-73; 75-82; 235-245 Ma) with duration up to 10 Ma; 3) in time, not every significant plume correlates with the epochs of intense ore formation; 4) spectral and wavelet-analysis of geochronological data reveals quasi-periodic cycles of 120-100, 69-60, 36-28, 20-15, 12-10, 8-7 Ma alternating at different time intervals. The latter two factors indicate the formation of porphyry Cu-Mo deposits is related not only with plumes but also with tectonic plate reorganization.

The investigations were supported by the Russian Foundation for Basic Research, grant 06-05-64860; Integration project of the Presidium of Siberian Branch and Far East Branch of RAS No. 6.1, and Grant of the Ministry for Russian Science and Education DSP.2.1.1.702.
**Raman-Spectroscopy – A powerful tool for life- and material-sciences**

J. POPP$^{1,2}$

$^1$Institute for Physical Chemistry, Friedrich-Schiller-University Jena (juergen.popp@uni-jena.de)
$^2$Institute of Photonic Technology, Jena

Raman spectroscopy has emerged in the last years as an extremely powerful method in almost all natural science disciplines. This renaissance of Raman spectroscopy was mainly triggered by the latest achievements in laser technology, by the design of very efficient filter to suppress the elastically scattered Rayleigh light, and by the development of extremely sensitive detectors. The advantages of Raman spectroscopy are its unprecedented high specificity and its versatility. Raman spectroscopy is a non destructive technique and does in general, require only minimal or no sample preparation. Solid, liquid, and gaseous samples can be measured as well as transparent or non transparent samples or samples with different surface textures i.e. Raman spectroscopy can be applied to any optical accessible sample, where a pre-treatment of the sample is not necessary.

In this presentation a report on a Raman spectroscopic characterization of a broad variety of biological probes will be given. Raman spectroscopy is an extremely capable, suitable and prominent method for probing the relationship between structure, dynamics and function of biomolecules. In this context micro-Raman imaging, the surface enhanced Raman scattering (SERS) technique and resonance Raman spectroscopy are commonly applied. These Raman techniques allow one to characterize the structure of e.g. isolated pharmacological relevant substances and the investigation of pharmaceutical relevant substances in plants and especially the localization of pharmaceutical relevant substances in tissues. Not only the localisation but also the investigation of the mode of action of drugs against infectious diseases on a molecular level will be presented. In addition Raman spectroscopy also allows the identification of microorganisms on a single cell level.

The main focus within the second major topic material photonics is concerned with the derivation of structure-property as well as structure dynamics relationships by means of Raman spectroscopy. In particular the characterization of mineralogical samples like e.g. extraterrestrial material (meteorites) and the derivation of structure-activity and dynamic relationships in artificial light harvesting systems or photocatalysts based on Ruthenium-polypyridyl complexes by means of resonance Raman spectroscopy will be presented.

In summary the presented examples convincingly demonstrate the great capabilities of Raman spectroscopy for life and material sciences making this technique to one of the most essential laser spectroscopical methods.

**Experimental evidence for rapid re-equilibration of water between melt inclusions in olivine and host magma**

MAXIM PORTNYAGIN$^{1,2}$ AND RENAT ALMEEV$^{2,3}$

$^1$IM-GEOMAR, Wischhofstr 1-3, 24148 Kiel, Germany, (mportnyagin@ifm-geomar.de)
$^2$Institut für Mineralogie, Leibniz Universität Hannover, Callinstrasse 3, Hannover, 30167, Germany, (r.almeev@mineralogie.uni-hannover.de)
$^3$Vernadsky Institute, Moscow Russia

Here we report the results of pilot experimental study aimed at evaluating the ability of olivine to protect melt inclusions at changable external conditions, which may readily take place in long-living magmatic systems.

For the experimental study, natural olivines containing glassy inclusions were picked from olivine-plagioclase-pyroxene phric submarine tholeiitic basalts from the Galapagos Plateau (sample PLO2-24-33 provided by D.Christie). Ninety six inclusions from this sample were preliminarily studied for major and trace elements. Water content in natural inclusions measured by ion probe ranged from 0.37 to 0.67 wt % (n=20) and was similar to matrix glass (0.43 wt %). Selected olivine grains (0.5-1 mm) with inclusions inside were loaded in Fe-presturated Au$_{80}$Pd$_{20}$ capsule together with reduced (QFM-1) powder of depleted synthetic MORB. The mixture was dopped with ~ 3 wt % of distilled water. Experiments were conducted in internally heated pressure vessel at 200 MPa and 1140 °C using Ar as pressure medium. The run duration was 48 hours.

Experimental products were studied optically, with electron and ion probe. Surprisingly, all of seven inclusions analysed after experimental treatment had high water content (2.0-2.7 wt%), close to the matrix glass (2.3 wt%) and ~5 times higher than in starting compositions and exhibited high MgO (8.1-8.9 wt% vs. 4.0-6.7 wt % prior experiment) corresponding olivine-melt inclusion equilibria at hydrous conditions. Incompatible trace elements, S, F and Cl content in the melt inclusions decreased only slightly after the experiment (due to host olivine dissolution), remaining within the range of natural Galapagos inclusions and ~10 times higher than in depleted synthetic matrix.

We conclude from this study that melt inclusions in olivine behave as semi-closed system at changing external conditions. Complete re-equilibration of water between inclusions in large olivines (up to 1mm in size) and matrix melt is achieved during 2 days or less, whereas incompatible trace elements and other volatile components (S, Cl, F and likely CO$_2$) behave as immobile. Rapid water (hydrogen) exchange between inclusions in olivine and host magma, which is faster than Fe-Mg diffusion in olivine, implies that those inclusions experienced detectable Fe-Mg re-equilibration with olivine can unlikely preserve initial water concentrations and most likely reflect water content in surrounding magma prior eruption.
Weathering of Bronze Age potsherds in a Mediterranean climate (Cres Island, Croatia)

H. POSILOVIĆ1, S. MIKO2, O. HASAN2 and S. MESIĆ2

1Faculty of Science, University of Zagreb, Geological department, Horvatovac bb. Zagreb 10000, Croatia; hposilovic@geol.pmf.hr
2Croatian Geological Survey, Sachsova 2, Zagreb 10000, Croatia

The aim of this study was to study the causes of well preserved status of potsherds in bronze age hill forts on Cres island (Northern Adriatic Sea) exposed to Mediterranean climate and their buried equivalents in colluvial deposits. The island of Cres has a long history of settlement and hosts some very important Mesolithic, Neolithic and Bronze age sites. Due to erosion large areas are bare karst lacking soil cover and prehistoric potsherds can be found in stonewalls of hill forts or caves.

The potsherds were analyzed by microscopy methods as well as geochemistry to study the weathering process in both exposed and buried potsherds. The colluvial soil containing potsherds was dated at Beta Analytic AMS facility (Beta-199264) and a calibrated $^{14}$C date ranging from 2030 to 1870 BC was obtained. Under the optical microscope, the potsherds are texturally homogeneous and display inclusions of similar type, abundance, and grain size.

The enrichment of Ca in exposed potsherd rims is accompanied by depletion of light REE’s and enrichment of heavy REE’s.

The results show that potsherds exposed to the Mediterranean climate for four thousand years have an improved durability due to calcite re-crystallization and notable change in the chemical composition of potsherd rims which have to be considered when using bulk geochemistry for provenance studies.

Constraining the role of anoxygenic phototrophic Fe(II)-oxidizing bacteria in the deposition of BIFs

N.R. POSTH AND A. KAPPLER

Geomicrobiology, Center for Applied Geosciences, University of Tuebingen, Sigwartstrasse 10, 72076 Tuebingen, Germany (nicole.posth@uni-tuebingen.de; andreas.kappler@uni-tuebingen.de)

Banded Iron Formations (BIFs) are Precambrian sedimentary deposits of alternating iron oxide and silica mineral layers. Their presence in the rock record ca.3.8-2.2 Ga makes them particularly intriguing formations for the debate over when oxygen became dominant on Earth. The mechanism(s) of BIF deposition is still unclear and suggestions include both abiotic and biotic processes. We are interested in constraining one of these proposed mechanisms; the direct biological oxidation of Fe(II) via anoxygenic Fe(II)-oxidizing photoautotrophs.

In order to find the limitations of photoferrotrophic BIF deposition, we take a holistic approach, investigating the oxidation of Fe(II) by modern Fe(II)-oxidizing phototrophs, the precipitation of Fe(III) (hydr)oxides, and the fate of the cell-mineral aggregates in the water column and at the basin floor.

Specifically, physiology experiments with Fe(II)-oxidizing phototrophs under various conditions of light intensity, pH, Fe(II) concentration and temperature allow us to determine the environmental limits of such organisms. We carry out precipitation experiments to characterize the sedimentation rates, aggregate size and composition in order to resolve the effect of reactions in the water column. Finally, we simulate the diagenetic fate of these aggregates on the basin floor by placing them in gold capsules under temperature and pressure conditions relevant for the Transvaal Supergroup BIFs of South Africa. Recently, we have developed a tank simulating the Archean ocean in which the strains grow in continuous culture and collect the aggregates formed under various geochemical conditions.

We aim to model the extent of and limitations to photoferrotrophs in BIF deposition. This information will help constrain whether biotic processes were dominant in the Archean ocean and will offer insight to the evolution of the early biogosphere.
Trace element and Nd-Sr isotope systematics of phonolite and other rocks of the Chico Sill Complex, Northeast New Mexico

LEE S. POTTER

Department of Earth Science, University of Northern Iowa, 121 Latham Hall, Cedar Falls, IA 50614, USA
(lee.potter@uni.edu)

Alkaline igneous rocks of Chico Sill Complex in northeastern New Mexico fall on the trend of the Jemez Lineament, an alignment of igneous centers that obliquely crosses the Rio Grande Rift. These 37 – 20 Ma intrusive rocks are spatially associated with younger rocks of the Raton-Clayton volcanic field, but clearly sample a different source. The sills were emplaced prior to rift extension. A subset of the spectrum of intrusive rocks (including phonolite, phonotephrite, trachyte, and lamprophyre dike rocks) is included in this study.

Phonolite is the most common rock type in the southeastern half of the sill complex and is the product of extreme fractional crystallization of a more mafic parent, but may not have evolved from the other lithologies studied. Trace element ratios and normalized-element plots suggest that at least two distinct differentiation trends produced phonolite, titanite fractionation played a role in differentiation, and a subduction component is absent from the phonolite source but may have contributed to other rock compositions. One odd feature is the enrichment of Zr as compared to other continental alkaline rock suites, in one phonolite trend relative to the other.

The subset of rocks studied shows initial Sr and Nd isotope ratios that are close to bulk-earth values, with epsilon Nd in the narrow range of 2.1 to –1.5 (144Nd/148Nd between 0.51275 and 0.51256), and initial 87Sr/86Sr ratios in the slightly broader, but still clustered range of 0.7042 to 0.7053. These isotope ranges are similar to many ocean-island basalts. The trail of the data toward higher 87Sr/86Sr values suggests a probable mixing curve with granitic or sedimentary rocks of the upper crust, although the degree of contamination must have been small and the contaminant is poorly defined.

Tracing global fallout using $^{210}$Pb and artificial radionuclides inventories in mountainous area

L. POURCELOT, G. LE ROUX, PH. RENAUD, F. VRAY AND O. MASSON

IRSN Cadarache BP3, 13108 Saint-Paul lez Durance cedex, France (laurent.pourcelot@irsn.fr)

Inventories of unsupported $^{210}$Pb in soils is used here as a tracer to estimate the effect of parameters such altitude, mean annual rainfall, vegetation on the long term input of atmospheric pollutants over mountainous area. Thus we examine exhaustively the magnitude and extent of soil inventories of unsupported $^{210}$Pb in French mountainous areas. In addition, we combine artificial radionuclides from global fallout (mainly $^{137}$Cs and Plutonium) with $^{210}$Pb to compare deposition mechanisms of artificial and anthropogenic radionuclides. With this view, soils were sampled between 2000 and 2006 along transects of increasing altitude and subsequently increasing annual precipitation rate, in different mountainous areas.

Data shows that $^{210}$Pb soil inventories are coarsely proportional to the mean annual precipitation occurring on each massif. Additionnaly in high-altitude sites, higher $^{210}$Pb inventories than expected are explained by orographic effects. At last, climatic parameters, such as the intensity of rain episodes in Mediterranean regions probably induce specific deposition processes of $^{210}$Pb explaining the relationship observed between soil inventories and rainfall. In addition to altitude and rain amount, the vegetation accounts for the intensity and the extent of $^{210}$Pb deposition, since the excess $^{210}$Pb in woodland soils reachs 30% with respect to grassland. Although the inventory of $^{137}$Cs and plutonium from atmospheric nuclear weapons in soil also increases with mean annual rainfall, a significant decrease of $^{137}$Cs/$^{210}$Pb ratios is observed in studied massifs from lowland to highland sites. This shows that at least two main tropospheric reservoirs with distinct $^{137}$Cs/$^{210}$Pb ratios contribute to the mountainous soil inventory of atmospheric pollutants.
Extracting sequentially Ra, Nd, Pa, Th and U from a unique natural sample, on the same column

C. Pradoux	extsuperscript{1}, C. Jeandel	extsuperscript{1}, C. Venchiarutti	extsuperscript{1}, F. Lacan	extsuperscript{1}, M. Bourquin	extsuperscript{1}, P. Van Beek	extsuperscript{1} and J. Riotte	extsuperscript{2}

\textsuperscript{1}LEGOs (CNES/CNRS/UPS/IRD), OMP, 14 Ave E. Belin, 31400, Toulouse, Fr (Catherine.Pradoux@cnes.fr)
\textsuperscript{2}LMTG (CNRS/UPS/IRD) OMP, 14 Ave E. Belin, 31400, Toulouse, Fr (Catherine.Pradoux@cnes.fr)

Multi-proxy approach is very promising for modern and past marine process investigation. However, extracting simultaneously several tracers from the same sample using the same column remains a challenge. Measuring any natural tracer requires sample collection, pre-concentration or mineralization, chemical extraction and spectrometric analysis. Natural concentrations being very low, when each tracer requires its own collection, huge volumes of water have to be taken from the rosette and/or filtered with in-situ pumps, which is time and money consuming. Since the GEOTRACES program objective is to analyse numerous tracers and isotopes along oceanographic sections, there is an urgent need to find ways to analyse as many elements as possible on the same sample. In addition, collecting more samples on the same marine cast will enhance the homogeneity of the final data, and improve the sampling resolution, therefore improving the data set quality.

A new procedure is presented, allowing the simultaneous extraction of 5 tracers (Ra, Nd, Th, Pa and U) from the same natural sample. In addition to isotopic ratios ($^{143}\text{Nd}/^{144}\text{Nd}$, $^{230}\text{Th}/^{232}\text{Th}$ and $^{234}\text{U}/^{238}\text{U}$) concentrations of $^{226}\text{Ra}$, $^{230}\text{Th}$ and $^{233}\text{Pa}$ are investigated requiring spike addition, i.e. $^{228}\text{Ra}$, $^{230}\text{Th}$ and $^{233}\text{Pa}/^{236}\text{U}$ respectively. Accuracy and precision of the analytical methods were evaluated using artificial standards and natural samples (marine suspended particles and rocks). Satisfactory purifications of Th, Pa and U were obtained from this unique column, whereas Nd and Ra extraction require light additional steps.

New productivity in the Eastern Arabian Sea during winter Monsoon

Satya Prakash and R. Ramesh

Physical Research Laboratory, Navrangpura, Ahmedabad, India 380 009 (satyap@prl.res.in; rramesh@prl.res.in)

The biogeochemistry of the Arabian Sea is driven by seasonally reversing southwest and northeast monsoons. Although both the monsoons trigger high primary production, the underlying mechanisms are different. Recent observations on the basis of ocean color studies have shown contradicting trends in ocean productivity for the western and eastern Arabian Sea; it has increased in the western Arabian Sea over last 6 years whereas no such trend is seen in the eastern Arabian Sea [1]. In this context, it would be interesting to know about the export production taking place in this part of the world’s ocean. Measurement of new production using $^{15}\text{N}$ tracer technique [2] provides an avenue to estimate the export production; integrated over an annual time scale new productivity is equal to the export of carbon out of the surface ocean i.e., the export production. We have carried out new productivity measurements in the eastern Arabian Sea during early and late winter monsoon. Our results suggest that during the early winter, though the column N-uptake is low (~8.91mmolN/m$^2$/d) over a large area of the eastern Arabian Sea the f-ratio (new production/total production) is relatively high (~0.66). Results from the late winter, in conjunction with the earlier reported results [3], reveal consistent high column N-uptake rate (~20.1mmol N m$^{-2}$ d$^{-1}$), particularly when the bloom (dominated by heterotrophic Noctiluca Scintillans) develops in the northeastern part. During this period the f-ratio is also very high (~0.86) suggesting enhanced downward transport of newly formed organic matter implying increased sequestration of carbon to the deeper ocean.

Stable isotopic trends in Neoproterozoic oceans: A record of global Snowballs, global Slushballs, global methane, global diagenesis, and/or palaeogeography?

1School of Geography and Geosciences, University of St Andrews, KY16 9AL, UK (ap13@st-andrews.ac.uk)
2Grant Institute of Earth Science, University of Edinburgh, Edinburgh UK (simone.kasemann@ed.ac.uk)
3Scottish Universities Environmental Research Centre, Glasgow, UK (T.Fallick@suerc.gla.ac)
4Department of Earth Sciences, University of Bristol, Bristol, UK (C.J.Hawkesworth@bristol.ac.uk)
5Geological Survey of Namibia, Windhoek, Namibia (khhoffmann@mme.gov.na)

The Neoproterozoic (1000 – 543 Ma) is a period of extraordinary Earth System change marked by extreme climatic fluctuations and hallmark biological innovations (advent of metazoans). Stable isotopic trends (C-O-B) associated with Neoproterozoic marine carbonate rocks display large amplitude fluctuations which many studies have shown are broadly reproducible worldwide and stratigraphically systematic. Amongst the most intriguing of these are from cap carbonates (carbonate rocks which rest directly on glaciogenic rocks, and/or the surface representing palaeo-glacial episodes) which show sharp negative C isotopic excursions (in many localities down to -6‰) followed by recovery to more positive values and concomitant B-isotopic excursions (about 9‰); these have generated lively debate and timing.

We have amassed a C-O-B dataset on cap carbonates from Namibia, North America and northern Europe that shows that δ13Ccarbonate trends can be distinguished based on location and inferred palaeobathymetric position within an individual basin. Along individual craton margins trends are systematic and variations can be reasonably attributed to varying palaeoenvironmental setting, i.e., they are self-consistent and compatible with the geology. However, inter-cratonal comparisons show that stratigraphic (temporal) patterns and amplitudes differ between basins. Although the duration of cap carbonate precipitation remains contentious, it is likely that deposition was relatively rapid (i.e., 10^3-4 years rather than 10^6 years). Our data can be used to imply that the isotopic composition of water masses varied from place to place in Neoproterozoic oceans. This suggests that cap carbonates and their isotopic signatures were a likely product of a dynamic interplay between palaeogeography and palaeooceanic circulation.

Adsorption and dynamics of ions at rutile and cassiterite surfaces

M. PŘEDOTA1, L. VLČEK2, M.L. MACHESKY3, D.J. WESOLOWSKI4 AND P.T. CUMMINGS2,4

1University of South Bohemia, České Budějovice, Czech Republic; and Institute of Chemical Process Fundamentals, Prague, Czech Republic (predota@icpf.cas.cz)
2Vanderbilt University, Nashville, TN (lukas.vlecek@vanderbilt.edu, peter.cummings@vanderbilt.edu)
3Illinois State Water Survey, Champaign, IL (machesky@uiuc.edu)
4Oak Ridge National Laboratory, Oak Ridge, TN (wesolowskid@ornl.gov)

The interface between aqueous solutions of ions (mostly Rb⁺, Na⁺, Sr²⁺, Cl⁻, Br⁻, F⁻) and metal oxide surfaces, represented by rutile and cassiterite, is studied using molecular dynamics computer simulations. The previously published results for adsorption of these ions at negatively charged surfaces at 25°C are extended to cover higher temperatures up to 150°C and the effect of pH-dependent surface charge density. The effect of the temperature and pH on occupancy of different types of adsorption sites will be compared with predictions of Multi Site Complexation models (MUSIC). The competition between adsorption of several cationic species present in mixed solutions used in titration experiments (e.g. Rb⁺ and Sr²⁺) and the adsorption dynamics of ions will be also discussed.

Recent discussion about Hf-Nd isotope geochemistry focused on the composition of lamproites and kimberlites as possible evidence for the existence of a hitherto unrecognized ‘hidden’ terrestrial reservoir. This was triggered by the discovery of an apparent discrepancy between terrestrial Hf-Nd isotopes and the BSE chondritic reference value, which could be resolved by the existence of a new geochemical reservoir with Hf-Nd isotopic values below the terrestrial array. Most lamproites do not follow the Hf-Nd array defined by other terrestrial samples, but have variable Nd at almost constant Hf isotopic values. This triggered an attractive hypothesis about their role in the evolution of the Earth and their potential to sample the ‘hidden’ reservoir. Here, we present Hf, Sr, Nd and Pb isotope results on Mediterranean lamproites that can be used to further test this possibility.

Mediterranean lamproites are derived from multi-component melts, which combine depleted and enriched end-members(s). The extremely variable radiogenic isotope composition of lamproites points to the importance of mixing relations between three contrasting geochemical components which appear in 206Pb/204Pb, 87Sr/86Sr and 143Nd/144Nd space: a crustal component, an ultra-depleted mantle component originating component. It is the third component which is the most relevant for the deflection of lamproites from the terrestrial Hf-Nd array.

Our modelling shows that the convective-mantle derived component has high Sr and Nb contents, low HFSE relative to LREE, significantly higher Nb/Ta and Zr/HF ratios, and lower Zr/Nb and Zr/Ta ratios relative to OIB and chondrite, whereas isotopic compositions are similar to OIB. This geochemical signature is considered as a “hallmark” of mantle carbonatite. In Hf-Nd isotopic space, this component is responsible for the shift of the lamproite values from terrestrial array. We interpret this shift as a mixing hyperbola between carbonatitic melts derived from sublithospheric mantle and lamproitic melts. The deviation from the array is due to the large range in Hf/Nd ratios that vary from up to 0.20 in lamproitic melts to <0.01 in asthenospheric melts, caused by extremely high Zr and Hf concentrations in lamproites (up to 1000 and 30 ppm, respectively), and very low Hf contents in carbonatitic melts. We discuss a geodynamic scenario which provides a suitable environment for the interaction of coeval asthenosphere-derived and lamproitic melts throughout the Mediterranean region.

REE in the oldest zircons, Okhotsk terrane

S.L. PRESNYAKOV, N.G. BEREZHNAYA AND S.A. SERGEEV

Centre of Isotopic Research, VSEGEI, St.-Petersburg, Russia (Sergey_Presnyakov@vsegei.ru)

For accurate definition of genetic characteristic of zircons from mafic granulites and gneisses and to find a solution of gneisses and granite-gneisses correlation, REE distribution in zircons had been studied, using SIMS SHRIMPII.

Hyp-Plag granite schist displays two oldest zircon generations: 1 (3.6-3.7Ga) with volcanic and 2 (3.5Ga) with magmatic inclusions. Volcanic zircons contain max concentrations of REE and (Lu6/Sm6=104-198, Eu/Eu*=0.2-0.39). Ultra-metamorphic zircons (2) and recrystallized grains (3) contain less REE, especially LREE, REE pattern is steeper (Lu6/Sm6=370-1305, Eu/Eu*=0.15-0.27).

Some zircons (4) correspond to Proterozoic metamorphic and metasomatic events are represented by altered discordant grains of high U contents and positive Eu anomalies (Lu6/Sm6=120-129, Eu/Eu*=2.1-2.9). Its REE concentrations are close to that of zircon 1, but REE pattern for most altered grains is flat (Lu6/Sm6=40, Eu/Eu*=1.16). Granite-gneisses zircons displays two types of REE distribution: for ultra-metamorphic cores (3.3Ga) (Lu6/Sm6=27-117, Eu/Eu*=0.1) and for metamorphic rims (2.7 Ga) (Lu6/Sm6=165-428, Eu/Eu*=0.2-0.5). Cores in zircons of granite-host gneisses (3.28 Ga) show REE pattern (Lu6/Sm6=45-166, Eu/Eu*=0.1-0.2) similar to that for cores of granite-gneisse zircons.

1. Chondritic normalised REE patterns of zircons with volcanic inclusions from Hyp-Plag granite schist are similar to that of zircons from gabбро (Hoskin, 2000) and correspond to magmatic pattern. It conforms to geochemical data and verifies belonging of such zircons to mafic volcanic protolith.

II. REE patterns of zircons with magmatic inclusions show distribution similar to zircons from leucosome of garnet-free granulites (Rubatto, 2002). III. Cores of zircons from gneisses and granite-gneisses show similar REE patterns, that indicate their origin from common protolith.

The critical role of indigenous metal-reducing bacteria in mediating the mobilisation of arsenic from shallow sediments in Bengal has been widely muted, however, there remains debate over the mechanistic details of the mobilisation processes, including the relative importance of enzymatic and abiotic processes. Observing, in suitable microcosm experiments, the behaviour of trace elements with contrasting biogeochemistries might provide some further insight.

Using sediment from 20 m depth from Chakdaha Block, Nadia, West Bengal, we conducted microcosm experiments under anaerobic conditions with 15 g sediment / 30 mL synthetic model Bengali groundwater (after Islam et al., 2004) amended with sodium acetate (as a proxy electron donor) to 0, 0.1, 1 or 10 mM at an initial pH of 7.0, 20°C & 1 atm. Triplicate microcosms were sampled after 1, 3, 7, 10, 14, 22 and 29 days. Trace elements were determined by HR-ICP-MS, As speciation by IC-ICP-QMS, Fe(II) by the UV-Vis based ferrozine method and H₂ by GC-RCD.

Reduction of As(V) to As(III) was observed within 7 days, followed by the mobilisation of As, Fe and Mn and the immobilisation of U mostly within 14 days suggesting increasingly reducing conditions. Release of Mg, Ca, Sr and Ba may be due to dissolution of carbonate phases consistent with increasingly acidic conditions that would be expected. Amendment with acetate made no systematic significant difference to the rate or magnitude of As, Fe or Mn release – this is consistent with large amounts of H₂ generated during the microcosms and the presence of highly reactive organic matter within the sediments. Null results from sterile controls confirmed the overall critical role of microbes. Work is ongoing to characterise the bacterial communities and the nature of the reactive organic components in the sediments.

Magmatic processes and the evolution of crust: Insights from the New Zealand/Kermadec subduction system

It is now well established that andesitic magmas have an ultimate origin in the mantle wedge but the extent to which erupted compositions are modified through crustal interaction is still being defined. Subduction-related volcanic rocks are commonly identified by their textures and by specific trace element characteristics. The textures reflect complex crustal level processes that include assimilation and crystal fractionation (ACF) and magma mixing or mingling. Although commonly interpreted to reflect slab fluid influences, the trace element characteristics are also specific to continental crust. Detailed studies (stratigraphy, major and trace element chemistry, Sr-Nd-Pb isotopes, U-series disequilibria) of andesitic eruptive sequences in New Zealand’s North Island indicate that they represent magmas that evolved through ACF processes operating on variable time scales in complex storage and feeder systems dispersed throughout the crust. Contrasts between individual volcanoes arise because of variations in storage and feeder systems and because, in the more extreme cases, for example Ruapehu and Taranaki, both mantle sources and the crustal assimilants are compositionally different. In the Taupo Volcanic Zone, the principal locus of volcanic activity in the North Island, rhyolitic magmatism marks the onset of rapid extension and high heat flow and is preceded by andesitic volcanism. The change from andesitic to dominantly rhyolitic eruptives reflects progressive thermal evolution of the lithosphere and a shift from mantle and lower crustal dominated genetic and evolutionary processes to those dominated by crustal melting and lower pressure crystal fractionation. These processes occur in both continental and oceanic segments of the New Zealand-Kermadec system demonstrating that it is the thermal evolution of the crust rather than its thickness or composition that controls the mix of lithologies in arc-type volcanoes.
Non-hydrocarbon compounds in oil and gas accumulations: Deep influx constrained by noble gases

A. Prinzhofer, S. Dreyfus, O. Donard and E.V. Dos Santos

1IFP, Rueil-Malmaison, France (alain.prinzhofer@ifp.fr)
2UPPA, Pau, France (sebastien.dreyfus@univ-pau.fr; olivier.donard@univ-pau.fr)
3Petrobras/CENPES, Rio de Janeiro, Brazil (eugenioneto@petrobras.com.br)

Recent oil and gas exploration demands deeper drilling and more complex targets. It is clear that fluids from a sedimentary basin cannot be considered isolated anymore from deeper fluids (metamorphic zones, continental basement, mantle). This induces negative consequences (occurrence of non hydrocarbon gases contaminating the hydrocarbon accumulations as carbon dioxide and nitrogen) and potential positive ones (high concentrations of helium as an economic resource, possible extra-generation of hydrocarbon gases through non organic processes). Different natural tracers allow us to quantify the importance of such deep fluids contaminants. Among them, the chemical and isotopic compositions of associated noble gases (from helium to xenon) give evidence, according to different oil fields, of mantle contributions from 0 to almost 100%. Very recent direct measurements of lead isotopes in associated liquid hydrocarbons confirm that mantle compounds may be associated both as inert gas molecules and heavy metals chemically associated with large organic molecules.

We present two examples of mantle-contaminated petroleum systems, where the noble gas chemical and isotopic patterns indicate a clear mantle contamination. Moreover, an excess of radiogenic 4He is sometimes present, due to a leaching of crustal rocks through the migration of deeper carbon dioxide and/or nitrogen carrier gas, coming from deeper sources. This implies that the usual 3He/4He ratio, used commonly as an indicator of mantle contamination, may be useless, whereas the use of 3He, associated with other gases (CH4, CO2, N2, etc...), indicates clearly a mantle signature for deeper sources. This implies that the usual 3He/4He ratio, used commonly as an indicator of mantle contamination, may be useless, whereas the use of 3He, associated with other gases (CH4, CO2, N2, etc...), indicates clearly a mantle signature for deeper sources.

U-Th-Ra fractionation in soil horizons of forested ecosystem (Strengbach catchment, France)

J. Prunier, M.C. Pierret, F. Chabaux and M. Tremolieres

1Centre de Géochimie de la Surface, Strasbourg, France (jprunier@illite.u-strasbg.fr)
2Centre d’Écologie Végétale et d’Hydrologie, Strasbourg, France

The 238U series nuclides 238U, 234U, 230Th and 226Ra are recognized as tracers and chronometers of weathering processes. Using these tracers requires to understand the parameters and processes controlling their fractionation in soils surface horizons. In order to constrain these processes, the different compartments (soil profile, soil solutions and vegetation : wood, leaves, branches and roots of beeches) of a experimental plot, situated in the Strengbach catchment (OHGE http://ohge.u-strasbg.fr, Vosges, France) have been sampled and analysed for major-trace elements and U-Th-Ra isotopes.

The shallower horizons of the soils have highest (226Ra/230Th) and lowest (230Th/234 U) activity ratios (a.r.), respectively 1.41 and 1.12 compared to the other horizons of the soil profile. The analytical data of the different compartments of the vegetation suggest that the plants are characterized by very high (226Ra/230Th) ranging from 20 to 164 and low (230Th/234 U) ranging from 0.84 to 0.97. Based on these results, we suggest that the geochemical signatures of the soils surface horizons (<40 cm) are influenced by litter recycling which could provide 226Ra and 234U excess in these horizons.

The (226Ra/238U) a.r. of the soil solutions (1.88-4.75) are higher than those of the corresponding soils (≈ 1.5). They decrease from the top of the profile to 30 cm depth and then increase weakly until 60 cm depth. The vegetation, which is responsible of both the litter recycling and the root uptake displays very high (226Ra/238U) ranging from 100 to 300. We propose that litter recycling influences the isotopic characteristics of the shallower soil solutions. The fractionation induced by root uptake, which mainly operate between 30 and 40 cm depth, could explain the lower (226Ra/238U) in soil solutions at these depths.

Therefore U series disequilibria allow to constrain the dynamics of a soil system. Moreover, the data point to the important role of the vegetation in controlling the geochemical/isotopic signatures of the soils surface horizons and soil solutions (<30 cm) by litter recycling and root uptake.

TiO$_2$ in OIB and the preservation of extreme isotopic signatures
J. PRYTULAK AND T. ELLIOTT
Bristol Isotope Group, Department of Earth Sciences, University of Bristol, UK (J.Prytulak@bristol.ac.uk)

We have examined liquid lines of descent for a large set of ocean island basalts (OIB) using a compilation of major element data from the GEOROC database. We focus on the moderately incompatible element titanium and identify a ‘reference’ TiO$_2$ value for each OIB, to reflect approximate primitive lava compositions before significant fractional crystallization or crystal accumulation. High reference values are observed in OIB with low inferred degrees of melt lying above thick lithosphere, whereas low reference values are seen in OIB with larger inferred degrees of melt, atop thinner lithosphere. We find that the reference abundances are in most cases too high to be produced by melting of any plausible peridotitic mantle composition. Therefore, an additional Ti-rich component is required in the source of virtually all OIB. Recycled mafic crust appears to be the most geochemically consistent source for the extra Ti.

The OIB we investigated cover the full range of radiogenic isotopic mantle endmembers. Notably, OIB with low reference TiO$_2$ values plot in restricted, depleted ranges in Sr-Nd isotopic space, whereas OIB with higher reference TiO$_2$ values exhibit enriched isotopic signatures and expansive ranges in Sr and Nd isotopic ratios. Since higher reference TiO$_2$ values likely result from smaller degrees of melting, they may preserve extreme isotopic ratios. Larger degrees of melting may dilute enriched isotopic signatures. Therefore, degree of melting in OIB may be a dominant control on both the observed range of isotopic ratios and the ability to preserve extreme signatures. However, recycled crust does not generally produce extreme isotopic signatures seen in endmembers such as EMI and EMII, making other components necessary to explain the full breadth of isotopic data.

Pt-Re-Os isotope and HSE systematics of Belingwe komatiites
I.S. PUCHTEL$^1$, A.D. BRANDON$^2$, R.J. WALKER$^1$ AND E.G. NISBET$^3$

$^1$University of Maryland, College Park, MD 20740, USA (ipuchtel@geol.umd.edu, rjwalker@geol.umd.edu)
$^2$NASA Johnson Space Center, Houston, TX 77058, USA (alan.d brandon@nasa.gov)
$^3$Royal Holloway, University of London, Egham TW20 OEX, UK (e.nisbet@gl.rhul.ac.uk)

Studies of the origin and evolution of the relative and absolute abundances of the highly siderophile elements (HSE) in the mantle provide information regarding the late accretionary history of the Earth, oceanic crustal recycling, timing of melt extraction from the mantle, and possibly the mechanisms and the extent of core-mantle exchange. We present high-precision data for HSE abundances and Pt-Re-Os isotope systematics for twenty drill-core whole-rock samples and olivine and chromite separates from the ~10-m thick Tony’s komatiite flow, which is among the freshest Archean komatiites on Earth. The emplaced lava contained 24% MgO, was depleted in LILE and had εNd(T) = +2.5. Re-Os data for two whole-rock samples and corresponding mineral separates define an internal isochron with an age of 268±11 Ma and a γ$^{187}$Os(T) = 0.13±0.08. Regression of the data for all samples yields an isochron with an age of 2674±44 Ma and a γ$^{187}$Os(T) = -0.22±0.48. A single B$_2$ sample analyzed for Pt-Os has an initial 186Os/188Os = 0.119832±8 determined earlier for the contemporary Pyke Hill komatiite source. Both sources have similar ε$^{186}$Os(T) = 0.05±0.11 and 0.05±0.07, respectively, relative to the bulk solar system initial 186Os/188Os = 0.1198269. The Belingwe source, thus, evolved with long-term 186Re/188Os = 0.400±4 and Pt/0s = 1.7±0.2, which are indistinguishable from those in chondritic meteorites. The IPGEs (Os, Ir, Ru) in the whole-rock samples are strongly positively correlated with MgO identifying the Belingwe komatiite as belonging to the Munro-type flows. The PPGEs (Pd, Pt) and Re show strong negative correlations with MgO, coincident with olivine-control lines. The HSE composition of the Belingwe source was calculated from the regressions of HSE abundance data vs. MgO for the whole-rock samples and the Pt-Re-Os isotopic data. The source contained (ppb): Re 0.23, Os 2.6, Ir 2.3, Ru 5.2, and Pd and Pt 4.3. The Ru/Ir = 2.3±0.3 and Pd/Ir = 1.9±0.2 in this source are higher than those in any known groups of chondrites, but match the recent estimates for the Earth’s primitive upper mantle derived from analyses of mantle xenoliths worldwide, or the recently obtained HSE data for some lunar impact melt breccias “fingerprinting” the composition of late accreted materials to the Moon and the Earth. The new data provide further constraints on the evolution of PUM in the Archean and stimulate additional studies of the composition of materials added to the silicate Earth in the form of the “late veneer”, as well as chondritic meteorites.
Noble gases composition of palaeo Archaean atmosphere and mantle

M. PUJOL1,2, B. MARTY1, J. CAUZID2 and P. PHILIPPOT3
1CRPG-CNRS, BP 20, 54501 Vancouvre-les-Nancy, France.
2ESRF, BP 220 38043 Grenoble Cedex France.
3IPGP-CNRS, 75225 Paris cedex 5, France.

Several models of the noble gas evolution of the Archaean atmosphere-mantle exist [1, 2, 3], with implications on our understanding of the development of the early Earth and the appearance of life.

Pristine drill core samples (Pilbara Drilling Project) from the 3.525 Ga chert-barite of the Dresser Formation (North Pole, Western Australia) allowed fresh samples preserving primary fluid inclusions unaffected by surface weathering to be directly analysed using synchrotron and mass spectrometer methods. The Dresser formation has been interpreted as a shallow basin strongly affected by hydrothermalism practically during formation of the basin and prior to early diagenesis [4, 5]. This chronology permitted primary fluids from different origins (marine, hydrothermal) to be trapped within the volcanic-sedimentary sequence.

Two studies, one of intrapillow quartz pods overlying chert-barite deposits [6], and the other of the same formation but 100 m deeper, have been carried out. Synchrotron X-ray microfluorescence shows the presence of three fluid endmembers (in different proportions) in fluid inclusions in quartz. Two of them, enriched in Ba and/or Fe, are likely to originate from the hydrothermalism while the third, metal-depleted, fluid is the North Pole seawater endmember. Primary fluid inclusions from the bottom of the Dresser formation are dominated by hydrothermal fluids, which allow us to constrain the noble gases hydrothermal signature.

Inclusion-trapped fluids were analysed by mass spectrometry (using a Helix Multicollector) following extraction of the fluids by in vacuo crushing. Neon isotopes, 36Ar and 40Ar, 84Kr, 129Xe, 132Xe and 136Xe were measured in fluid inclusions and in the host matrix. The results show mixing between two fluids, confirming previous studies. The Seawater pole reveals the composition of the palaeo atmosphere thus it is possible to determine the composition of palaeo archaean mantle within the signature of hydrothermal fluid.

Constituting groundwater residence times in a fractured aquifer using noble gas isotopes

R. PURTSCHERT, A. LOVE AND U. BEYERLE
(purtschert@climate.unibe.ch; love.andrew@saugov.sa.gov.au; urs.beyerle@psi.ch)

In fractured rock aquifers, groundwater ages obtained with environmental tracers usually do not represent the hydraulic age of the water. Solutes in the water have diffusive access to the micro pores of the rock matrix and are therefore retarded compared to the water flux in the fractures. In a system of parallel fissures, the ratio between the apparent tracer age and the water age depends on the extend of diffusive penetration between the fractures and the matrix. Visa versa is the penetration depth in transient conditions a function of the groundwater residence time in the fractures (Maloszewski and Zuber, 1994). This intrinsic dilemma for groundwater dating can only be reduced by the use of multiple tracers with different decay constants and input histories. In the present study 85Kr (T 1/2: 10.76 yr, 39Ar (T 1/2: 269 yr) and 14C (T1/2: 5730 years) were used in order to constrain the groundwater residence times in a fractured aquifer in the Clare Valley Australia (Love et al., 1999). In the atmosphere 39Ar is mainly produced by cosmic ray induced 40Ar(n,2n)39Ar reactions. In this study the subsurface secular equilibrium 39Ar activity due to the 39K(n,p)39Ar reaction exceeds the atmospheric value of 1.8 mBq/L Argon (Loosli, 1983) by a factor of two. The subsurface ingrowth rate can, however, be interpreted in terms of groundwater residence time. The obtained time scales support findings from indicators of past recharge conditions. (Love and Herczeg, 2001).

U and Th deficit in primitive mantle xenoliths and the nature of core power activity

Y.D. PUSHKAREV AND L.P. NIKITINA
Institute of Precambrian Geology and Geochronology, St.-Petersburg, Russia (ydcanon@rambler.ru)

The goal of this study was to check the hypothesis according to which the core energy activity is due to radioactive decay of U and Th contained in the core. The idea of such checking consisted in the following: to identify xenoliths of the geochemically closed primitive mantle (PM) material, to determine concentration of U and Th in them and using balance calculation to estimate the content of these elements in the core which is a complementary reservoir to the PM. Original analytical data for 53 mantle xenoliths together with the numerous published data were analyzed. The material of geochemically closed PM was identified on the basis of MREE and HREE concentration, Al/Mg, Ca/Al, Mg/Si, Sr/Mg ratios and isotope composition of Pb and Os. Concentration of U (13-36 ppb) and Th (37-59 ppb) in such material is similar to that in chondrites, but lower than concentration of these elements, which would take place in silicate shell formed from chondrites after segregation of the core devoid of U and Th content. This deficiency is most distinctly apparent if to compare the U and Th concentration observed in the PM xenoliths with that in the silicate shell produced from CV-chondrites. All this allows us to assume that deficient elements of the primitive mantle are located in the liquid core complementary to it. The balance calculation showed that, according to the results obtained, the U concentration in the core corresponds to 19 ppb at initial concentration of Bulk Earth like that in Cl and 25 ppb at this initial concentration like that in CV. According to the calculations [1], such U content is high enough to generate a thermal energy from 3 up to 4.5 TW out of 7 TW attributed to the core. Taking into account that the estimated U and Th concentration in the core corresponds to the minimal value (because their content in the PM may be overestimated due to some contamination of xenoliths by hosted basalt) the hypothesis of the core power activity generated by radioactive decay of U and Th looks valid.

The study was supported by RFBR, project 07-05-00527a.

A mechanism of fluid transport through minerals

CHRISTINE V. PUTNIS1, HÅKON AUSTRHEIM2 AND ANDREW PUTNIS1
1Institut für Mineralogie, University of Münster, Germany (putnisc@uni-muenster.de)
2PGP, University of Oslo, Norway (h.o.austrheim@geo.uio.no)

Previous explanations for the movement of aqueous fluids through rocks have concentrated on the availability of pre-existing pathways, such as grain boundaries and stress fractures (Kostenko et al., 2002). Such pathways undoubtedly play a major role in allowing easy access for fluid transport. However, there is a lot of evidence that fluids migrate through minerals, which are reactive in the presence of an interfacial fluid layer (Putnis et al., 2005; Putnis and Putnis, 2007). Using time-lapse photography, fluid movement through a single crystal of a simple salt is observed at room T and P and presents a model for more complex mineral systems, showing similar textural and compositional equilibration features. The pseudomorphic replacement of one phase by another is characterised by the development of porosity in the product phase. This porosity provides the pathway for mass transport through the parent phase, which is replaced by the product at a moving interface within the mineral during an interface-coupled dissolution-reprecipitation replacement process. Replacement textures commonly occur in relation to fluid-driven regional metamorphism and large scale metasomatism e.g the gabbro - to eclogite facies transition, western Norway (John et al., 2007), serpentinitization and rodentinization of the oceanic lithosphere and scapolitization of gabbro (Austrheim et al., 2007), suggesting that dissolution-reprecipitation is an important mechanism behind large-scale metamorphic and metasomatic processes.

Global volcanic emissions of SO₂, halogens and trace metals, 1998 - 2005

DAVID M. PYLE1, GENEVIEVE A. MILLARD2, TAMSIN A. MATHER1, MELANIE WITT1 AND ROBERT J. ANDRES3

1Department of Earth Sciences, University of Oxford, Parks Road, Oxford, OX1 3PR, UK (davidp@earth.ox.ac.uk)
2Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge, CB2 3EQ, UK (gmi105@esc.cam.ac.uk)
3Department of Space Studies, University of North Dakota, USA

We have quantified annualised global volcanic emission rates based on a compilation of measurements at 60 active volcanoes, for the years 1998 – 2005. The global mean emission rate is 16 Tg SO₂/yr, of which 9 Tg/yr (56%) is emitted by non-explosive activity. Corresponding mean annualised halogen emissions are ca. 4 Tg HCl/yr; 0.3 Tg HF/yr and 0.6 Tg HBr/yr.

There is, as expected, a large interannual variability, with measured global volcanogenic SO₂ emissions varying between 13.3 Tg/yr in 1998 to 21.3 Tg/yr in 2000; most of this variability was due to sustained emissions from two persistently degassing volcanoes (Popocatepetl and Miyakejima). There were no major explosive eruptive sources (no eruptions of VEI 5 or larger; 1 eruption of VEI 4) during this period. Extrapolation to account for the un-measured emissions at a further 58 active volcanoes may extend the annual average SO₂ emission rate to ca. 20 Tg SO₂/yr for the period 1998-2005.

Using this global volcanic sulphur emissions inventory as a basis, and combined with appropriate field measurements, we can now extend the analysis to make well constrained projections of the fluxes of other important volatiles (H₂O, CO₂); volcanic nano-particles, and volatile trace metals (e.g. Hg) to the troposphere, and thereby evaluate the importance of persistent volcanic degassing to global geochemical budgets. Considerable uncertainty remains over the trace gas and trace metal emissions to the stratosphere associated with explosive volcanic eruptions, due to a lack of appropriate measurements.

Geochemistry and genesis of the Qibaoshan gold-copper deposit in Shandong Province, eastern China

JIAN-SHENG QIU, SHAO-YONG JIANG AND XI-SHENG XU
State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, China (jsqiu@nju.edu.cn)

The Qibaoshan is a medium-sized Cu-Au deposit located in a caldera near the east of Yishu deep fault zone. This deposit consists of two parts, the upper part is a gold-containing breccia pipe, and the lower part is a copper-bearing stockwork.

The caldera covers an area of 10-12 km² and rocks around it are distributed in ring shape. The inner ring consists of subvolcanics, such as pyroxene monzonite, quartz monzonite porphyry, and trachyandesite porphyry; the outer ring comprises predominantly of trachyte, trachyandesite and minor rhyolite. In southeast of the central intrusive body, there is a cryptoexplosive breccia pipe which develops gold and copper mineralization.

Mineral association of this deposit displays a clear vertical zoning, i.e., from 0 to -20 m, the dominant mineral is gold-bearing specularite; main minerals are commonly specularite, manganosiderite, quartz and minor amounts of pyrite and chalcopyrite from -20 to -70 m; and pyrite and chalcopyrite from -70 to -120 m. Wall-rock alteration is widespread in the ore district. Main alteration types are phyllic alteration, silicification and carbonatization, and in the deep part of the pipe there also develops potassic alteration.

Fluid inclusion studies show that the homogenization temperatures range predominantly from 250°C to 350°C. The estimated salinities of ore-forming fluids vary between 10.6 and 32.6 wt% equiv. NaCl. The main compositions of ore-forming solutions are characterized by enriched in Ca²⁺, Na⁺, Cl⁻ and depleted in Mg²⁺, K⁺, F⁻. The F⁻/Cl⁻ ratios of hydrothermal fluids increased obviously from the main mineralization stage to late mineralization stage, indicating that the ore materials were transported predominantly as chloride complexes.

The δ³⁴S values of sulfides vary between 0.30‰ and 3.59‰, with a δ³⁴SΣS value of 2.80‰. Overall, the H, O and S isotopic data suggest that the ore-forming fluids and materials might be originated mainly from magmatic source.

Hydrous and anhydrous metal formates – Properties and applications

B. RAAB AND H. PÖLLMANN
Martin-Luther-University Halle-Wittenberg,
Mineralogy/Geochemistry, Von-Seckendorff-Platz 3,
Germany (bastian.raab@geo.uni-halle.de)

Synthesis and Results
The metal formate hydrates are synthesized by reaction of metalcarbonate, metalhydroxide or metaloxide and formic acid in an aqueous solution. The crystallisation process takes place at a temperature of 20°C.
The characterisation of the crystals was done by X-ray diffraction, thermogravimetry, scanning electron microscopy and Karl-Fischer-titration.

Figure 1: SEM image of Cu(HCOO)₂, dehydrated from Cu(HCOO)₂·4H₂O at 20°C and the crystal structure

Discussion
It is important to investigate the crystallographic properties of the formate and their stability to investigate in further experiments the effect on acceleration and retardation of formates as admixture in Ordinary Portland Cement. In addition, we investigate the dehydration and decomposition of the metal formate to produce particles in nanometer size. The metal carboxylate are suitable because of their low decomposition temperatures.

Conclusion
By using the crystallographic information of hydrous and anhydrous metal formates, theoretical predictions for applications are be obtained.

Molecular dynamics simulations of fission track annealing in apatite

JEREMY A.L. RABONE¹ AND NORA H. DE LEEUW²
¹School of Crystallography, Birkbeck College, Malet Street, London WC1E 7HX (j.rabone@mail.cryst.bbk.ac.uk)
²Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ (n.h.deleeuw@ucl.ac.uk)

Our aim is to use molecular dynamics simulations to elucidate how the composition of apatite minerals Ca₁₀(PO₄)₆(F,Cl,OH)₂ affects the annealing rate of the natural fission tracks, which form in the apatites as a result of the spontaneous fission of uranium. Knowledge of the effects that the many species present in natural apatites, particularly fluoride, chloride and hydroxide, have on the annealing rate is invaluable in interpreting accurately the results of fission track data for geothermochronometry.
The fission tracks formed by uranium fission in apatite are typically 14 µm long and 50 Å in diameter. The formation of tracks in apatite can be adequately modelled using a method where atom velocities are altered perpendicular to the track, which model produces tracks which are consistent with those observed experimentally.
The simulations show that the diameters of tracks formed in two crystal directions are similar for a series of six apatites of different composition. In pure chlorapatite the simulated tracks are somewhat larger in both crystal directions, whereas in fluoride-bearing apatites small clusters of calcium fluoride are consistently formed in the track region.

Figure 1: Disrupted atoms looking down a fission track.
The apparent activation energy for biotite dissolution by in situ Atomic force microscopy (AFM) observations

K.V. RAGNARSDOTTIR\textsuperscript{1}, S.J. HAWARD\textsuperscript{1,2}, AND T.J. MCMASTER\textsuperscript{2}

\textsuperscript{1}Department of Earth Sciences, University of Bristol, Bristol, UK. (Vala.Ragnarsdottir@bristol.ac.uk)
\textsuperscript{2}H.H.Wills Physics Department, University of Bristol, Bristol, UK. (S.J.Haward@bristol.ac.uk, T.McMaster@bristol.ac.uk)

In this study we used in situ AFM imaging of biotite (001) surfaces to observe dissolution processes in oxalic acid and hydrochloric acid solutions in real time. In oxalic acid solutions at pH 2 and 1 we observe the combined dissolution processes of slow etch pit formation, followed by relatively fast etch pit growth. The etch pit depth is found to be consistent with the thickness of 1 \textit{tot} layer (~1 nm). Measurements of the fractional surface area covered by etch pits over time provide dissolution rates in the acid solutions. Experiments over a range of temperature, 10°C < T < 35 °C, in the pH 1 solution allow an estimate of the apparent activation energy, $E_a = 49 \pm 2 \text{ kJmol}^{-1}$ using the Arrhenius equation. We find that the average radius of etch pits grows linearly with time for all T, and use these growth rates to obtain a second value of $E_a = 53 \pm 3 \text{ kJmol}^{-1}$. We also find a linear relationship between the dissolution rate and the density of step edges on the surface for all values of T. However, $E_a$ is found to vary between ~ 40 kJmol\textsuperscript{-1} and >100 kJmol\textsuperscript{-1} at low and high step density, respectively. This variation may reflect the greater energy required for etch pit formation compared with etch pit growth. In an HCl solution of pH 1 we do not observe the formation of discrete etch pits, but a more general degradation over the entire biotite (001) surface. We conclude that etch pit occurrence in the oxalic acid solution proceeds through chelation of aluminium ions in the (001) surface by the oxalate ligand. This may destabilize the silicate structure, leading to the removal of the entire \textit{tot} layer, as observed. In the HCl solution the aluminium cations are less soluble due to the lack of organic ligand so the silicate structure remains intact.

Metal silicate partitioning of Ge, Mo, Ga and P: Constraints on core formation

N. RAI, M.J. WALTER, AND C.J. HAWKESWORTH

Dept. of Earth Sciences, University of Bristol, U.K. BS8 1RJ; (n.ra@bris.ac.uk)

Siderophile element signatures in Earth’s mantle are a result of segregation of the iron rich core from the silicate mantle. It is generally argued that during the metal silicate differentiation process these elements were substantially partitioned into the core leaving behind lithophile elements in the silicate mantle. Several core formation models have been proposed to account for the observed abundance of elements in mantle rocks. A recently proposed model [1] suggests that the core formed at the base of a magma ocean which deepened with accretion and in which conditions became more oxidising with time. This also accounts for 5-7% Si in the core.

To test this hypothesis of early reducing magma ocean [1] we are studying the metal silicate partitioning behaviour of selected siderophile and nominally lithophile elements, characterizing the dependence of the metal silicate partition coefficient, D, on oxygen fugacity. We report new experimental results on the partitioning behaviour of Ga, Ge, Mo and P, and these are compared with our previous work on Si, Ta, Nb and V. All these elements can exist in variable and high oxidation states and their partitioning could also be sensitive to silicate melt composition [2]. Experiments were made at 2 GPa and 2000 K, over a range of relative oxygen fugacities from ~IW-2 to IW-6. Silicate melts range from basaltic to peridotitic in composition. The melt compositional parameter, NBO/T, is used as a proxy for silicate melt composition, and has values from 0.7 to 4. Isobaric, isothermal data for each element were regressed using the equation:

$\ln D_{\text{met/sil}} = a + b fO_2 + c(NBO/T)$. 

Regressions show that at the experimental conditions Ge has a likely valence state of +2, Ga, Nb and V exist in 3+ valence states, Si shows a valence state of +4, whereas P and Ta appear to exist in a 5+ valence state. Observing the partitioning behaviour of these elements over the redox range investigated, Si exhibits the least siderophile tendency and it appears unlikely for 5-7% Si to sequester into the core under reducing conditions without disturbing the mantle’s budget of other siderophile and refractory lithophile elements. Further experiments are in progress to provide more constraints on the influence of fO\textsubscript{2} and melt composition on the metal silicate partitioning of these elements.

Chemical stratigraphy of UG2, Bushveld Complex, SA: Comparison of analytical methods

D. Rammlmaier, B. Harazim, H. Lorenz, J. Stummeyer and F. Korte

BGR, Stilleweg 2, 30655 Hannover, Germany; (rammlmair@bgr.de)

The aim of the detailed investigation was to develop and to validate the EDXRF method as a fast tool to outline zones of interest regarding PGE, Ni and Cu mineralization by using these and other pathfinder elements.

Several methods were applied to obtain geochemical, mineralogical and textural information from UG2-chromitite horizons.

The fastest information was obtained by profiles along half cores using the EDXRF-geoscanner with 250µm steps at 1 to 30 sec/point for major and trace elements. Elemental maps were collected by EDXRF-microscopy in 100µm steps, at 0.5 sec/step for selected areas. Polished thin sections were optically scanned, and investigated by SEM for PGE distribution. Besides these fast methods sub-samples (0.5 to 5 cm) with a more representative sample volume were analyzed by XRF for major and trace elements. The XRF glass beads were digested and analyzed by ICP-MS for REE. Another set of glass beads was produced in graphite containers, embedded in araldite, polished and analyzed for PGE by LA-ICP_MS. For control, the rest of the glass beads was digested in nitric acid and PGE were collected by the telluride precipitation method (Evans et al., 2003). Since our observation with SEM confirmed that most of the PGE minerals occur in the interstices of the chromite, selective leaching of the PGE and silicates by nitric acid in the microwave was performed.

Conclusions
A comparison of the methods shows that EDXRF-scanning is a fast and accurate tool to highlight areas of unusual Ni, Cu, PGE pattern. EDXRF mapping provides textural patterns for hand specimen scale and reduces the amount of polished sections needed. Ni, Cu anomalies could easily be verified by other methods (e.g. SEM). PGE distribution patterns have to be treated carefully, since nugget effects might occur or diffraction peaks obliterate the distribution pattern.

Lithogeochemistry of parautochthonous Variscan metasediments (Northern Portugal). Implications of metamorphism and metassomatism

R. Ramos and M. A. Ribeiro

Centro de Geologia, Departamento de Geologia, Univ. do Porto, Rua do Campo Alegre,687, 4169 - 007 Porto, Portugal (ramos@fc.up.pt; maribeir@fc.up.pt)

The studied metasedimentary rocks, belonging to different lithostratigraphic units, are inserted in the lower Parautochthonous of Galiza Trás-os-Montes Zone (2GTM), in Northern Portugal Variscan belt. The studied area involve two geographic sectors separated by the Regua-Verin fault. In the western block of the fault the metasedimentary rocks are intruded by abundant pegmatite-aplite bodies and quartz veins and show higher metamorphic conditions: staurolite to biotite zone. In the western block the metamorphic condition are biotite to chlorite zone.

The metasedimentary lithologies are mainly phyllite and quartz-phyllite rocks in an imbricate structure. Lithogeochemical studies revealed a slow sedimentary sorting and high geochemical maturity in both sectors. The Th/Sc versus Zr ratios indicates, for the two sectors, a geotectonic environment ranging from an Active Continental Margin (ACM) to a Continental Insular Arc (CIA).

The normalization to upper continental crust (UCC) diagrams showed that similar lithologies present geochemical variations according to their proximity to the pegmatite-aplite veins. Next to the veins a deficit in mobile elements in fluid phases are evident, namely in, Rb, U, Th.

Figure 1: Crustal normalization of samples near and far from pegmatite-aplite veins.

So, the lithologies next to the aplite-pegmatites had been affected by fluid circulation (metassomatic effects) in a high temperature and low pressure (HT-LP) metamorphic conditions, while the lithologies in the both sectors, far from these intrusive bodies, present a isochemical metamorphism.
Nd isotope is a powerful indicator tracing the provenances of eolian materials [1]. However, Nd isotopic characteristics of different particle sizes of eolian materials are unknown in detail yet. We report here $\varepsilon_{\text{Nd}}(0)$ values in different grain sizes of eolian dust in the Duanjiapo section of Chinese Loess Plateau and eolian sand in the Mu Us Desert (Table 1 and Fig.1).

<table>

<td>-8.7</td>
<td>-8.6</td>
</tr>
</tbody>
</table>

Table 1 $\varepsilon_{\text{Nd}}(0)$ in different grain sizes ($\mu$m) of eolian dust

Eolian dust in the Duanjiapo section is fine, mostly <75$\mu$m, whereas the Mu Us desert sand is coarse, mainly >75$\mu$m in diameter. $\varepsilon_{\text{Nd}}(0)$ values change little with grain sizes of eolian dust, moreover, are similar among loess, paleosol and red-clay (Table 1), suggesting a uniform source region. But, different grain size fractions of desert sand have obviously different $\varepsilon_{\text{Nd}}(0)$ values (Fig.1), implying they have different provenances. In addition, $\varepsilon_{\text{Nd}}(0)$ values of different grain-size fractions of desert sand are all more negative than those of eolian dust in the Duanjiapo section, showing the Mu Us desert is not its main source region.

As a result, the Mu Us desert sand is distinct in Nd isotope from eolian dust in the Duanjiapo section, both are probably little related in provenance.

Coupling crushing and laser ablation in submarine glasses provide new constraints on noble gases composition of Earth’s mantle

A. RAQUIN1, M. MOREIRA1 AND M.D. KURZ2

1Equipe de Geochimie et Cosmochimie, Institut de Physique du Globe de Paris, 4 place Jussieu, F75005 Paris, France: (raquin@ipgp.jussieu.fr)

2Department of Marine Chemistry and Geochemistry. Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, United States

Rare gases released with traditional experimental procedures in mantle-derived rocks generally display mixing trends between a mantle and an atmospheric component. The origin of atmospheric contamination is still debated and is interpreted to result from surface contamination or recycling in the mantle.

In order to examine this problem, we analyzed noble gases in single vesicles in submarine glasses, because it gives the possibility to look at the end members. Here, we compare data obtained by crushing and by measurement of in single vesicles using a laser UV ablation system on two samples: 2πD43, considered to be representative of upper mantle volatiles from the northern MAR, and one from the western Galapagos, which appears to sample one of the most primitive mantle noble gas reservoirs.

Helium isotopic ratios in single vesicles are constant for both MORB and OIB sample with a mean values of 90,500±3,500 and 32,000±1,000, respectively. The systematic Ne-Ar in single vesicles of sample 2πD43 indicates that there is only one population of vesicles, with a mantle composition (the mean value of 40Ar/36Ar is 25,000±4,000 and is associated to a 20Ne/22Ne of 11.5±0.6). This lower 20Ne/22Ne ratio compared to those measured by crushing can be explained with a small contribution of gases, with an air-like composition, dissolved in the matrix. We conclude that isotope variations observed by crushing are due to superficial contamination.

In contrast, analyses from individual vesicles of the Galapagos sample show heterogeneities on the scale of individual vesicles (40Ar/36Ar ratio vary from 3,000±500 up to 7,500±300 and being associated to a 20Ne/22Ne from 10.3±0.5 to 11.9±0.3). Such high 40Ar/36Ar values are not observed during crushing.

Application of statistical methods in geochemical anomalies identification, Baidjan area, North of IRAN

IRAJ RASA1, SOMAYE BOKHARAEI2 AND MOHAMMAD HADI NEZAMPOUR3

1Earth Sciences Faculty, Shahid Beheshti University, Tehran, Iran. (i-rasa@sbu.ac.ir)

2Sciences Faculti, North Tehran Azad University, Tehran, Iran. (S_bojarai@yahoo.com)

3Earth Sciences Faculty, Shahid Beheshti University, Tehran, Hadi.(nezampour@gmail.com)

Methods

Baidjan Exploration Area is situated in the South of Amol, North of Iran, Whose total surface area is 140 km². A total of 264 samples of the fine grained fraction of active stream sediments were collected and were analysed by ICP-MS method. Chemical variable after replaced censored data and normalized on the base of upper stream rock unit processed and mapped by means of R_mode factor, K¬_Means Cluster and Scatter plat methods.

Discussion and result

In these ways were determined three anomaly area in north, centre and west of exploration area. In the north and most important promise point, anomalies at the local scale were identified for Au (up to 37 ppb) and As (95.4 ppm). In this anomaly area, the correlation between these threshold values and silisified carbonate or carbonate hosted silisic veins is clearly shown. The second anomaly point, in central of exploration area, anomalies at a local scale were identified for Ag (up to 3 ppm), Sb (up to 5.6 ppm), Bi (up to 2.2 ppm), Zn (up to 231 ppm) and Cu (up to 72.8 ppm). This anomaly reflected mainly a local distribution of the outcropping rock type, mainly silisified andesit and basalt that malachite and azurite in the silisic zone or veins clearly shown. The west anomaly shown threshold obtained for REE, especially Ce (up to 541 ppm) and La (up to 104 ppm) and Cu (up to 70 ppm). This anomaly was correlated to altered Eocene tuffite.

Conclusion

The high grade of Ce, La and relatively Au, Cu and Zn and association with favourable geological phenomena, ambient needing further validation, gave some indicative references to the economic potential of this area for these elements mineralization.

Detection of hydrocarbon micro-seepage using geo-microbiological method: A case study from Deccan Syncline, Maharashtra, India

M.A. RASHEED, D.J. PATIL AND A.M. DAYAL
Stable Isotope and Surface Geochemical Prospecting Lab. National Geophysical Research Institute, Hyderabad, India. (rasheedmicro@rediffmail.com)

Geo-microbial method for hydrocarbon exploration is the search for surface microseeps as clue to the presence of an active petroleum system and / or to the location of possible oil and gas accumulation. It is a surface prospecting technique used to detect the anomalous population of hydrocarbon oxidizing bacteria in the surface soils, which indicate the presence of subsurface oil and gas accumulations. This method is based on vertical seepage of light hydrocarbon gases (C_1 - C_4) from the oil and gas pools to the shallow surface, and are utilized by hydrocarbon oxidizing bacteria. These bacteria utilize hydrocarbon gases as their only food source and are found enriched in the near surface soils above the hydrocarbon bearing structures. These hydrocarbon-oxidizing bacteria used as indicators of invisible hydrocarbon microseepage, and are used to evaluate subsurface hydrocarbon potential. Microbial activity profiles have indicated a good contrast between oil producing and non-oil producing areas.

This paper presents geo-microbial study carried out in Deccan Syncline areas of Maharashtra. In the present study, propane-oxidizing bacteria were considered as indicator microbes as propane gas originates from petroleum pools only. Sub-surface soil samples were collected aseptically in an interval of 5 x 5 km, and analyzed for propane oxidizing bacterial concentration. The propane oxidizing bacterial count in the soil samples of the studied area ranged from 1 x 10^2 to 6.7 x 10^5 cfu/gm of soil sample. Two microbial blooms of high concentration of propane oxidizing bacteria were identified and mapped in the study area. Microbial prospecting method has emerged as an important tool for hydrocarbon prospecting and integration of microbial data along with geological, geophysical, and geochemical data, can lead to the successful grading of exploration leads and prospects. The success rate of Microbial Prospecting for Oil and Gas is upto 90% (Wagner et al., 2002). The paper presents the details of microbial prospecting methodology developed at National Geophysical Research Institute and its importance in hydrocarbon exploration.

Evidence for the collapse of upper water masses during ice-rafting events: a multi-species planktonic foraminiferal δ^{18}O approach

H. RASHID, S. LODESTRO, B FLOWER AND T. QUINN (hrashid@marine.usf.edu)

We have measured δ^{18}O in three planktonic foraminiferal taxa Neogloboquadrina pachyderma (s), Globigerina bulloides, Globigerinoides ruber and benthic foraminifera Cibicidoides wuellerstorfi from IODP Site U1313. Concentration of the ice-rafted debris (IRD) and benthic foraminiferal assemblages were also counted. We found similar δ^{18}O values from mixed-layer and thermocline-dwelling planktonic foraminifera during the large amplitude IRD-events suggesting the collapse of upper water masses. This data suggests that the planktonic foraminifera taxa calcified their shells at similar temperatures in a homogenized upper water column. Similar collapse can be seen from the northern margin of the IRD-belt, implying that this homogenization of water masses were widespread in the region. We suggest that an increase in storminess during large IRD event intensifies vertical mixing of meltwater from ice-rafting in the upper ocean. Lighter δ^{13}C values correspond to those large IRD-events suggesting coupled perturbation of both surface and deep waters at the subtropical latitude.
Trace elements fractionation in Ca-rich and Ca-poor alkaline-ultrabasic series

I.T. RASS
Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry, Russian Academy of Sciences, Moscow, Russia (rass@igem.ru)

Two separate coexisting series, high-Ca melilite-bearing rocks and more common melilite-free alkaline-ultrabasic rocks, compose the alkaline-ultrabasic association in carbonatite massifs of Maimecha-Kotui Province, NW Siberian Platform [1]. Two analogous series are now known also in other complexes.

The trace element distributions (XRF and ICP data) in the above rocks, comparable in differential degree, from the different massifs, are clearly different. Their logarithmic relations in the sequential derivatives of the series, resulted due to fractionation according to the Rayleigh model, with different partition coefficients; then quite different rock-forming and trace element contents and their zoning patterns in coexisting minerals (EPMA data), dependent on their affiliation to the above series; as well as recent results of melt inclusion investigation in olivine of melilite-bearing rocks from the Guli and Kaiserstuhl complexes, suggest that two parent primary magmas do exist. The separate primitive magma, essentially richer in Ca, was preliminary carbonatised and enriched in Sr, REE, and Nb. Ca-poor magma can fractionate during its ascent from great depths. In turn, primary magma with higher Ca, parent for melilite-bearing rocks, fractionates only at shallower depths where CO₂ activity is lower and oxygen fugacity during crystallization of the melilite-bearing rocks is higher, as compared with conditions during differentiation of Ca-poor magma.

Orbital Forcing, Timescales, and the Pacing of Global Glaciations

MAUREEN E. RAYMO¹, LORRAINE LISIEcki¹,KENJI KAWAMURA² AND BEN COSTANZA¹

¹Dept. of Earth Sciences, Boston U., 685 Commonwealth Ave., Boston, MA 02215 USA (raymo@bu.edu, lisiecki@bu.edu, costanza@bu.edu)
²National Inst. of Polar Research, 1-9-10 Kaga, Itabashi-ku, Tokyo 173-8515, JAPAN (kawamura@nipr.ac.jp)

Not long after Hays et al. (1976) proved that orbital variations control climate, the technique of using orbital pacing inherent in climate proxy records to improve geologic time scales was developed. Orbital-tuning of marine or terrestrial records requires assumptions about what specific component of insolation is forcing (usually indirectly) the climate proxy, as well as the magnitude of the lag between this forcing and the climate proxy. Despite these uncertainties, the time scales developed resulted in a significant improvement over paleomagnetic time scales and even led to a reassessment of the errors inherent in radiometric dating techniques. Recently, the orbital tuning of the O₂/N₂ ratio of trapped air in Antarctic ice cores (e.g. Kawamura et al., submitted) is based on a direct physical link between local summer solstice radiation and ice metamorphism; this new method may prove to be a gold standard for orbital tuning as well as make the essential point that not all orbital tuning is equally uncertain.

The extension of ice core records into the early Pleistocene, combined with O₂/N₂ time scales, should allow assessment of one of the major drawbacks of the marine δ¹⁸O record; namely, that it does not speak to where, geographically, the ice volume component of climate variance originates. Since the development of the δ¹⁸O proxy the general assumption has been that the ice volume signal of the last 3 Ma originated almost entirely in the Northern Hemisphere with little variance contributed by the Southern Hemisphere. By contrast, we have recently proposed (Raymo et al., 2006) that from ~3 to 1 Ma a terrestrial ice margin sensitive to local summer insolation may have characterized much of the East Antarctic ice sheet. Because Earth’s orbital precession is out of phase between hemispheres while obliquity is in phase, 23 kyr changes in ice volume in each hemisphere would cancel in globally integrated proxies such as ocean δ¹⁸O or sea level leaving the in-phase obliquity (41-kyr) component of insolation to dominate the record. To test this idea for the origin of the 41-kyr world, well-dated proxy records sensitive to local climate and the lateral movement of ice margins (in both the NH and SH) are needed. Would such records show precessional and obliquity pacing?

238U- and 232Th-decay series constraints on the timescales of generation and degassing for phonolite erupted in 2004 near Tristan da Cunha

M.K. REAGAN1, S. TURNER2, M. LEGG1, K.W.W. SIMS3, and V. L. HARDS4

1U. Iowa, Iowa City, IA, USA, (mark-reagan@uiowa.edu)

3WHOI, Woods Hole, MA, USA, (ksims@whoi.edu)
4British Geological Survey, UK, (vicky@mvo.ms)

Phonolite pumice found floating offshore of Tristan da Cunha following intense seismic activity 20 to 30 km southeast of the island July 29-30, 2004 was analyzed for 238U- and 232Th-series nuclides including 230Th, 226Ra, 210Pb, 210Po, and 228Th. The initial (210Po/210Pb) value of 0.16 for the phonolite shows that, like most subaerial lavas, this subaqueous tephra degassed most of its 210Po upon eruption. The (230Th/232Th) and (238U/232Th) values for the phonolite are similar to those of more mafic magmas from Tristan da Cunha. However, in contrast with trachyandesites erupted in 1961 from Tristan da Cunha (Oversby and Gast, 1968), the activities of 210Pb and 230Th are both strongly enriched with respect to 226Ra in the phonolite, which is likely due to 226Ra partitioning into feldspars and hornblende in the decades leading to eruption. Moreover, the initial (230Th)/232Th) value was 0.94±0.03 (1σ), suggesting that Ra was being fractionated from Th until just before eruption. The (230Th/232Th) and (238U/232Th) values for the phonolite are similar to those of more mafic magmas from Tristan da Cunha. However, in contrast with trachyandesites erupted in 1961 from Tristan da Cunha (Oversby and Gast, 1968), the activities of 210Pb and 230Th are both strongly enriched with respect to 226Ra in the phonolite, which is likely due to 226Ra partitioning into feldspars and hornblende in the decades leading to eruption. Moreover, the initial (230Th/232Th) value was 0.94±0.03 (1σ), suggesting that Ra was being fractionated from Th until just before eruption. These disequilibria were modeled to have resulted from continuous crystal fractionation for about 2 centuries assuming that the fractionation began with a 1961-like trachyandesite and involved hornblende, anorthoclase, apatite, and sphene. The implied fractionation rates are 2-3×10⁻³ y⁻¹, which are one to several orders of magnitude faster than has been calculated for most other magmas. Nevertheless, these rates are similar to those calculated for the relatively low volume (0.1 km³) trachyte erupted from Fogo in 1563 (Snyder et al., 2007). These data imply that the 2004 magma was not the differentiated cap of a much larger magma body that remained at depth. Instead, it was likely the residue of a relatively small magma body that migrated rapidly through the crust southeast of Tristan da Cunha and underwent extensive and rapid crystal fractionation.

Carbon isotopes vs temperature: Contact metamorphism in graphitic metapelites at western Venezuela

K. REATEGUI, M. MARTÍNEZ, W. MELÉNDEZ AND S. MARRERO

Centro de Geocquímica, Instituto de Ciencias de la Tierra, Facultad de Ciencias, Universidad Central de Venezuela. Apartado Postal 3895, Caracas 1010 A (katya_reategui@ciens.ucv.ve)

Isotopic characterization of graphitic materials associated with the metamorphic aureole of the La Soledad Granite and the non-carbonatic phyllites of Cerro Azul Association, at western Venezuela, was used to evaluate the correlation between the variations in δ¹³C with the progress of the metamorphic process.

Raman spectroscopy was used to evaluate the graphite crystallinity and the maximum metamorphic temperature reached. Additionally, petrographic determination was also applied in this work. The mineralogical assemblage and the presence of andalusite mineral indicated an intermediate metamorphism.

The intrusion process produced, at the contact zone, an increase of δ¹³C (from -28.3 to -27.5‰) which could be linked with the temperature gradient and hydrothermal fluid action. Isotopic signals showed greater dispersion in zones closer were higher hydrothermal activity was present. However, isotopic data cannot be employed in the evaluation of the metamorphic grade of the rock, because no correlation was found with the calculated temperature derived from spectroscopic parameters (528 to 510 ± 16 °C ). Just a weak correlation with %C (0.4 – 2 %C) in the bulk rock was observed, demonstrating that other aditional factors than kinetic ones could be involved.

Several parameters are affecting %C and δ¹³C in the studied zone, these are: a) temperature; b) composition of hydrothermal fluids and c) the reactions between hydrothermal fluid with the mineral assemblage present in the the rock, as well as with graphite. Results allow us to infer that, for this type of geological environment, isotopic signature of graphite must not be employed as geothermometer.

The riverine fluxes of N and P have been significantly increased by human activities, while the anthropogenic input of Si to the Scheldt estuary is considered to be negligible. This excess delivery of N and P compared to Si has affected the phytoplankton speciation and succession in the Belgian coastal zone. The regeneration and retention of Si in the estuary, and particularly in the sedimentary column, is still poorly known. During the year of 2004, surface sediments and cores were collected along the Scheldt continuum. Dissolution kinetics of biogenic silica (BSi) was carried out in batch reactors for several months on sediments from different locations and depths, and the effect of salinity on the dissolution rate was investigated. Preliminary results show that the salinity effect is stronger for low salinity values, but becomes negligible for higher values. Our results also exhibit high BSi dissolution rates in the second centimetre of the sediments cores, with lower values in the first centimetre but also at depth. These results are coherent with the BSi profiles, as well as the microscopic observations of the sediments that showed a higher abundance of biogenic opal debris in the second centimetre with respect to the first centimetre. A model taking into account a two-phase dissolution was used to fit the experimental data, the two phases considered corresponding to biogenic and lithogenic silica, respectively. Overall, the dissolution rates are low and the amorphous silica saturation concentration is never reached, suggesting that the recycling of the biogenic material in the sedimentary column is very low. Part of the opal reaching the sediments probably dissolves at the surface, while the rest is rapidly incorporated within the sedimentary column where dissolution continues along with other diagenetic reactions.

Controlling and predicting subsurface calcium carbonate precipitation for capture of inorganic contaminants

G. Redden¹, Y. Fujita¹, Yi-Lin Fang², T.D. Scheibe², A.M. Tartakovsky², M. Beig³ and R.W. Smith³

¹Idaho National Laboratory
²Pacific Northwest National Laboratory
³University of Idaho at Idaho Falls

In situ manipulation of biogeochemical conditions to induce the formation of mineral phases is one approach for immobilizing metal contaminants in subsurface environments. Examples include U and Tc bioreduction, engineered precipitation of U phosphate minerals, and microbially facilitated coprecipitation of ⁹⁰Sr in calcite. Strategies for controlling the formation and distribution of precipitated minerals usually require introduction of soluble chemical amendments to the subsurface. The challenges involve not only controlling the distribution of amendments and resulting reactions, but also predicting how permeability and flowpaths evolve as solid phases are deposited (including biomass). The changing flowpaths and geochemical environment will impact the propagation of solid phases and contaminant mobility. Computational models that can account for the scale-dependent coupling between physical, chemical and biological processes over a range of spatial and temporal scales are not well developed.

Experiments in 2- and 3-dimensional packed-sand media have been conducted where calcium carbonate precipitation and co-precipitation of Sr²⁺ is induced by one of two mechanisms. The first is by propagating calcium carbonate precipitates within the fluid-fluid mixing zone between two solutions that flow in parallel. The second approach involves in situ generation of carbonate, in the presence of dissolved calcium, by enzyme catalysed hydrolysis of urea. This is an analog for a natural biological process. In both cases, within the reaction zone, a wide range of saturation indices and ion ratios can be established at the pore scale depending on the relative rates of solute transport, mixing, and precipitation. Multiple precipitation modes (e.g., homogeneous and heterogeneous nucleation and growth), different carbonate phases, and varying morphologies can occur in close proximity. The thermodynamic, kinetic and physical control of precipitate deposition influences Sr partitioning in the porous media, as well as permeability and flow paths in the porous media.

We have simulated solute mixing and flow modifications at the pore scale using the Smoothed Particle Hydrodynamics (SPH) method. Continuum-scale simulations of the experimental results were also conducted using grid-based methods. A goal is to use SPH simulations as the basis for parameterization of macroscopic finite-element multi-component reactive transport models, correlating results from the two model scales with our experimental results.
Rapid hydrogen isotopic exchange between aqueous hydrocarbons and water under hydrothermal conditions

E. Reeves¹, J. S. Seewald², S. Sylva³

¹MIT/WHOI Joint Program, Woods Hole Oceanographic Institution, Woods Hole, MA (reeves@whoi.edu)
²Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution

Numerous experimental studies have investigated D/H isotopic exchange between sedimentary organic matter (e.g., kerogen/oil) and ambient water during thermal maturation (Schimmelmann et al., 2006). However, isotopic exchange involving low molecular weight hydrocarbons and water has revealed relatively little attention. Due to its high activation energy for exchange, alkyl-bound hydrogen (H) is widely considered to be isotopically conservative and incorporation of water-derived H is assumed to be limited to cracking reactions during catagenesis.

We conducted experiments to investigate D/H exchange between aqueous n-alkanes and water using a flexible cell hydrothermal apparatus. C₃–C₅ n-alkanes were heated at 325°C and 350 bar in aqueous solutions of varying initial D/H ratio (δD) in the presence of a pyrite-pyrrhotite-redox buffer. Extensive incorporation of water-derived H into C₂–C₅ n-alkanes was observed on timescales of months. In contrast, relatively little incorporation was observed for CH₄. Isotopic exchange observed on timescales of months in reducing aqueous environments, reaction mechanisms exist involving low molecular weight hydrocarbons and water has received relatively little attention. Due to its high activation energy for exchange, alkyl-bound hydrogen (H) is widely considered to be isotopically conservative and incorporation of water-derived H is assumed to be limited to cracking reactions during catagenesis.

We conducted experiments to investigate D/H exchange between aqueous n-alkanes and water using a Au-TiO₂ flexible cell hydrothermal apparatus. C₁–C₅ n-alkanes were heated at 325°C and 350 bar in aqueous solutions of varying initial D/H ratio (δD) in the presence of a pyrite-pyrrhotite-redox buffer. Extensive incorporation of water-derived H into C₂–C₅ n-alkanes was observed on timescales of months. In contrast, relatively minor incorporation was observed for CH₄. Isotopic exchange appears to be facilitated by reversible equilibration of n-alkanes and their corresponding alkynes by the reaction:

\[ \text{C}_n\text{H}_{2n}(aq) = \text{C}_n\text{H}_{2n-2}(aq) + \text{H}_2(aq) \]  (1)

Where H₂(aq) is derived from water. The lack of substantial n-alkane decomposition on the timescale of observation, combined with an approach to steady-state isotopic composition, suggests that n-alkane δD values may reflect an approach to isotopic equilibrium rather than kinetically-controlled fractionation effects associated with degradation reactions. Substantially lower amounts of exchange were observed for ethane relative to C₃–C₅ n-alkanes, suggesting that alkene isomerization may enhance incorporation of water-derived H in these compounds. Thus, in reducing aqueous environments, reaction mechanisms exist that allow rapid D/H exchange of alkyl-H with water at elevated temperatures and pressures on timescales much shorter than previously assumed.

Nickel isotope anomalies in iron and chondritic meteorites

MARCEL REGELOUS¹,², TIM ELLIOTT², AND CHRISTOPHER D. COATH²

¹Department of Geology, Royal Holloway University of London, Egham, Surrey, U.K.
²Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol, U.K.

⁶⁰Fe decays to ⁶⁰Ni with a half-life of 1.49 Ma, and can be used to obtain relative ages for meteorites and processes that occurred within the first ~10 Ma of the formation of the Solar System. Radiogenic ⁶⁰Ni variations of <50 ppm are expected in iron meteorites, given ⁵⁸W core formation ages of asteroids and an initial ⁶⁰Fe/⁵⁶Fe ratio of 4 x 10⁻⁷. However, previous studies have not been able to resolve the predicted variations in ⁶⁰Ni between magmatic iron groups having different Fe/Ni.

We have developed methods for high-precision Ni isotope analysis of metal and silicate samples. Ni is separated using a 3-stage ion exchange procedure, which includes dimethylglyoxime to yield a Ni fraction free of impurities, in particular Fe, Ti, Sn that potentially form interferences on Ni masses. Ni isotopic ratios are measured using a Finnigan Neptune MC-ICPMS in medium resolution mode in order to resolve ⁴⁰Ar/³⁰O from ⁵⁶Fe and correct for ⁵⁸Fe on ⁵⁸Ni (<5 ppm). ⁵⁸Ni signals of 900pA are measured on a Faraday detector equipped with a 10¹⁰ Ω resistor. Each sample was analysed a minimum of 4 times. Using this procedure we obtain a reproducibility of ~5 ppm on the ⁶⁰Ni/⁶⁰Ni ratio. Terrrestrial samples (JP-1, BHVO-2, NIST 361 steel) have Ni isotopic compositions that are identical within error of the SRM 986 standard.

Our results show that magmatic iron meteorites have variable ⁶⁰Ni/⁶⁰Ni, ranging from a terrestrial value in high Fe/Ni group IIAB, to ~15 ppm deficits of ⁶⁰Ni in low Fe/Ni group IVB samples. Although a positive Fe/Ni/⁶⁰Ni/⁶⁰Ni correlation is consistent with ⁶⁰Fe decay, we find that ⁶⁰Ni/⁶⁰Ni ratios are inversely correlated with variations in ⁶²Ni/⁶⁰Ni, which are likely to be of nucleosynthetic origin. Moreover, ordinary chondrites (LL) and volatile poor (CV) carbonaceous chondrites cover the same range in Ni isotopic composition as seen in the magmatic iron meteorites. These combined observations show that Ni isotopic heterogeneity within bulk planetary samples is widespread, but do not yield clear evidence of live ⁶⁰Fe during planetesimal core formation. Bizzarro et al. (2006) have previously noted variable ⁶²Ni/⁶⁰Ni in bulk meteoritic material but our different sample set illustrates several contrasting systematics. In particular, we find that iron meteorites have ⁶⁰Ni/⁶⁰Ni both higher and lower than terrestrial values. We suggest that Ni isotopes may provide a valuable means to link iron and chondrite groups, with IVB samples apparently derived from a CV-like parent body and IIAB from LL chondrite. Interestingly, the only meteorite group we have found to have Ni isotopic systematics identical to Earth are the enstatite chondrites.
Influence of model aggregation on the parameterization of biogeochemical reaction kinetics in ecosystem models

P. Regnier¹, S. Arndt¹, G. Lacroix², N. Gypens³ and C. Lancelot²

¹Utrecht University, Utrecht, The Netherlands, (regnier@geo.uu.nl, arndt@geo.uu.nl)

³Université Libre de Bruxelles, Bruxelles, Belgium, (ngypens@ulb.ac.be, lancelot@ulb.ac.be)

Marine biogeochemical models focusing on organic matter production and consumption are compared to study the effects of complexity on model results. The various models differ in their level of spatial and biogeochemical detail. Reduction of biogeochemical complexity is performed by aggregating the highly detailed, physiologically based, MIRO model (Lancelot et al., 2005). In particular, we investigate the relevance of biogeochemical rate constants, determined in situ or through lab experiments, for ecosystem modeling. Results show that models characterized by distinct levels of spatial resolution provide different quantitative estimates of the biogeochemical rates, especially those strongly influenced by the system’s heterogeneity. An aggregation of different functional groups or the microbial loop also requires an adaptation of reaction rate constants. The rate constants of the aggregated model have to account implicitly for the processes, which are no longer explicitly included. A direct transfer of rate constants determined experimentally or by the calibration of other models is thus strongly dependent on the respective model formulation.

Contrasting evolutionary trends in magnetite from carbonatites and alkaline silicate rocks

E. Reguir¹, N. Halden¹, A. Chakhmouradian¹, P. Yang¹ and A.N. Zaitsev²

¹Department of Geological Sciences, University of Manitoba, Winnipeg, Canada (umreguir@cc.umanitoba.ca)
²The Natural History Museum, London, United Kingdom (a.zaytsev@nhm.ac.uk)

Magnetite (Mgt) is a common accessory mineral in carbonatites and associated alkaline rocks, and a sensitive petrogenetic indicator. We examined the chemical evolution of Mgt in calciocarbonatite (MCrb) and ijolite (MIj) from Kerimasi, Tanzania. MCrb is characteristically enriched in Mg (0.18-0.32 apfu), Mn (0.05-0.14 apfu) and Al (0.01-0.26 apfu), but depleted in Ti (0.04-0.11 apfu) with respect to MIj (< 0.08 apfu Mg, 0.03 apfu Mn, 0.04 apfu Al, and > 0.21 apfu Ti). MCrb has much lower levels of Cr, V, Co, Ni and, to some extent, Nb (< 16, 1210, 120, 100 and 17 ppm, respectively), but noticeably higher Zn (1310-2770 ppm) than MIj (up to 1880 ppm Cr, 1800 ppm V, 190 ppm Co, 210 ppm Ni, 46 ppm Nb and 1150 ppm Zn). The two samples are virtually identical in terms of their Ga, Zr, Hf and Ta contents. MCrb shows a trend of decreasing Ti and increasing Mn (at nearly constant Mg) from the earliest generation to crystallize (macrocryst cores) toward the latest (rims and small groundmass grains). The early generation of MCrb is also distinguished by its higher V, Nb and Nb/Zr values. In ijolite, we distinguished two varieties of magnetite differing in their Mg, Ti, V, Ga, Nb, Ta, Co and Hf contents. The two types are also characterized by very different Zr/Hf and Co/Nb ratios. Both varieties show a trend of increasing Mg, V, Zr, Nb, Hf and decreasing Ti and Ga from the earliest generation (subhedral crystals) to the later-crystallized interstitial grains. There is also a trend of increasing Ta in variety-one magnetite, whereas variety-two is Ta-free. The significant differences in major- and trace-element chemistry of the studied carbonatite and ijolite indicate that these rocks did not originate from a single magma, but are products of two distinct magmas characterized by different distribution coefficients of trace elements with respect to magnetite.
Characterizing Fe-rich dunite xenoliths as cumulates of Phanerozoic and Archaean flood basalt magmatism

TATJANA REHFELDT1, STEPHEN F. FOLEY1, DORRIT E. JACOB1, RICHARD W. CARLSON2

1Johannes-Gutenberg Universität Mainz, Institut für Geowissenschaften, Becherweg 21, 55099 Mainz, Germany; (rehfeldt@uni-mainz.de)
2Carnegie Institution of Washington, Department of Terrestrial Magnetism, Washington, DC 20015, USA

Fe-rich dunite xenoliths occur amongst a large abundance of mantle xenoliths, in the kimberlites of the Kimberley cluster, but their origin has been unclear. On the basis of texture, major and trace elements, as well as Re-Os isotope characteristics, we interpret these dunites as cumulates of flood basalt magmatism related to the ~183 Ma Karoo and the ~2.7 Ga Ventersdorp events in southern Africa.

The Fe-rich dunites mainly comprise olivine neoblasts with subordinate olivine porphyroclasts and parallel-oriented needles of ilmenite, which enclose spinel in some samples. Olivines have lower forsterite and NiO contents than mantle peridotite xenoliths (Fo87-89 versus Fo93-95 and 1300-2800 ppm versus 2200-3900 ppm, respectively), which rules out a restitic origin. Cr-rich spinels are remnants of the original cumulate mineralogy that survived a late stage metasomatic overprint related to the production of the host kimberlite, producing ilmenite and phlogopite in some samples. Olivine porphyroclasts and neoblasts have different trace element compositions, the latter having higher Ti, V, Cr and Ni and lower Zn, Zr and Nb contents, indicating contrasting origins for neoblasts and porphyroclasts. The dunites have high 18O/16O ratios (0.11-0.15) indicating young (Phanerozoic) model ages for most samples, whereas three samples show isotopic mixtures between Phanerozoic neoblasts and ancient porphyroclastic material. Most Fe-rich dunite xenoliths can be interpreted as cumulates of fractional crystallization of Karoo flood basalt magmatism, whereas the porphyroclasts are interpreted to be remnants from the much earlier Archaean Ventersdorp magmatic episode.

The calculated parental magma for olivine neoblasts in Fe-rich dunites corresponds to low-Ti Karoo basalts, whereas olivine porphyroclasts had a parental magma with higher MgO contents similar to Archaean high-Mg and komatitic rocks. Modelling the crystal fractionation of the parental magmas with pMELTS yields element fractionation trends that mirror the element variation of primitive low-Ti Karoo basalts and the basal section of the Ventersdorp Klivriviersberg Group.

Volcanic Outgassing and the Tl Isotope Composition of the Oceans

Thallium is a conservative element in seawater with a marine residence time of ~20 kyr [1]. It is thus unsurprising that the present oceans have a nearly constant Tl isotope composition of ε205Tl = -6 ± 1 [2-4]. This uniformity is also expressed in the recent growth surfaces of hydrogenetic ferromanganese (Fe-Mn) crusts, which incorporate seawater-derived Tl by adsorption and display ε205Tl = +13 ± 1 [2].

Time-series analyses of six Fe-Mn crusts from the Atlantic, Indian and Pacific Oceans revealed nearly constant Tl isotope compositions over the last 30 Myr. In contrast, it was also shown that the ε205Tl-values of Fe-Mn crusts changed dramatically from about +6 at 60 Ma to +13 at about 30 Ma [5]. This change has been confirmed by a recent high-resolution time-series study of the Pacific Fe-Mn crust CD29-2 [6].

Given these systematics, it is not unreasonable to assume that the time-series data reflect a change in the Tl isotope composition of seawater. Of particular interest is the possibility that the trend was generated by larger fluxes of Tl derived from subaerial volcanism in the early Cenozoic. This interpretation is in accord with observations that (i) volcanic emissions presently provide ~30% of the global input flux of Tl into the oceans [1], and (ii) such emissions may display low ε205Tl from 60 to 30 Ma may furthermore be essentially synchronous with the decrease of atmospheric CO2, as inferred from B isotope data [7], and a 5‰ shift in the S isotope composition of seawater sulfate [8]. It has been proposed that both of these changes could reflect decreasing rates of volcanic outgassing during the early Cenozoic [7, 8].

Preliminary Tl isotope data show that volcanic gases have ε205Tl-values as low as -8, and this demonstrates that changes in volcanic inputs may indeed alter the Tl isotope composition of the oceans. To further investigate this possibility, we will acquire Tl isotope data for a larger suite of volcanic emanations from Etna, Kilauea, Merapi, Vulcano and White Island.

Heavy isotope fractionation in the solar system – A volatile perspective

M Rehkämper1,2, M Schön bächler1,2, F Wombacher3, RGA Baker1,2, SG Nielsen4 and HM Williams5

1Impact and Astromaterials Research Centre (IARC), Imperial College, London SW7 2AZ, UK
2The Natural History Museum, London SW7 5BD, UK
3Institut für Geologische Wissenschaften, FU Berlin, 12249 Berlin, Germany
4Dept. of Earth Science, Parks Road, Oxford OX1 3PR, UK

It is well recognized that most solar system bodies are significantly depleted in volatile constituents relative to primitive CI chondrites but the origin of this signature is only poorly understood. Stable isotope studies of volatile elements in meteorites are well suited for addressing this fundamental question. This conclusion is underlined by the observation that for chondritic meteorites, heavier but more volatile elements (such as Cd) typically display larger isotopic effects than lighter and less volatile constituents (e.g., Zn). This suggests that partial vaporization and condensation play an important role in generating stable isotope variations [1-3].

The isotope data acquired for a number of volatile elements indicates that stable isotope effects are generally much larger for ordinary than for carbonaceous chondrites. The large isotope variations determined for ordinary chondrites (e.g., ~25‰ for 114Cd/110Cd) are thought to reflect redistribution of volatile constituents by thermal metamorphism on the meteorite parent bodies [1,2]. In contrast, most carbonaceous chondrites display only small or no resolvable isotope effects of ≤0.15‰/amu for Ag, Zn, Cd, and Tl [1-5]. This demonstrates that the variable volatile abundances of carbonaceous chondrites reflect either partial equilibrium condensation/evaporation or mixing processes.

Refractory (CAI- & chondrule-rich) separates from Allende display light Cd and Zn isotope compositions (of about ~1‰/amu) relative to the bulk meteorite [2,3]. These signatures cannot reflect Rayleigh evaporation but are more readily explained by the interaction of refractory materials with a volatile-rich nebular gas. Such processes may also be responsible for the lack of nucleosynthetic isotope anomalies of volatile elements in CAI’s.

The short-lived 107Pd-107Ag and 205Pb-205Tl decay systems are well suited for studying the time scales of volatile loss in the early solar system. Such studies must be carried out with care, as Ag and Tl have only two isotopes, such that radiogenic and stable isotope effects may not be readily discernable. One example are the troilite inclusions of IAB irons, which appear to have Ag and Tl isotope compositions that were fractionated (~1‰/amu) by diffusion [6,7].

High-resolution geochemistry and lithology of laminated sediment in the Weddell Sea, Antarctica

L. Reichelt1, M. E. Weber2, G. Kuhn3 and W. Ricken4

1Institute for Geology and Mineralogy, University of Cologne, Germany (L.Reichelt@gmx.de)
2Institute for Geology and Mineralogy, University of Cologne, Germany (michael.weber@uni-koeln.de)
3Alfred-Wegener-Institute, Bremerhaven, Germany (gerhard.kuhn@awi.de)
4Institute for Geology and Mineralogy, University of Cologne, Germany (wricken@uni-koeln.de)

Methods
Sediment sites PS1789 and PS1791 from the southeastern Weddell Sea (Antarctica), were investigated for geochemical and lithological variability. We used several non-destructive means to obtain information at ultrahigh resolution (mm to sub-mm scale). An x-ray-fluorescence core scanner should reveal relative chemical composition of some selected elements. Magnetic susceptibility records were compared to counts of ice-rafted debris (IRD). We determined sediment color using both a photospectrometer, RGB readouts from a line scanner, and gray-scale images from x-radiographs. Stratigraphy relies on previously published AMS14C dates.

Results
The glacial sediment sections reveal mostly laminated sediments and rarely intercalated fine-grained turbidites. Bioturbated section occur at the top and are linked to Holocene or late-glacial times. Geochemical composition is relatively stable during the glacial; only bioturbated sediment shows elevated Fe and diminished Al and Si contents, whereas turbidites reveal the opposite.

In order to reveal whether or not the laminations is a result of an interannual (seasonal) variability, we developed tools for semi-automated layer counting of the gray-scale scans. First results indicate that the lamination is most likely an innerannual process, e.g., site PS1789 contains 4860 visually detectable layer between 199 and 1211 cm core depth, where AMS14C dates indicate an age difference of 2430 years, i.e., more than 90% of the expected layers encountered.

Future Work
More sites will have to be investigated to corroborate the preliminary stratigraphic results. Geochemical investigation will focus on the differentiation between the seasonal layers, i.e., there is a compositional difference between the darker and lighter layers documented in the gray-scale images or is the alteration caused by grain-size changes only.
In step with time: *In situ* geochronology meets microscale records of geologic processes

MARY R. REID

Department of Geology, Northern Arizona University,
Flagstaff, AZ 86011; mary.reid@nau.edu

The profound record of geologic phenomena at sub-millimeter scales can be revealed by *in situ* geochronology and geochemistry in the context of key textural relationships. Complementary in situ geochemical and isotopic analyses reveal, for example, fluid evolution during cementation, the evolution of low as well as high grade metamorphism, subduction and exhumation, and the nature and duration of crustal growth. The improved accuracy and precision of U-Pb dating at <50 µm by LA-ICP-MS is increasing use of this method for *in situ* dating, especially for provenance studies and reconnaissance geochronology. Efforts to develop more matrix-matched reference materials will continue to improve the accuracy of *in situ* dating and geochemistry.

Dating of igneous and environmental samples by 234U/238U and 230Th/234U disequilibria is also possible at a spatial resolution of <100 µm. Vazquez and Reid (2004) coupled in situ U-series geochronology with crystal-scale allanite chemistry to reveal a t-T-X record for heterogeneous accumulation of the voluminous Toba rhyolite. The advent of the Ti-in-zircon geothermometer (Watson and Harrison, 2005) will ensure further crystal-scale insights into magmatic processes. In situ 235U-231Pa zircon ages may augment 238U-230Th geochronology (Schmitt, 2006). For environmental samples that contain ≥1 ppm U, dating by LA-ICP-MS affords high-resolution reconnaissance studies that can cope with open systems like bones, teeth, and possibly molluscs without chemical preparation (e.g., Eggins et al., 2005). Fluctuations in initial (234U/238U) and trace element concentrations, such as those found in 2-200 µm thick opal layers in soils, can be linked to glacial-interglacial transitions by ionprobe 230Th/234U dating (Maher et al., in prep.).

Finally, extension of *in situ* laser analyses to (U–Th)/He geochronology enables dating of 25 µm domains for provenance and unroofing studies (Boyce et al., 2006).

Continental scale geochemical mapping and the geochemical background

C. REIMANN

Geological Survey of Norway, 7491 Trondheim, Norway,
(Clemens.Reimann@ngu.no)

Since 1995, large domains in Northern Europe have been mapped at ever decreasing sample densities: 1 site/300 km² in the Kola Project, 1 site/1000 km² in the Barents Project and 1 site/2500 km² in the Baltic Soil Survey. The geochemical atlas of Europe, based on a sample density of 1 site/5000 km², was published in 2005 (see www.gtk.fi/publ/foregsatlas). Results demonstrate that such low-density geochemical mapping allows for the construction of robust geochemical maps of large areas at reasonable cost. The maps contain important new information and politically vital reference data about the varying levels of chemical elements in the surface environment at the continental scale.

The data demonstrate that there exist a number of natural processes that influence the regional distribution of chemical elements in the surface environment at a variety of scales. Many of the displayed large-scale patterns are surprising and unpredictable based on geological reasoning alone. The distribution of chemical elements at the earth surface has an important impact on animal and human health. Continental scale geochemical maps of a variety of sample media, reflecting different compartments of the ecosystem, are thus urgently needed.

The anthropogenic impact on the natural environment cannot be reliably judged and interpreted without continental-scale geochemical maps and sound knowledge and documentation of the geochemical background. The observed natural variation of element concentrations in all sample materials collected so far covers several orders of magnitude. The statistical definition of a geochemical background or action levels for, for example, metals in soils of Europe, is thus fraught with problems. Obviously there is no single "natural" background value that is valid for a large area. Rather background will change from area to area within a region and between regions. The inherent connections between scale and background variation are key features for understanding environmental processes.
EXAFS analysis of reactive nanoscale iron oxidation in water

B.C. REINSCH1, G.V. LOWRY2 AND C.S. KIM1

1Department of Chemistry, Chapman University, Orange, CA USA, (reins100@chapman.edu)
2Civil and Environmental Engineering, Carnegie Mellon University, Pittsburgh, PA USA, (glowry@cmu.edu)

Nanoscale zerovalent iron particles rapidly degrade chlorinated solvent groundwater contaminants into non-toxic products in situ. The efficacy of this approach is partially dependent on the reactivity and longevity of the zerovalent iron, which is readily oxidized in groundwater. Oxidation on the surface of the nanoscale iron particle can passivate the particle, potentially resulting in lowered reactivity toward target contaminants. A fundamental understanding of the chemical and structural changes that occur as a result of oxidation at the nanoscale surface in aqueous systems is necessary to assess the related impacts on reactivity and to determine the ultimate utility of the particles towards remediative goals.

Nanoscale zerovalent iron particles (initially 70% Fe0/30% Fe3O4 core/shell particles) were allowed to oxidize in anaerobic water for various times ranging from a few days up to 1 year. The resulting iron particles with varying degrees of oxidation were studied using high intensity synchrotron radiation methods at Stanford Synchrotron Radiation Laboratory, beamline 11-2. Iron K-edge extended X-ray absorption fine structure (EXAFS) spectra provided element-specific information regarding the short-range structural order around iron in the nanoparticles. Fitting of the iron EXAFS spectra using model phase and amplitude functions allowed quantification of the direct relationship between oxidation time and relative amount of oxygen present in the atomic structure. Specifically, over the range of samples analyzed the average Fe-Fe coordination number declined from 8.2 ± 0.4 to 2.5 ± 0.3 while the average Fe-O coordination number increased from 1.2 ± 0.8 to 3.1 ± 0.9. The Fe-O and Fe-Fe interatomic distances and coordination numbers determined from the EXAFS fitting process were then compared to those of known crystalline iron oxides/oxyhydroxide phases in order to characterize the progressive structural transformation of the nanoparticles during their oxidation in water.

Metals from agriculture in oxic fluvial sediments: A case study in Western Iberia

A. R. REIS1, A. PARKER2 AND A. ALENCOÃO1

1Department of Geology, University of Trás-os-Montes and Alto Douro, Vila Real, Portugal, and Centre for Geophysics, University of Coimbra, Coimbra, Portugal, (anarreis@utad.pt, alenkoao@utad.pt)
2Department of Soil Science, University of Reading, Reading, UK, (a.parker@reading.ac.uk)

The transport of fine fluvial sediments and associated pollutants in mountainous rivers is very dynamic, in response to precipitation episodes. The present study highlights the impact of human activities, mainly farming, in a “natural” mountainous catchment in Northern Portugal, underlain by crystalline rocks, in a temperate climate. Some inferences regarding Cu, Pb, Zn and Ca concentrations, their spatial and temporal variability, and potential bioavailability in oxic fluvial sediment samples are presented.

The study was performed on the <63µm sediment fractions. The modified BCR sequential extraction procedure (Rauret et al., 1999) was used to assess metal contents in geochemical phases. The residual phase was decomposed by aqua regia. The element concentrations were obtained by ICP-AES.

The studied metals had contents in the ranges (ppm) Cu (1-99), Pb (5-154), Zn (29-448) and Ca (362-40860), showing higher contents in sampling stations located at those points draining areas with intense agriculture. These elements are common components of fertilizers, pesticides and animal manures (cow, horse, rabbit), the last widely used in the studied area. In these sites, the metals' relative contents present in the soluble, oxidisable, and organic fractions are considerably higher. However, differences in the distribution of the potential bioavailable fraction are observed, with marked increases in different phases: Cu in the organics, Zn in the soluble and oxidisable, and Pb in the oxidisable.

Calcium was also considered in this study. Although ubiquitous in natural water systems, its concentrations in the sediment samples are relatively high, considering the local geology (granites and schists). Calcium is a major component in the chemical fertilizers used in the studied area. Calcium is low in the residual fraction, owing to its geochemical behaviour, but is present in considerable amounts in the soluble fraction. The correlations between Ca and Cu, Pb and Zn are highest at the end of the dry period. The first autumn rain leads to increased transport of these elements, either by runoff or leaching of agricultural lands.

Microbially mediated formation of gold in calcrete anomalies in Australia

F. Reith1, A. Schmidt Mumm2

1The University of Adelaide, Geol. & Geophys., Adelaide, Australia (Frank.Reith@csiro.au)
2The University of Adelaide, Geol. & Geophys., Adelaide, Australia (andreas.schmidtumm@adelaide.edu.au)

Regolith carbonates (calcrete) are widely used in Au exploration in Australia, because Au, which is often finely dispersed in calcrete, and Ca are highly correlated suggesting co-precipitation. The genesis of carbonates in pedogenic environments is dominantly ascribed to microbial processes, in particular to microbially mediated carbonate precipitation via ureolysis. Contrary to a genesis model recently published by Lintern et al. (2006), Schmidt Mumm and Reith (2007) proposed a comprehensive coupled model that includes a microbial component, which may control Au and Ca co-precipitation (Fig. 1).

Figure 1: Model for the microbially mediated formation of gold in calcrete anomalies (Schmidt Mumm and Reith, 2007).

Using microcosms and microbial enrichment culture experiments to assess the ureolytic capacity of the bacterial community combined with molecular profiling (shotgun cloning and DGGE of 16S rDNA), showed that Bacilli spp. resident in calcareous materials at the Barns anomaly are capable of producing Au anomalous Ca-carbonates. Within 96 to 240 h from the start of the incubation the urea was turned over to NH4+, the pH in solution rose by approximately 1 unit to pH 9 and Ca2+aq was precipitated as Ca-carbonate crystals; in sterile the controls no carbonates were precipitated. Gold (been added as Au-aspartic acid complexes to the growth medium) was co-precipitated with Ca and uniformly dispersed in the dominantly vaterite crystals, as shown by laser ablation ICP-MS and SEM. These results suggest that microorganisms play an important role in the formation of Au anomalies in calcrete in Australia.

Origin of brines in the northern Gulf of Mexico

A. Reitz1, M. Haeckel1, K. Wallmann1, C. Hensen1, and K. Heeschen2

1Leibniz-Institute of Marine Sciences, IFM-GEOMAR, Kiel, Germany (areitz@ifm-geomar.de; mhaeckel@ifm-geomar.de; kwallmann@ifm-geomar.de; chensen@ifm-geomar.de)
2National Oceangraphy Centre, Southampton, U.K. (kyh@noc.soton.ac.uk)

Brines from the northern Gulf of Mexico show distinct differences with respect to element concentrations and oxygen, hydrogen, and strontium isotope signatures. Three sites at different water depth were investigated; Bush Hill, GC415 East, and GC415 West at water depths of 540, 950 and 1050 m, respectively. All three locations accommodate near-surface gas hydrates and chemosynthetic communities at the sediment surface. They are characterized by a distinct increase in salinity with depth, however, the origin of this increasing salinity is different for the GC415 sites and Bush Hill and the depth source of the brines is considerably different for all sites. The more saline brines of the GC415 sites result from the dissolution of halite (Fig. 1) by formation water. The brine of GC415 East has most likely a deeper origin and experienced elevated temperatures leading to intensive mineral/water reactions. This process is expressed by the heavier oxygen isotope values and distinct Li, Sr, and Ca enrichments. The brine of GC415 West has a shallower origin which is expressed by a smaller enrichment in Li, Sr, and Ca and lighter oxygen isotopes (Fig. 1). The brine from Bush Hill is less saline and its fluid signature indicates intensive water/mineral interaction. Oxygen (Fig. 1) and hydrogen isotope values as well as Na/Cl and Br/Cl molar ratios indicates that the salt enrichment could have been caused by phase separation under sub-critical conditions. A simple heat flow model simulation suggests sub-critical phase separation at a depth of ~1650 m at ~350°C.

Fig. 1: Cl vs. δ18O plot. Solid lines show the evaluation path of Cl vs. δ18O values for (i) evaporation at ~25°C, (ii) gas hydrate (GH) formation, (iii) illite formation, and (v) dissolution of halite; the field expected for phase separation (no fractionation) is indicated by the solid circle.
Molecular identification of the Deuterium-rich carrier in insoluble organic matter in carbonaceous chondrites

Insoluble organic matter (IOM) in primitive carbonaceous chondrites is known to be enriched in deuterium, with D/H ratios > 350×10^-6. It is also characterized by a high degree of isotopic heterogeneity, as demonstrated by the observation of D-rich “hot spots” in NanoSIMS ion microprobe images (Robert et al. 2006). Understanding the origin of this heterogeneity represents a fundamental challenge with implications for the origin and distribution of organics in the interstellar medium and in the protoplanetary disk from which our planetary system formed.

We have determined the carrier of the isotopically anomalous hydrogen in IOM isolated from the carbonaceous chondrite Orgueil. Electron Paramagnetic Resonance spectroscopy has shown that hydrogen in the benzylid bond of organic radicals has a deuterium to hydrogen (D/H) ratio of 1.25±0.75×10^-2 in Orgueil IOM, which is the highest solar system D/H ratio ever reported (Delpoux et al. 2007).

By combining these data with quantitative image analysis recorded at a high spatial resolution with the NanoSIMS, we are able to prove that the organic radicals can account for the deuterium excess in the IOM D-rich “hot spots”. Furthermore, the radicals fall on a well-defined trend between D/H ratio and C-H bond energy (Remusat et al. 2006), consistent with a new interpretation of the hydrogen isotopic variations in solar system organics according to which pre-existing organics exchange their D with highly deuterated gaseous molecules, such as H2D+ or HD2+. The distributions of these deuterated species is now being mapped in protostellar disks (Ceccarelli and Dominik 2005).

This conclusion runs contrary to previous interpretations, according to which the IOM is an interstellar product reprocessed in the protosolar gas and deuterium-rich “hot spot” relics of pristine interstellar organic matter, which escaped solar nebula or parent body processes.

The effects of sodium and chlorine on the solubility of molybdenum in aqueous vapour

K.U. REMPEL, A.E. WILLIAMS-JONES AND A.A. MIGDISOV
McGill University, Earth & Planetary Sciences, Canada
(kirsten@eps.mcgill.ca; willyj@eps.mcgill.ca; artas@eps.mcgill.ca)

There is growing evidence that the solubility of Mo in water vapour may be high enough for metal transport in the vapour phase to be an important mechanism in the formation of porphyry Mo deposits (Rempel et al., 2006). Molybdenum is typically considered to be transported as a hydrated oxide, but research on Mo speciation in H2O-free vapour suggests that the formation of Mo oxochlorides and sodium molybdates may be important (Hultgren and Brewer, 1956; Choudary et al., 1975). This study reports the results of experiments designed to investigate the effects of Na and Cl on Mo solubility in high-temperature water vapour.

The experiments were conducted in NaCl- and HCl-bearing aqueous vapour at 350°C and 60-160 bars. At fHCl<0.5 bars, Mo concentration appears to be independent of fHCl. However, at fugacities of HCl typical of volcanic gases (fHCl from 0.5 to 5 bars), the sum of the fugacity of Mo species increases with increasing fHCl in a ratio of ~1:2. At all fugacities of HCl, Σ/Mo species increases with increasing fH2O in a ratio of 1:2. These observations suggest that the predominant Mo species in the HCl-H2O system is a hydrated chloride or oxychloride. In the case of the former, the stoichiometry would likely be MoCl2•2H2O, whereas the latter could be MoO2Cl2•2H2O, a species that has been reported to occur in HCl gas (Hultgren and Brewer, 1956). The sum of fugacities of Mo species in NaCl-bearing vapour rises linearly with increasing Σ/Na species in a ratio of 3:4. Furthermore, Σ/Na species is about two orders of magnitude higher than predicted for the partitioning of NaCl between H2O liquid and vapour (Bischoff 1991), indicating that the dominant Na species in the vapour is not NaCl. Values of Σ/Mo also increase linearly with fH2O (in a ratio of 1:3), suggesting the formation of hydrated Na molybdates. The ratio of Σ/Mo to Σ/Na of 3:4 implies the formation of two or more hydrated Na molybdates, e.g. Na2MoO4•3H2O or NaHMoO4•3H2O.

The results of this study, in conjunction with the known elevated concentrations of Na and Cl in magmatic vapours, suggest that such vapours are more than capable of dissolving the concentrations of Mo required to form porphyry Mo deposits.

Status of the impact crater age database

P.R. RENNE\textsuperscript{1,2}, F. JOURDAN\textsuperscript{1,2}, W.U. REIMOLD\textsuperscript{3}

\textsuperscript{1}Berkeley Geochronology Center, USA (fjourdan@bgc.org)
\textsuperscript{2}University of California, Berkeley, USA
\textsuperscript{3}Museum f. Natural History, Germany

The Earth impact crater database (http://www.unb.ca/passc/ImpactDatabase/) includes a total of 174 confirmed impact structures. Ages listed in the database are based on dates recommended in the most recent published papers. Precise and accurate age constraints are crucial in (1) correlating causes and effects on the bio- and geosphere for these catastrophic processes, (2) better constraining the impactor flux through geological time and evaluation of potential impact periodicity, (3) calibrating the absolute chronostratigraphic time scale, and (4) calibrating the age of within-crater continental sedimentary deposits (e.g., for regional paleo-climatic analysis).

Of the 174 confirmed impact structures only a few have ages constrained precisely enough (mostly using radio-isotopic techniques, e.g. U/Pb and \textsuperscript{40}Ar/\textsuperscript{39}Ar), with 26 ages having a stated precision better than 2% and 15 ages with a precision better than 1%. Yet, even in this very restricted subset of the database the accuracy of some of these ages can be challenged and probably improved based on more detailed and statistically more rigorous interpretations. Although geochronologists are often circumspect and advise caution in accepting calculated ages, these ages tend to propagate into the literature without further critical evaluation and become “robust” and widely accepted ages. A quick review of the age data of the 26 short-listed structures suggest that 11 ages seem accurate, 13 are at best ambiguous, and 2 are not well characterized and should not be reported with any uncertainty. We report examples of misleading ages and/or age uncertainties (e.g., poor stratigraphic constraints, data over-interpretations, ambiguity due to inconsistent results) and highlight the robustness of 11 well defined ages. We also provide some suggestions (see also \cite{1}) based on observations and modeling, in order to obtain better ages. This brief review should be interpreted as a call for drastic qualitative and quantitative improvements of the crater age database in the near future.

Arsenic uptake and release on sulfide nanoparticles

D. RENOCK\textsuperscript{1}, S. UTSUNOMIYA\textsuperscript{2}, T.J. GALLEGOS\textsuperscript{3}, K.F. HAYES\textsuperscript{2}, R.C. EWING\textsuperscript{2} AND U. BECKER\textsuperscript{2}

\textsuperscript{1}Dept. of Geological Sciences, University of Michigan, Ann Arbor, MI., U.S.A. (drenock@umich.edu)
\textsuperscript{2}Dept. of Geological Sciences (utu@umich.edu, rodewing@umich.edu, ubecker@umich.edu))
\textsuperscript{3}Dept. of Civil and Env. Engineering (tgallegos@umich.edu, ford@umich.edu)

Descriptions of molecular-level processes that control the uptake and release of As on sulfide nanoparticle surfaces were obtained from microbeam, spectroscopic, and quantum mechanical modeling techniques.

The precipitation of As-sulfide phases on nanoparticulate mackinawite (FeS) is identified as a possible mechanism for As(III) immobilization under anoxic conditions (Gallegos \textit{et al.} 2007). A major challenge in identifying As-sulfide growth phases is their nanoscale dimensions. High-angle annular dark field scanning-TEM and energy-dispersive X-ray spectrometry were used to identify amorphous AsS phases precipitating on FeS nanoparticles after As(III) adsorption at pH 5. The oxidation state of As in the surface As-sulfide precipitates was determined to be “realgar-like” from X-ray photoelectron spectroscopy results showing an As 3d binding energy of 43.0 eV.

The reverse process, the oxidative dissolution of realgar (As\textsubscript{4}S\textsubscript{4}) and orpiment (As\textsubscript{2}S\textsubscript{3}) nanoparticles, is a mechanism by which As is released back into natural waters. \textit{Ab initio} quantum mechanical methods were employed to describe indirect electronic perturbations (proximity effects) between surface adsorbates on As\textsubscript{4}S\textsubscript{4} nanoclusters. Proximity effects between O and (OH)\textsuperscript{-} ion adsorbed on a single As\textsubscript{4}S\textsubscript{4} cluster were determined to be on the order of 1 eV, depending on the O-(OH)\textsuperscript{-} distance. Calculations also show that adsorption of (OH)\textsuperscript{-} to As\textsubscript{4}S\textsubscript{4} could affect the adsorption energy of O to a neighboring As\textsubscript{4}S\textsubscript{4} separated from the former by a van der Waals gap (as is the case in As\textsubscript{4}S\textsubscript{4} molecular crystals). The findings suggest that As\textsubscript{4}S\textsubscript{4} is more susceptible to oxidative attack with the co-adsorption of (OH)\textsuperscript{-} ions.

The results of this study can be used to improve adsorption isotherms and surface complexation models that describe the factors that control As concentrations in natural waters.

Volcán de Colima, an andesitic volcano fed by a dacitic reservoir. Is that typical of continental arc magmatism?

OLIVIER REUBI AND JON BLUNDY

Dept. of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK (olivier.reubi@bristol.ac.uk)

Volcán de Colima, Mexico is the archetype of an andesitic arc stratovolcano and is one of the most active volcanoes in North America. All historically erupted magmas have bulk andesitic compositions, yet the melt inclusion and phenocryst assemblages indicate that the melt crystallizing in the subvolcanic system is consistently dacitic in composition. Similar mismatches between whole rock and melt inclusion records are documented for several other andesitic volcanoes, which raises questions about the abundance of true liquids with andesitic composition.

Melt inclusions (MI) in phenocrysts of pyroxenes from Volcán de Colima magmas are distinctly more silicic than whole rock compositions (64-75 and 57-62 wt% SiO₂ respectively). A significant proportion of the melt inclusions have “exotic” compositions thought to be produced by grain boundary melting of co-genetic crystal-clots. The other MI show trends consistent with crystallization of the phenocryst assemblage observed in the magmas. Volatile content of these melt inclusions are distinctly low (<2.5 wt% H₂O, ≤360 ppm CO₂) and indicate crystallization in a volatile-saturated system between 90 and 0 MPa (<7 km in depth). The magmas contain ubiquitous gabbroic fragments up to few mm in size. The whole-rock compositions of the andesites systematically lie on mixing lines between the gabbroic fragments and the less evolved melt inclusions, indicating that entrainment of these gabbroic fragments is the primary factor controlling the bulk andesitic composition and, importantly, that the melt inclusions effectively record the composition of the crystallizing melt. Overall, this implies that despite the monotonous andesitic composition of the erupted magmas, the magmatic system that feeds Volcán de Colima comprise a shallow, variably crystallized dacitic magma reservoir and a pre-existing gabbroic plutonic body. It is therefore bimodal in composition, with no andesitic melt.

A compilation of published melt inclusion data for several other continental arc andesite volcanoes also shows a bimodal distribution with a marked minimum at andesite. This implies that andesitic melts are typically minor components of the upper crustal magmatic reservoir feeding arc volcanoes and that the abundance of erupted andesitic magmas reflects in large part effective mixing of these two components within the subvolcanic reservoir and/or on the way to the surface.

The building stones of the Khmer-temple at Angkor/Cambodia: A petrological and geochemical approach towards a conservation oriented characterisation of the inventory

R. REUCHER¹, H. LEISEN², E. V. PLEHWE-LEISEN³ AND R. KLEINSCHRODT¹

¹Institut of Geology and Mineralogy, University of Cologne, Zülpicher Str. 49b, 50923 Cologne (research@stone-gate.eu, rkleinsc@uni-koeln.de)
²Institut of Restoration and Conservation Sciences, University of Applied Science, Cologne, Ubierring 40, 50678 Cologne, (jaeh.leisen@freenet.de)
³Untersuchungslabor für Fragen der Natursteinerhaltung (LPL), Schulze-Delitzsch-Str. 88, 50968 Cologne (jaeh.leisen@freenet.de)

The Angkor Park / Cambodia, as a prominent member of the Unesco world heritage, is one of the outstanding cultural relics on earth. Countless Khmer temples were successively built between 9th – 13th century.

During the preparation of interventions in individual temples the building stones were investigated concerning their most important properties in regard to conservation strategies. It turned out that there are considerable differences in weathering behavior between the sandstones used at different temples and that the composition and texture of the building stones are determining factors for the degree and the type of decay. The study presented aims at a detailed geochemical and mineralogical characterisation of the building stones starting with samples from some of the most prominent temples. Together with petrophysical data this shall provide a material oriented database for future conservation conceptions.

The material was characterised petrographically by optical microscopy, the components were analysed by electron microprobe and whole rock chemistry of main and some trace elements that were determined by XRF-analysis. X-ray diffraction was used for determining clay minerals in selected rocks.

On a petrographic base most of the rocks can be classified as feldspathic greywackes (according to Pettijohn et al. 1972), in one, the Banteay Srei temple, lithic greywackes were found. Inspite of this similarity the rocks display a distinct variability in regard to their chemical composition and texture. The combinations of the methods show clear accordances in the observed variability of the temples building stones. On the other hand the building stones from the Ta Keo (feldspathic greywackes) and the Banteay Srei temple (lithic greywackes) are distinctly different from the others. They also show no correlation with the samples of the ancient quarries.

Future investigations extend to temples (also smaller ones) and ancient quarries in the wider surrounding of the Angkor Park aiming at the set-up of a database on the variability and historical variations in the building stones used during the five centuries of construction.
Aerogels – A kind of ceramic? Properties and applications
MICHAEL REUB AND SUSANNE LISINSKI

Deutsches Zentrum für Luft- und Raumfahrt (DLR), Institut für Materialphysik im Weltraum, D-51170 Köln, Germany

Michael.Reuss@dlr.de, susanne.lisinski@dlr.de

Aerogels are nanostructured materials, containing until 99 wt.-% air. They are manufactured by a sol-gel process [1]. After formation of a 3D network of colloidal particles, the wet gel has to be dried without shrinkage to avoid destruction of the network by capillary forces. The drying process can be supercritical or subcritical, depending on the kind of aerogel. Because of their very special properties (extremely low density, extremely low thermal conductivity,....), aerogels are very interesting for different applications [2]. Aerogels can be classified into organic and inorganic aerogels.

The first aerogels (organic, silica aerogels) were manufactured already in 1931/32 by Kistler [3]. Inorganic aerogels are inert against metal liquids and cannot be wetted by them. We use them as crucible material for solidification of metal alloys. It is possible to watch the solidification process directly or by CCD-camera, because these kinds of aerogels are often transparent in a wide range of 350-2700 nm.

In the past few years, there has been a great deal of interest in the synthesis of hybrid materials with nonlinear optical properties, especially second harmonic generation (SHG). We prepare ferroelectric aerogels, like LiTaO₃ and LiNbO₃, and silica/titania aerogels loaded with ferroelectric nano -and microparticles, like BaTiO₃ or KNbO₃. Whenever an infrared laser light wave (e.g. 1064nm) penetrates these materials, the aerogel generates green light (532nm).

In recent years, organic aerogels were presented as a new, nanostructured material with possible applications like binding material for sand cores and moulds in the foundry industry [5] or in its pyrolyzed carbon form as a material for supercapacitors. The well investigated Resorcinol-Formaldehyde (RF) aerogels [6,7] are typically catalyzed with weak bases like sodiumcabronate. Instead of base catalysis it was recently considered to use acid catalysts, especially sodium hydroxide, for the drying of RF aerogels [8].

Opal records of abrupt changes in the Southern Ocean over Termination II
B.C. REYNOLDS¹, S. MANTOURA² AND A. SHEMESH³

¹IGMR, ETH Zürich, Switzerland. reynolds@erdw.ethz.ch
²Formally at the Dept. of Earth Sciences, University of Cambridge, UK. (s.mantoura@nature.com)
³Dept. of Earth Sciences, The Weizmann Institute of Science, Israel. (aldo.shemesh@weizmann.ac.il)

Diatoms sequester CO₂ and other nutrients into their organic matter, as well as forming biogenic silica (opal), and can account for over half of the world’s primary productivity in the surface oceans. Silicon (Si) is an important oceanic nutrient for their growth and primary production in surface waters, especially at high-latitudes. Opal bio-mineralization leads to a mass-dependent Si isotope fractionation, such that the Si isotope composition (expressed as δ²⁹Si) of seawater and biogenic opal reflect the degree of Si utilization in ocean surface waters by siliceous algae, analogous to variation in carbon isotopes, but linked only to diatom productivity.

An unprecedented high temporal-resolution Si-isotope record has been measured from the South Atlantic from ODP site 1094 over the penultimate deglaciation. The qualitative trends observe a very large shift from low glacial values to high interglacial values over Termination II. These large changes are in accordance with a record from the Antarctic zone of the South Atlantic (Core RC13-259, [1]). The high temporal-resolution of this study allows us to ascertain two important features which have hitherto not been demonstrated:

Firstly, we can compare the time of changes in δ⁴₀Siopal to changes in the other stable isotope proxy of seawater, namely δ³⁴S and δ¹₃C [2], secondly, we can demonstrate that δ⁴₀Siopal changed by 1‰ in less than 2 kyr.

The changes in diatom productivity estimated from both δ⁴₀Siopal and δ¹₃C records, actually occur significantly prior to the change in δ³₀Siopal (~1 kyr). This also suggests that change in the N utilization do not occur at the same time as change in Si utilization. Overall, the degree of change (1.3‰) is greater than the isotope enrichment factor during the utilization of Si by diatoms (~1.1‰), so cannot be explained as only changes in the degree of utilization (this cannot be more than 100%). Secondly, the rate of change is similar to the mixing time of the oceans (~1500 years) and many times less than the residence time of Si in the oceans (~15 kyr), so cannot be related to changes in marine inputs to the oceans. The observed shift in δ³₀Siopal must be caused by a dramatic switch in provenance of waters coming into the Antarctic Sector of the Southern Ocean with distinctly different Si isotope compositions as well as any potential change in diatom productivity.

The FE-EMPA – Applications for the sub-micron analysis in geosciences

D. RHEDE
GeoForschungsZentrum Potsdam (GFZ), Potsdam, Germany,
(rhede@gfz-potsdam.de)

The use of a thermal field-emission cathode in an electron microprobe (JEOL Hyperprobe JXA-8500F) has opened a new window in the analysis of structures in the sub-micron range. Small electron-probe beam size (< 50 nm) with variable probe current (5–200 nA) at low accelerating voltage (5–10 keV) allow a sub-micron spatial resolution for single spot analyses and detailed X-ray mapping of composition contrast in the range of 100 nm. The results are afflicted by reduced intensities of the X-rays (high energy K-lines are not excited, demanding the use of L- and M-lines), peak overlapping, a higher current density, and contamination. The quality of the sample polish and the thickness of the coating layer are essential. New measurement strategies and unconventional approaches are required to overcome these problems.

A selection of examples should demonstrate the improved possibilities of the FE-EMP as a tool between conventional EMP and TEM:
- Measurement of the chemical composition and the internal zoning of exsolution lamellae and symplectite in feldspars.
- Characterization of small reaction rims in natural samples in order to study the transport mechanism for the rutile-titanite transformation via a fluid phase.
- Study of the complex, diffusion-controlled growth of orthopyroxene reaction rims (zonation of Fe and Mg).
- Investigation of inclusions in minerals (unaffected by their host) down to 500 nm size, depending on composition and density.
- “Chemical” age dating of Th–U-containing minerals occurring as microinclusions in other minerals.
- Characterization of complex zoning patterns of small areas in accessory minerals (zircon, monazite, xenotime, etc.).

Preliminary characterization of São Jorge island mantle source (Azores)

L. P. RIBEIRO¹, Z. FRANÇA²,³, B. RODRIGUES⁴
AND V. H. FORJAZ²,³

¹EMEPC – Estrutura de Missão para a Extensão da Plataforma Continental, Portugal, (luisapr@emepc.gov.pt)
²Depart. de Geociências da Univ. Açores, Portugal
³OVGA – Observatório Vulcanológico e Geotérmico dos Açores, Portugal
⁴Depart. de Geociências da Univ. Aveiro, Portugal

The Azores archipelago, formed by nine islands spread along the Azores Plateau, is situated in a complex tectonic setting, containing the junction of three tectonic plates, the American, Euroasiatic and Nubia plates. East of the MAR is located the central group island where São Jorge island developed (38°46' – 38°33'N and 28°20' – 27°45'W). This is an elongated shape island (WNW-ESE) with aligned volcanic cones and dikes unveiling the importance of the regional tectonic setting during volcanic activity. Stratigraphically, the island developed during three main volcanic phases (Forjaz & Fernandes, 1975), giving place to Topo complex in the SE, Rosais complex in the NW and to Manadas complex that covered the centre of the island.

São Jorge lavas are dominantly alkaline with Y/Nb ≤ 1.0, and experience some degree of differentiation extending from basanite and tephrite to basaltic trachyandesite composition. The analyses of REE and incompatible elements of the more primitive samples (Mg# ≥ 0.44 and Ni ≥ 110 ppm) can be good indicators of the petrogenesis of the three complexes.

The REE diagram shows LREE enrichment, relative to HREE, as is common in ocean island where garnet is present in the source. We also found, in Topo complex, differences between Caldeira and Cubres sequences as for instance REE ratios [(Tb/Yb)n] and incompatible elements patterns. Primitive lavas from Rosais, when compared with other lavas, are relatively enrich in La, Rh, Ba and Th contrasting with only a small K anomaly and relatively high Ba/Ce ratio. This could be explain if during partial melting Rosais lavas sampled a slightly different compositional source, constituted by a K enriched phase as reported in other Azores islands as Corvo (França et al., 2006) and Atlantic islands (Halliday et al., 1995, Ribeiro, 2001).

The question is how source composition and partial melting affected magma composition in these continuous lava sequences and the relation with the remaining Azores islands and seamounts in the Azores region.

Comparative study of geospeedometry methods
D. Richard, F. W. V. Aulock, K.-U. Hess and D. B. Dingwell
Department of Environmental and Earth Sciences, Ludwig-Maximilians-Universität, Munich, Germany
(richard@min.uni-muenchen.de)

Limitations of classical geospeedometry
The natural cooling rate of natural glasses is an important parameter in the assessment of volcanic hazards because it influences the degassing and flow behavior of lava. Relaxation of enthalpy (ΔH) has been successfully used to estimate cooling rates of natural glasses. This method consists of heating and cooling a glassy sample at various rates and using the Tool-Narayanaswamy model (1971) to obtain a natural cooling rate. It is however challenging to apply this technique to some glasses where the heat capacity (ΔH/ΔT) curves are not reproducible due to possible degassing and/or the ΔH/ΔT peaks are too small to be modelled.

An advanced dilatometric method
A method recently developed by Helo et al. (2006) considers the volume relaxation of multiphase samples during heating at a fixed rate, with the advantage of measuring samples containing only small amounts of glass. This method allows us to (1) estimate the calorimetric glass transition temperature (Tg_cal) and (2) measure the dilatometric glass transition temperature (Tg_dil), which corresponds to the softening point of the material. A pantellerite from Pantelleria, Italy, was heated through the glass transition. From length changes, we estimated a Tg_dil of 521°C, and from enthalpy changes measured with a scanning differential calorimeter, we obtained a Tg_cal of 524°C. These temperatures are identical within the precision of the instruments.

An alternative to classical geospeedometry
Moreover, repeated dilatometric heating at 10 K/min and cooling at 15 K/min revealed a gradual exponential increase in the Tg_dil from 625°C to 649°C, possibly due to water degassing. The first heating of the sample produced a Tg_dil of 611°C, which plotted below the trend produced by the subsequent measurements. We attribute this gap to the natural cooling rate, which we estimate to be about 10 K/min. This is the first time that a geospeedometry method considers changes in material properties to estimate a natural cooling rate. Classical geospeedometry assumes that Tg does not change through a series of cooling and heating treatments. However, we show that for some glasses, another method is required because Tg may change due to a number of processes such as degassing.

A thermodynamic model of uranium reduction by organic matter in the Proterozoic hydrothermal systems of Oklo (Gabon)
Laurent Richard and Aleyda Traoré
G2R, Nancy-Université, BP 239, 54506 Vandoeuvre-lès-Nancy, France (laurent.richard@g2r.uhp-nancy.fr)

Numerous geological, mineralogical, and geochemical studies have been carried out at and around Oklo (southeastern Gabon) over the last four decades, which have contributed to a better understanding of the reactions involved in the formation of these uranium deposits (e.g. Gauthier-Lafaye and Weber, 1989; Nagy et al., 1991; Cuney and Mathieu, 2000). The Oklo deposits represent one of the best examples of associations between uranium and organic matter, which raises the question of the role played by hydrocarbons in the reduction of uranium-VI to uraninite. The observation of uraninite crystals entrapped within solid bitumens in the Oklo uranium deposits led Nagy et al. (1991) to propose that a liquid, aliphatic-rich bitumen may have acted as a reductant to precipitate uraninite from hydrothermal solutions. Advances in theoretical organic geochemistry have led to the constitution of an extensive set of thermodynamic properties for solid and liquid organic compounds of geochemical interest (Helgeson et al., 1998; Richard and Helgeson, 1998), which makes it possible to investigate organic/inorganic interactions in geological processes.

A thermodynamic analysis has been made as a function of temperature, pressure, and oxygen fugacity of the reactions responsible for the formation of the uranium deposits at Oklo (southeastern Gabon). The generation of liquid hydrocarbons at 150°C as a result of the maturation of Proterozoic kerogens in the FB shales has been characterized and quantified with the aid of activity diagrams. Mass transfer calculations have been carried out to describe the alteration of U-bearing monazites and the mobilization of uranium by oxidizing hydrothermal fluids circulating in the FA sandstones, as well as the reduction of aqueous uranyl by the liquid hydrocarbons as a result of the mixing between the hydrothermal fluids and the petroleum. The latter calculations resulted in the simultaneous precipitation of uraninite and pyrobitumen, in agreement with the petrographical observations.

The massifs of the eastern Pyrenees have been the focus of a number of extensive studies and have made a significant contribution to our understanding of mantle composition and evolution. Specific problems remain, in particular the relationship between adjacent harzburgites and lherzolites, which have been proposed to be either; (1) melt depletion of an original lherzolite [2, 3] or, (2) refertilisation of a primary harzburgite by basaltic melt [1, 4].

Whole rock and clinopyroxene compositions of the peridotites and associated pyroxenites offer a means of resolving the nature of the relationship between harzburgites and lherzolites. Whole rock major and trace element analyses show that the lherzolites have a range of compositions while the harzburgites are relatively uniform. Laser ablation analyses of individual clinopyroxenes indicate some variation of lherzolite sample composition whilst harzburgites alone display marked LREE enrichment.

Whole rock 187Os-188Os values define a broad positive correlation with 186Re-188Os and indices of melt depletion (Al2O3 and S). Model ages derived from these correlations range from ~1.4Ga to ~1.5Ga. Re-Os isotope systematics alone define an errorchron corresponding to an age of ~1.7Ga. These model ages are all younger than those reported in the literature [3, 5], which previously suggested a melt depletion event across the Pyrenean suite at 1.9-2.4Ga.

U(VI) sorption on sandstone: Experiments and modeling
A. RICHTER, C. NEBELUNG AND V. BRENDLER

Forschungszentrum Dresden-Rossendorf e.V., Institute of Radiochemistry, P.O. Box 510119, 01314 Dresden, Germany (Anke.Richter@fzd.de)

Experimental
The sorption of U(VI) on natural and synthetic sandstone was investigated in batch sorption experiments (air atmosphere, 0.1M NaClO4, pH 3-11, [U(VI)] 10^-9-10^-4M. The synthetic sandstone was a mixture of quartz with muscovite and hematite. The surface area (N2-BET) of quartz was 0.047 m2/g, of muscovite 0.88 m2/g, of hematite 0.89 m2/g and of natural sandstone (mainly quartz) 0.69 m2/g.

Results and discussion
The pH dependence shows a maximal sorption between pH 5.5-7.5. The U(VI) sorption varied between 95% (10^-9M) and 7% (10^-4) on natural sandstone, and between 80% (10^-9M) and 2% (10^-4M) on synthetic sandstone. Fig. 1 shows the comparison of sandstone with pure components (at similar conditions) quartz, muscovite, and hematite. More U(VI) was adsorbed on natural and on synthetic sandstone, than on quartz. The higher sorption are caused by the other components muscovite and hematite, and by the higher surface area.

I will discuss three types of mass transport related isotope fractionations. 1. Isotope fractionation by evaporation of silicate liquids. 2. Isotope fractionation by chemical diffusion in liquids. 3. Isotope fractionation by thermal diffusion in molten basalt.

We (Richter et al., 2002 and work in progress) have carried out a large number of experiments on isotope fractionation during evaporation and find that it follows a Rayleigh fractionation law of the form \( R_i/R_{10} = f_i^{0.1} \) where \( R_i \) is the ratio of isotopes i and j when a fraction \( f_j \) of isotope j remains in the condensed phase and \( R_{10} \) is the original isotope ratio of the of the condensed phase. The fractionation parameter \( \alpha \) is the ratio of the isotopic composition of the evaporation flux to that of the substrate. In the case of magnesium evaporating from silicate liquid at 1400°C, (relevant to the evaporation history of Ca-Al-rich inclusions found in primitive meteorites), we find \( \alpha = 0.9910 \), which is significantly different from the often assumed value of \( \alpha = (24/25) = 0.9798 \) for the fractionation of \( ^{25}\text{Mg}/^{24}\text{Mg} \) in the evaporation residue.

We (Richter et al., 1999, 2003) reported the results of experiments for the isotopic fractionation of Li, Ca, and Ge (used as a Si analogue) during diffusion between molten basalt and rhyolite, and now have new data on the isotopic fractionation of Mg is this system. We have also carried out experiments on the isotopic fractionation of Li, Mg, and Cl during diffusion in water (Richter et al., 2006). The results are reported in terms of the exponent \( \beta \) in \( D_i/D_f = (m_j/m_i)^\beta \), where the \( D_i \) is the self diffusion coefficients of isotope k and \( m_j \) is its atomic mass. For molten silicate we found \( \beta_{^{7}\text{Li}/^{6}\text{Li}} = 0.215, \beta_{^{44}\text{Ca}/^{40}\text{Ca}} = 0.075, \beta_{^{26}\text{Mg}/^{24}\text{Mg}} = 0.05, \beta_{^{7}\text{Li}/^{7}\text{Li}} \leq 0 \). In water \( \beta_{^{7}\text{Li}/^{6}\text{Li}} = 0.015, \beta_{^{37}\text{Cl}/^{35}\text{Cl}} = 0.025, \beta_{^{26}\text{Mg}/^{24}\text{Mg}} = 0 \). Note the very much smaller fractionations in water.

Our most recent experiments involve isotopic fractionations by thermal diffusion (often also called Soret diffusion). We are finding surprisingly large isotopic fractionations (~8‰ for \( ^{26}\text{Mg}/^{24}\text{Mg} \)) associated with a change of only about 150°C across molten basalt. We are in the process of determining the thermal isotopic fractionation factors of the other major elements in molten basalt.

**Deglacial rearrangement of carbon and nutrients in surface and intermediate depth waters**

R.E.M. Rickaby 1, D.J. Harding 1, G. Bayon 2, and I. R. Hall 3

1Department of Earth Sciences, Parks Road, Oxford, UK OX1 3PR (Rosalind.Rickaby@earth.ox.ac.uk)

2Departement Geosciences Marines, IFREMER, 29280 Plouzane, France

3School of Earth, Ocean and Planetary Sciences, Cardiff University, Cardiff, Wales, UK CF10 3YE

Changes in the pattern of conveyor circulation, reconstructed from the combined nutrient proxies Cd/Ca and \( \delta^{13}\text{C} \), have been implicated in abrupt climatic events of the last deglaci. But, the assumption that characteristic endmember water mass signatures derived from southern nutrient rich surface waters close to sea ice, and northern nutrient depleted ice free surface waters, have remained invariant in time, has recently been called into question. We contrast new deglacial planktonic and benthic foraminiferal histories from intermediate depths in the high latitude North and Equatorial Atlantic with records from the South Atlantic and Pacific. The timing and amplitude of the deglacial minimum in \( \delta^{13}\text{C} \) of atmospheric CO\(_2\) from Taylor Dome, is captured by the surface \( \delta^{13}\text{C} \) records. The surface \( \delta^{13}\text{C} \) minimum is paralleled at intermediate depths in the high northern latitudes throughout the early deglacial. This may indicate continued northern sourced ventilation with an altered endmember \( \delta^{13}\text{C} \) signature, which can account for the early deglacial warming documented in the North Atlantic. Globally, intermediate depth signatures converge to the same value at the start of the deglaciation. Our data are consistent with vertical fractionation of carbon and nutrients into a poorly mixed deep reservoir during the last glacial, which is reventilated at the deglaciation and the sequestered carbon mixed via the intermediate waters to the surface and atmosphere. Divergence between the surface and intermediate depth chemical signatures occur only during the Younger Dryas. Our results confirm that endmember water mass signatures change significantly on a glacial-interglacial cycle.
Seasonal variation of oxygen and organic carbon isotopes and skeletal aragonite from *Unionidae* in the Rhine river

¹University of Cologne, Department of Geology and Mineralogy, Cologne, Germany (wrieken@uni-koeln.de)
²The Petroleum Institute, Abu Dhabi, U.A.E. (tsteuber@pi.ac.ae)
³Institute of Age Determination and Isotope Research, University of Kiel.

Seasonal variations in the oxygen and carbon isotopic composition of Rhine River water were compared with the isotopic record from recent and historical specimens of freshwater bivalves (*Unionidae*). The purpose of this study was to investigate these aragonitic bivalves as proxies for climate change. Seasonal variations in the river water δ¹⁸O are on the order of 1 to 2 ‰. During the summer, the run-off is dominated by Alpine melt-water, resulting in average values of -10 to -10.5 ‰, whereas the non-Alpine contribution is higher during winter, as indicated by mean δ¹⁸O values of -8.5 to -9 ‰. The δ¹⁸O of growth increments in the prismatic shell layer of *Unio crassus nanus* corresponds perfectly to what is predicted by known fractionation of ¹⁸O between water and aragonite. Variations in δ¹⁸O and the river water temperature are faithfully recorded by relatively large growth increments during summer. The isotopic signatures of individual flood events are also recorded in the shells. In summer, snowmelt-related Alpine waters with low DIC contents and heavy δ¹³C lake productivity signals (-9 ‰) were observed at Cologne. In winter, however, the components of the non-Alpine Rhine dominate the discharge at Cologne. Waters had light δ¹³CDIC signals of –11‰ soil respiration in the non-Alpine zone. Sampling of Lake Constance waters showed the effect of bioproductivity in the summer surface water. Bioproductivity is related to the withdrawal of light organic carbon and has a positive δ¹³CDIC increase of 2 ‰ in the surface waters.

Speciation of Cu and Zn in natural hydrothermal boiling systems: Evidence from fluid inclusion studies by X-ray absorption techniques

K. RICKERS¹²³, J. CAUZID³, J.-L. HAZEMANN⁴, O. PROUX⁵ AND V. LÜDERS²

⁵LGIT, UJF CNRS, Grenoble, France; (olivier.proux@esrf.fr).

Metal speciations in fluids are responsible for the partitioning of metals into the liquid and vapour phase during fluid phase separation and can lead to major changes in fluid compositions of hydrothermal systems. Here we present data for the partitioning behaviour of Cu and Zn in coexisting liquid and vapour phase fluid inclusions formed by sub-critical phase separation. Synchrotron-radiation induced micro X-ray fluorescence analysis (SR-XRF) and temperature-dependant X-ray absorption near edge structure (XANES) experiments were performed on individual inclusions. The studied fluid inclusion boiling assemblages are hosted in quartz from miarolitic cavities of the Torres del Paine granite complex (Chile). The formation temperatures of hydrothermal quartz in vugs range between 280°C and 340°C.

SR-XRF element maps revealed that Cu and Zn show a contrasting partitioning behaviour: while Cu is dominantly detected in vapour-rich inclusions, zinc is more abundant in brine-type inclusions.

XANES experiments were performed at temperatures up to 460°C using a Linkam THMSG-600 heating-stage. Measurements were carried out at ID22 and FAME, ESRF with spot sizes of 4 and 15 µm, respectively. In vapour-rich inclusions, most of the Cu is concentrated in daughter crystals. During heating runs, the daughter crystals dissolve and Cu oxidation state changes between 190°C and 280°C from Cu²⁺ to Cu¹⁺. While Cu²⁺ seems to be coordinated with water ligands forming the complex Cu[H₂O]₆²⁺, Cu¹⁺ is coordinated by two chlorine ions forming Cu[Cl₂]⁻. In brine-type inclusions, Cu is contained in the liquid phase. XANES-spectra show that Cu dissolved in brines has an oxidation state of 2⁺ between 25°C and 460°C. These findings are in accordance with the interpretation that at temperatures of phase separation Cu¹⁺ species is more stable and responsible for the concentration of Cu in the vapour phase.

XANES spectra indicate that Zn is most probably complexed as ZnCl₄⁻ in the temperature range 25 –370°C for both, liquid and vapour rich inclusions. This shows that in contrast to Cu, changes in speciation are not responsible for the partitioning of Zn into the liquid and the vapour phase.
Numerous studies have documented the sources and behaviour of Nd in the present day ocean providing a background for paleoceanographic interpretations. In contrast, much less information is available on Hf isotopes. As a consequence, there is still an ongoing debate on the sources of Hf in seawater.

We present isotopic compositions for the dissolved Hf and Nd in seawater samples taken on a transect from the Bay of Biscay to Cape Town (RV Polarstern cruise ANXXIII/1 in 2005). Hafnium and Nd were pre-concentrated by iron co-precipitation from 70 to 140 liters of filtered (0.45 µm) seawater. Separation of Hf and Nd followed previously established ion chromatographic procedures. Hafnium and Nd isotopic compositions were measured by MC-ICPMS (Nu Plasma) with a 2σ external reproducibility of 0.65 and 0.3 ε - units, respectively. Sample sizes varied but were typically in the range of 5 to 7 nanograms of Hf.

Surface seawater as well as deep water samples extending to ~5,000 m, plot on the “seawater array” defined previously from measurements of ferromanganese crusts and nodules. Surface seawater isotopic compositions are rather uniform for Hf and Nd at most sampling locations ranging from +0.1 to +1.7 in εHf and from -12.1 to -11.5 in εNd. Two locations at 22.5°N and 10.5°N show less radiogenic compositions in the subsurface (εNd down to -12.9 and εHf down to -0.8).

Deep water compositions range from +0.8 to +4.2 εHf. The εHf variations with depth in the different profiles generally follow the patterns observed for εNd. The overall variations in deep water Nd isotopes in our data set is twice as large as that of Hf isotopes (εNd between -13.9 and -7.9) but the spread in Hf isotopes of some depth profiles is significantly larger than for Nd.

Particularly unradiogenic Nd signatures are found in the Angola Basin, where εNd is as low as -15.4. This may reflect inputs from the Congo River or sediment seawater exchange within the basin. Hafnium isotopes, however, do not show such a shift.

Neodymium isotopes are in general agreement with the results of earlier studies. Antarctic Intermediate Water, however, has been sampled at three locations where it is clearly less radiogenic (εNd = -11.1, -13.9 and -11.4) than reported before (εNd = -8.9 to -6.2).
Greenhouse gas driven hyperthermals of the Paleogene: How much carbon, how fast?

A. RIDGWELL1, K. PANCHUK2 AND L. KUMP2

1School of Geographical Sciences, University of Bristol, Bristol, UK (andy@seaq2.org)
2Dept. of Geosciences, Penn State, University Park, PA, USA (kpanchuk@geosc.psu.edu, kump@geosc.psu.edu)

Terrestrial and marine deposits from the early Cenozoic record a 55 million year old transient warming of the Earth’s surface, dubbed the ‘Paleocene/Eocene Thermal Maximum’ (PETM). The occurrence of a prominent carbon isotopic excursion indicates massive release to the ocean and atmosphere of CO2 and/or CH4, thought to be similar in magnitude to current fossil fuel reserves. The PETM thus represents a potentially compelling analogue candidate for future greenhouse gas driven global change. In particular, understanding this event could provide us with invaluable insights into key mechanisms of feedback between climate and global carbon cycling as well as what the long-term impacts on calcifying plankton and animals of surface ocean ‘acidification’ might be. However, the parallels that can be drawn with anthropogenic climate change hinge critically on the magnitude and time-scale of the greenhouse gas forcing of this hyperthermal event.

Here we apply an Earth system model (GENIE-1) to the interpretation of the marine geologic record of the PETM and tackle the question of what the rate and total input of carbon to the ocean and atmosphere might have been.

Surface structural modeling at the solid-solution interface of nanocrystalline anatase

MOIRA K. RIDLEY1, MICHAEL L. MACHESKY2, DOUGLAS A. BLOM3, LAWRENCE F. ALLARD3 AND VINCENT A. HACKLEY4

1Texas Tech University, Lubbock, TX (moira.ridley@ttu.edu)
2Illinois State Water Survey, Champaign, IL (machesky@uiuc.edu)
3Oak Ridge National Laboratory, Oak Ridge, TN (blomda@ornl.gov, allardlfjr@ornl.gov)
4National Institute of Standards and Technology, Gaithersburg, MD (vince.hackley@nist.gov)

To begin to assess the effects of particle size on the surface reactivity and charging of metal-oxide nanoparticles in aqueous solutions comprehensive experimental and characterization studies were completed. Commercially available crystalline anatase (TiO2) particles were used in the study. Particle size ranged from 200 to 3 nm diameter, with corresponding BET surface areas of 10 to 350 m²/g, respectively. Potentiometric and electrophoretic mobility titrations of the anatase samples were performed in NaCl media at ionic strengths from 0.005 to 0.3 molality, at 25ºC. All samples were characterized extensively; using electron microscopy and aberration corrected electron microscopy (ACEM), neutron and X-ray small-angle scattering, and laser diffraction techniques.

A principle parameter obtained from the surface titration studies was the pH_{zpc} value. The pH_{zpc} of 40 nm diameter anatase particles (pH_{zpc} = 6.22) corresponded closely to previously published values; whereas, the pH_{zpc} value of 3 nm particles was higher (pH_{zpc} = 6.90). Furthermore, the development of positive surface charge was enhanced for larger anatase nanoparticles (>20 nm) over 3 nm diameter particles; in spite of this, the overall development of negative surface charge, relative to the respective pH_{zpc} values, was approximately the same for all particles sizes studied. At high ionic strengths the apparent pH_{zpc} value of the 3 nm particles was offset slightly toward lower pH values, which suggests some specific adsorption of the Na+ electrolyte ions.

Surface complexation modeling (SCM) was completed to rationalize the bulk surface titration data. The SCM’s incorporate all available molecular information (e.g., Ti-O bond lengths), with crystallographic information acquired from the ACEM. ACEM imaging revealed that the [100] face predominates on the 20 nm particles, and edges/facets include [010], [001], and [0-11]. A MUSIC model description of surface protonation permitted rationalization of the decrease in pH_{zpc} values with increasing particle size. Additionally, a Stern-layer representation of the EDL, and inner-sphere adsorption geometry of the electrolyte cation were also accounted for.
Fluid influence on retrograde assemblages in UHP eclogites

ASTRID RIEMANN, ANDREAS MÖLLER AND ROLAND OBERHÄNSLI

Institut für Geowissenschaften, Universität Potsdam, Germany
(ariemann@geo.uni-potsdam.de)

This study is a combination of modelling the phase stability, fluid availability and observations in ultra high pressure (UHP) rocks from the Chinese Continental Scientific Drilling (CCSD) project. We investigate the origin of the fluid and its influence on the mineral chemistry and (re-)equilibration processes for a better understanding of the retrograde PT-path. All investigated sample lithologies (eclogites, ortho- and paragneisses and schists) have been influenced by fluids to varying degrees. The main evidence for these fluids are different types of fluid inclusions, healed cracks, pro-and retrograde formation of hydrous minerals and late crosscutting veins. Retrograde assemblages in the eclogites range from UHP to greenschist facies. These form in centimetre wide zones that can be subdivided into a transition zone and a strongly altered inner part. While the fluid inclusion bearing assemblage garnet-omphacite-coesite-phengite-rutile reflects UHP conditions, albite-clinopyroxene symplectites appear in the first stage of retrogression as a response to post peak decompression. Garnet in the transition zone is cracked and rimmed by pargasitic amphibole, signaling fluid influence in the amphibolite facies. Fluid also triggers the breakdown of garnet and omphacite to an amphibole bearing symplectite and intergrowth of rutile and newly formed ilmenite. Phengite adjacent to omphacite breaks down to biotite, albite and white mica. The inner part of the retrograde zone is a greenschist facies assemblage with a new white mica generation, which contains fluid inclusions. Quartz and calcite veins crosscut the rock in a late stage of retrogression. These different stages of metamorphic reactions influenced by fluids allow new PT estimates for the retrograde path. This evolution indicates the influence of various fluids during the exhumation history that have a significant effect on (re-)equilibration.

Cd/Ca ratios of in situ sampled planktonic foraminifera

S. RIPPERGER1, M. REHKÄMPER2, R. SIEBEL3 AND A. N. HALLIDAY4

1Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, CH-8092 Zurich, Switzerland, (ripperger@erdw.ethz.ch)
2Department of Earth Science and Engineering, Imperial College, London SW7 2AZ, UK, (markrehk@imperial.ac.uk)
3School of Ocean & Earth Science, National Oceanography Centre Southampton, Southampton SO14 3ZH, UK, (rxs@soc.soton.ac.uk)
4Department of Earth Sciences, University of Oxford, Parks Road, Oxford OX1 3PR, UK, (alex.halliday@earth.ox.ac.uk)

The Cd/Ca ratios of fossil planktonic foraminiferal tests are of particular interest to paleoceanographers as they can be used to reconstruct past surface water nutrient utilization [1]. The reliability of this proxy has hitherto not been comprehensively studied, however. In order to fill this gap, we performed Cd/Ca analyses of planktonic foraminifera (G. ruber, G. sacculifer and G. bulloides) collected from the water column and from surface sediment samples at approximately the same locations. These analyses utilized an isotope dilution technique and a MC-ICPMS instrument equipped with a multiple ion counting system.

The Cd/Ca ratios obtained for G. ruber sampled from the natural habitat in the upper 80 m of the water column generally display a correlation with seawater phosphate content. No such trend, however, was observed for G. sacculifer and this indicates that vital effects may be responsible for the different Cd/Ca systematics of these species. Moreover, the results reveal differences in Cd/Ca between (i) specimens collected from their habitat (live specimens), (ii) settling shells (deceased specimens) and (iii) tests from surface sediments. SETTING TESTS OF G. RUBER EXHIBIT ABOUT 2-5 TIMES LOWER Cd/Ca VALUES THAN LIVE SPECIMENS. THIS SUGGESTS THAT Cd IS PREFERENTIALLY RELEASED DURING PARTIALLY DOLLS OF CALCIUM DURING SETTLING OF THE TESTS THROUGH THE WATER COLUMN. FOSSIL SHELLS OF G. RUBER DISPLAY Cd/Ca RATIOS THAT ARE UP TO 15 TIMES LARGER COMPARED TO RESULTS OBTAINED FOR SETTLING SHELLS FROM THE SAME SPECIES. THIS OBSERVATION IS MOST EASILY EXPLAINED, IF SEDIMENTARY TESTS ARE DEPOSITED IN MASS SINKING EVENTS THAT ARE ASSOCIATED WITH MUCH HIGHER SINKING VELOCITIES IN COMPARISON TO THOSE EXPERIENCED BY SINGLE SETTLING SHELLS. FURTHERMORE, THE Cd/Ca RATIOS OF G. RUBER, G. SACCUFILTER AND G. BULLOIDES FROM SURFACE SEDIMENTS ARE CONSIDERABLY HIGHER THAN THOSE OBTAINED FROM LIVE COLLECTED SPECIMENS FROM THE NATURAL HABITAT. POST-DEPOSITIONAL ALTERATION OF THE TESTS IS UNLIKELY TO BE RESPONSIBLE FOR THIS DISCREPANCY. A NUMBER OF ALTERNATIVE EXPLANATIONS ARE POSSIBLE BUT THESE REMAIN SPECULATIVE AT PRESENT.

Tracing the sources of carbon in the rivers of Lesser Antilles

K. Rive1, J. Gaillardet2, P. Agrinier1 and S. Rad3

1Lab. Géochimie des Isotopes Stables, IPGP, 4pl. Jussieu, 75005 Paris, France. (rive@ipgp.jussieu.fr)

At long timescales, the continental weathering of volcanic areas is one of the processes that control the atmospheric CO2 (e.g. Louvat, 1997, Dessert et al., 2003). However, the nature of the links between CO2 cycle and the chemical weathering of volcanic rocks is poorly known.

The CO2 consumption by chemical weathering can be estimated with the concentration of Dissolved Inorganic Carbon (DIC ≈ HCO3-) in the rivers. Nevertheless, some processes are likely to modify the DIC concentration in the river (e.g. equilibration with the atmosphere, precipitation of calcite, photosynthesis, respiration).

The processes governing the CO2 consumption by chemical weathering were studied in three volcanic islands in Lesser Antilles (Guadeloupe, Martinique and Dominica). The Lesser Antilles are ideal sites for the study of weathering due to their tropical climate and high relieves, inducing high weathering rates (Rad et al., 2006). Carbon stable isotopes of DIC and major elements chemistry were studied in streams, springs and soil solutions of these three islands during dry and wet season.

The δ13C of DIC and major elements concentrations, highly variable, allowed us to identify the origin of DIC as a mixing between soil CO2 (average value of δ13C = -29.1 ± 2.0‰) and volcanic CO2 (δ13C = -3.25 ± 0.25‰, Agrinier et al., 2002). In addition, we observed an equilibration process of the riverine DIC with the atmospheric CO2. Finally, as highlighted by Rad et al. (2006) for major elements, this isotopic study of the DIC cycling in the river demonstrates the importance of the volcanic fluids on chemical weathering processes.

Sedimentary 232-Th as a tracer of dissolved detrital inputs to the ocean

Laura F Robinson1, Taryn L Noble1 and Jerry F Mcmanus2

1Dept of Marine Chemistry and Geochemistry, Wood Hole Oceanographic Institution, Woods Hole, MA, 02543.
2Dept of Geology and Geophysics, Wood Hole Oceanographic Institution, Woods Hole, MA, 02543

This study uses long lived thorium isotopes as a tracer for dissolved detrital inputs to seawater. 232Th is derived exclusively from the partial dissolution of detritus. 230Th is produced at a predictable rate by the decay of uranium, and its subsequent removal by efficient adsorption onto settling particles provides a method to quantify dissolved 232-Th fluxes to the seafloor. Ten core-top sediment samples were treated with up to eight leaching techniques and a total digestion to determine the best method for the separating adsorbed from lattice-bound thorium. Adsorbed (and total) ratios giving high dissolved (and total) 232-Th fluxes were measured in sediments from locations with high expected detrital inputs. These fluxes are reasonable by comparison to global estimates of detrital inputs to the ocean. The half-lives of both thorium isotopes are long enough to allow us to apply this technique to sediments that span several glacial-interglacial cycles. Coupled with total sedimentary 232-Th fluxes this data has the potential to evaluate various proposed linkages between ocean and atmospheric processes in the past. Preliminary downcore results display higher 232-Th/230-Th ratios that are consistent with enhanced ice-age dust deposition in the central Atlantic, North Pacific and three out of four Southern Ocean sites. However the two- to four-fold glacial increases indicated by the thorium isotope proxy are smaller than the order of magnitude changes recorded in high latitude ice cores.
Crustal contamination of the upper mantle: Evidence from ophiolites

P. T. ROBINSON¹, R. TRUMBULL¹, S. KOSTROWSKI¹, J. ERZINGER¹, A. SCHMITT² AND R. EMMERMANN¹

¹GeoForschungsZentrum, D-14473 Potsdam, Germany (robinson@gfz-potsdam.de; bobby@gfz-potsdam.de; sankos@gfz-potsdam.de; ez@gfz-potsdam.de; emmermnn@gfz-potsdam.de)
²Department of Earth and Space Sciences, UCLA, Los Angeles, California (axel@argon.ess.ucla.edu)

Our studies of podiform chromitites in the Luobusa ophiolite, Tibet and the Semail ophiolite, Oman provide evidence that their mantle sources were contaminated by crustal minerals. The chromitites contain rounded, reworked grains of zircon, corundum, quartz, feldspar, diopside and amphibole(?). These are associated with moissanite (SiC), graphite, PGE minerals, rutile, Fe, Ti and Si alloys and native elements. Careful sample collection and preparation, and duplication of results in several laboratories rule out natural or anthropogenic contamination.

The zircon grains range from 20 to 300 µ across, are typically well rounded and have complex internal zonation. Rare grains are subhedral and have regular, concentric zoning. Some contain inclusions of quartz, rutile, orthoclase, mica, ilmenite or apatite. In situ ²⁰⁶Pb/²³⁸U dates by SIMS for the Luobusa zircons are very heterogeneous and range from 1657-549 Ma, far older than the ophiolite (~120 Ma), clearly indicating a mixed population of crustal protoliths.

The grains of quartz, corundum, feldspar and diopside range from 0.1 - 0.5 mm and are moderately to well rounded.

The morphology, composition and age of these minerals strongly suggest that they were originally derived from reworked sedimentary or metamorphic material transported into the mantle by subduction and later incorporated into the chromitites. Their occurrence with ultrahigh pressure minerals such as diamond, and coesite in the Luobusa ophiolite suggests derivation from depths of at least 100 km.

Olmec serpentinitic pieces from La Merced: isotopic and geochemical constraints

J. ROBLES-CAMACHO¹, H. KÖHLER², P. SCHAAF³ AND R. SANCHEZ-HERNANDEZ³

¹Instituto Nacional de Antropología e Historia, Mexico (jasinto_robles@yahoo.com, jadeite@hotmail.com)
²Institut für Mineralogie, Petrologie und Geochemie. L-M-U München, Germany (hermann-koeehler@hotmail.com)
³Instituto de Geofísica, UNAM, Mexico (pschaaf@geofisica.unam.mx)

Geoarcheology and petrological methods

The olmec (1,200 B.C. to 400 B.C.) was the first mesoamerican culture, characterized by extensive use of serpentinites (Heizer, 1961; Rodríguez and Ortiz, 2001). To know the geological provenance were performed XRF, ICP-MS, EM-WDS, and thermal ionization MS (Rb-Sr and Sm-Nd isotopic systems) on 17 archeological samples (SAO) from La Merced and 15 geological (GS) from Mexico and Guatemala.

Discussion of results

Mineralogy and geochemical composition (V, Zr, Zn, Cr, Ti; REE series) show a better correlation among SAO and GS from south Mexico. Likewise, Sr isotopic ratios for SAO ⁸⁷Sr/⁸⁶Sr (0.70567-0.71258) and the Nd isotopic system displays ε-Nd values from -5.4 to +6.6.

Conclusions

Petrological information indicate that only the Sierra de Juárez geological samples have affinities to the SAO objects from La Merced; near Vista Hermosa fault.

A depleted lithosphere component in the Hawaiian plume: Noble gas evidence from plume-related mantle xenoliths

A. ROCHELL 1, D. GÜNTHER 2, M. TRIELOFF 3, AND R. WIRTH 4

1Department für Geo- und Umweltwissenschaften, Universität München, 80333 München, Germany, (rocholl@min.uni-muenchen.de)
2Laboratory of Inorganic Chemistry, ETH Hönggerberg, 8093 Zürich, Switzerland, (guenther@inorg.chem.ethz.ch)
3Mineralogisches Institut, Universität Heidelberg, 69120 Heidelberg, Germany, (trieloff@min.uni-heidelberg.de)
4GeoForschungsZentrum Potsdam, 14473 Potsdam, Germany

Garnet pyroxenite (GPX) xenoliths from Salt Lake Crater, Oahu, are interpreted as high-P cumulates (60-90 kbars depth) of Hawaiian plume-derived basaltic melts [e.g. 1,2]. Two generations of secondary melt/ fluid inclusions document two distinct episodes of metasomatic overprint: (1) Young, immature and irregularly shaped “type-A” inclusions represent nephelinitic host magma, trapped along poorly sealed cracks during eruption some 0.3 Myrs ago. (2) Old, mature and polygonal “type-B” inclusions aligned along well-sealed cracks document pre-eruptive metasomatism of the mantle. LA ICP-MS analyses of “type-B” inclusions indicate high contents in siderophile and chalcophile trace elements including the PGEs. TEM and spectroscopic evidence shows that, after trapping, a highly reducing C-O-H-S-Cl-rich melt differentiated into a CO2-rich gas phase, “basaltic” glass and nm-sized “exotic” minerals including nano-diamond, native Fe and Cu, PGE minerals, and corundum [3]. Combined step-heating, TEM and isotope data reveal a distinct degassing behaviour of both inclusion types. Highly “depleted” [e.g. 4] noble gas signatures of type-B inclusions (40Ar/36Ar ≈ 12000, 3He/4He ≈ 7 R/Ra, 21Ne/22Ne ≈ 0.05, 20Ne/22Ne ≈ 12) indicate generation of the trapped melts within a depleted MORB-type mantle and are compatible with the presence of old, recycled, depleted lithosphere intrinsic to the Hawaiian plume, as also suggested by the Hf-Nd-Sr isotope systematics of the GPX host [1] which the melts infiltrated. Alternatively, the melts may have originated from upper mantle material incorporated into (or enveloping) the Hawaiian plume.

Interaction of gypsum and As(V)aq at different pH ranges

J.D. RODRÍGUEZ-BLANCO 1, A. JIMÉNEZ 1, S. GARCÍA-GRANDA 2, AND M. PRIETO 1

1Facultad de Geología. Universidad de Oviedo. C/ Jesús Árias de Velasco, s/n. 33005 Oviedo. (juanreygeo@geo.uniovi.es)
2Facultad de Química. Universidad de Oviedo. C/ Julián Clavería, 8. 33006 Oviedo. (sgg@fq.uniovi.es)

This research is focused on the study of As(V)-gypsum interactions in aqueous solution within different ranges of pH and concentration. The main goals of this study are: 1) to evaluate the capacity of gypsum to remove arsenic from aqueous solutions; 2) to understand the nature of the processes by which the removal takes place and, 3) to characterize the solid phases derived from these interactions. Although the mobility and toxicity of arsenic in the environment has been abundantly studied, the crystal-chemistry, thermodynamic properties and solubility products of arsenates continue to be poorly known. This lack of data is an important handicap because an in-depth study of arsenate mobility in natural systems requires a precise knowledge of the solid phases that may or may not precipitate, as well as their crystal-chemistry, and their solubility.

The study has been carried out at different pH ranges using batch experiments. The aqueous solutions were characterized by AAS, ion chromatography, and ICP-AES. The solids were characterized using SEM-EDS, powder, grazing incidence, and single-crystal XRD.

Figure 1: pharmacolite (CaHAsO4·2H2O) overgrowth on gypsum.

The results show that at high pH (>10.5) there is a virtually complete removal of As(V) due to the surface precipitation of amorphous Ca₈(AsO₄)₂·nH₂O and crystalline NaCaAsO₄·7.5H₂O. In contrast, the effectiveness of the uptake process is very low at lower pHs, as it involves the surface precipitation of different calcium arsenates (guerinite, sainfeldite, pharmacolite, ferrarisite). The study included determinations of solubility products, growth morphologies, and epitaxial relationships. In addition, structural characterization by single crystal XRD has been carried out for NaCa₂H(AsO₄)₂·6H₂O and NaCaAsO₄·7.5H₂O.
Modelling transfer of elements from the continent to the ocean at the large watershed scale in a tropical environment

C. ROELANDT, Y. GODDERIS, M.-P. BONNET, AND F. SEYLER

1LMTG, CNRS-IRD, Observatoire Midi-Pyrénées, Toulouse, France, (godderis@lmtg.obs-mip.fr)

Continental weathering of silicate rocks has been recognized as a major driver of climatic changes at the geological timescale. New evidences and preliminary modelling works [1] show that the impact of continental weathering on the geochemical cycles and climate might be non negligible at shorter time scales, from $10^2$ to $10^4$ years, with for instance an increase in total continental weathering by 12% from the LGM towards the present day [2].

Continental weathering at large scale ($10^6$ km$^2$) is generally described through parametric laws (see for instance [3]), linking weathering rates to mean annual air temperature and continental runoff. These laws are masking numerous other parameters, implicitly included, such as the role of vegetation and physical erosion. These laws generally overestimate weathering rates in tropical area, because of high local temperature and runoff. It was indeed stressed by Edmond et al. and others [4] that chemical weathering in tropical environment might be extremely low due to the development of thick soils undergoing weak physical erosion.

A coupled model of biospheric and weathering processes has been developed to estimate the transfer of elements to the ocean originating from tropical watersheds. The BERNI model is the result of the coupling of LPJ – dynamic global vegetation model [5] with the WITCH model [6] that estimates dissolution/precipitation of minerals in the soil environment from kinetic laboratory laws.

Here we present results obtained for the Orinoco watershed. Output of the coupled model includes major ion concentrations that are compared to available data, and CO$_2$ consumption through weathering for a tropical environment. We emphasize the need for the development of mechanistic numerical models of weathering processes working at the continental scale.

Microbial leaching of iron from magnetite under aerobic and anaerobic environments

YUL ROH, JONGMIN OH, YONGJAE SUH, AND HEE DONG JANG

1Chonnam National University, Gwangju, South Korea (rohy@chonnam.ac.kr)
2Korea Institute of Geoscience and Mineral Resources, Daejeon, South Korea

It is in its infancy to use bacteria as a novel biotechnology for leaching precious and heavy metals from raw materials. The objective of this study was to investigate biogeochemical processes of iron leaching from magnetite reduction by iron-reducing bacteria isolated from intertidal flat sediments, southwestern part of Korea. Microbial leaching experiments were performed using both Aldrich magnetite and magnetite ore, in well-defined media with and without bacteria under aerobic and anaerobic environments. Water soluble Fe production was determined by Inductively Coupled Plasma Spectroscopy (ICP) analysis of bioleached samples in comparison to uninoculated controls, and the resulting precipitated solids were characterized by X-ray diffraction (XRD) and scanning electron microscopy (SEM).

The pH typically decreased from 7.3 to 5.5 during 4-week incubations. The Eh of the initial medium decreased from ~ 40 mV to -550 mV under anaerobic environments upon incubation with the metal reducing microorganisms. Measured pH and Eh are consistent with the thermodynamic stability of ferrous iron formation. The decrease in pH is due to glucose fermentation producing organic acids and CO$_2$. The extent of iron leaching from magnetite in the aerobic conditions (Fe = 107 ppm) was higher than that in the anaerobic environments (Fe = 94 ppm). In the anaerobic conditions, Fe(III) in the magnetite was also reduced to Fe(II), but no secondary mineral phases were observed. Amorphous iron oxides formed in the medium under aerobic conditions where there was sufficient supply of oxygen from the atmosphere. This study suggests that the reduction processes involve dissolution-precipitation mechanisms as opposed to solid state conversion of magnetite to amorphous iron oxides. The ability of bacteria to leach soluble iron and precipitate amorphous iron oxides from crystalline magnetite could have significant implications for biogeochemical processes in sediments where Fe(III) in magnetite plays an important role in the largest pool of electron acceptor as well as the tool as a novel biotechnology for leaching precious and heavy metals from raw materials.
Provenance of Lower Cretaceous sediments from Svalbard and NE Greenland: A detrital zircon study

T.S. RÖHR1, T. ANDERSEN2 AND H. DYPVIK3

1Department of Geosciences, University of Oslo, P.O. Box 1047 Blindern, 0316 Oslo, Norway (t.s.rohr@geo.uio.no)
2(tom.andersen@geo.uio.no)
3(henning.dypvik@geo.uio.no)

Upper Jurassic – Lower Cretaceous sedimentary successions in the Wandel Sea Basin of North Greenland have previously been shown to correlate stratigraphically with similar aged formations on Svalbard, including the mainly fluvial Helvetiafjellet Fm (Dypvik et al., 2002). Detrital zircons from Lower Cretaceous sedimentary formations from the Wandel Sea Basin (Kilen and Peary Land) and Svalbard (the Helvetiafjellet Fm.) have been dated by U-Pb and analysed for Lu-Hf isotopes by laser ablation plasma source mass spectrometry (LAM-ICPMS). Samples from all three areas display a similar range of U/Pb ages, with significant zircon populations at 1.0 – 1.2, 1.8 – 2.0 and 2.6 – 2.8 Ga. Major hiatus occur between 2.1 and 2.4 and from 0.48 to 0.91 Ga. Low initial 176Hf/177Hf ratios indicative of recycled older crust are predominant in Caledonian-aged zircons, in the Palaeoproterozoic 1.8 – 2.0 Ga populations, and among late Archean zircons. Other U/Pb age populations in the studied samples are dominated by zircons with positive εHf values, indicating a significant contribution of mantle-derived material. There is commonly a narrow range of εHf values seen within the various U/Pb age population, and the values seen in the different samples are in general correlated with the different age populations. One exception is the 1.8 – 2.0 Ga population where variatations suggest variable sources for this age group. The U/Pb data indicate that Greenland could be the sole source of the studied sandstones, which to a large extent is supported by Lu/Hf data. However, concordant ages in the range 1.0 – 1.1 Ga are generally infrequent in the published record from Greenland, and no large terrane of this age have as yet been discovered in Greenland. This mismatch suggests the presence of a source outside the Greenland subcontinent.

The sedimentological link between Mesozoic sediments on Svalbard and North Greenland has been known for some time. This work demonstrates that the two areas most likely had the same areas of provenance, documented by near identical U/Pb age and Lu/Hf isotope signatures of detrital zircons.

Metal saturation in the upper mantle

A. ROHRBACH1,2, C. BALLHAUS1, U. GOLLA–SCHINDLER3, P. ULMER3 and D. SCHÖNBOHM1

1Mineralogisch–Petrologisches Institut, Universität Bonn, Germany (rohrbaa@uni–muenster.de)
2Institut für Mineralogie, Universität Münster, Germany
3Institut für Mineralogie und Petrographie, ETH Zürich, Switzerland

The uppermost mantle represented by samples and partial melts appears to be quite oxidized at oxygen fugacities (fO2) around the FMQ equilibrium. However, whether the oxidation states found in shallow mantle regions are representative for the entire upper mantle remains unclear. There is evidence for reduction with depth. Thermodynamic model calculations and analyses of natural garnet peridotite samples indicate that Fq2 in the upper mantle decreases with increasing pressure [1]. In addition, experiments have shown that phases stable in the transition zone (400 to 670 km) and the lower mantle (670 to 2900 km) can incorporate so much Fe3+ that an Fe–rich metal phase is likely to be stable [2,3].

To simulate redox controls in the upper mantle experimentally, we have equilibrated Fe2O3-free synthetic fertile mantle material in metallic Fe capsules between 1 and 14 GPa and 1220 to 1650°C. fO2 at run conditions, approximated from the FeO content of the silicates, are IW – 0.5 to –1.2. Analyses of pyroxene and garnet with Electron Energy Loss Spectroscopy (EELS) show that above 7 GPa, subcalcic pyroxenes and majoritic garnets incorporate so much ferric iron that a mantle composition with 8 wt.% FeO and 2000 ppm Fe2O3 will be within metal saturation. Hence, the earth’s upper mantle at > 250 km depth is likely to be saturated with an (Fe,Ni) metal phase.

It was proposed [3] that the high ferric iron concentrations noted in experimental transition zone and lower mantle phases may be derived by disproportionation of ferrous iron components in silicates, according to 3FeO = Fe° + Fe2O3. If this was the case for the upper mantle, the Fe°–Fe2O3–Fe3O4 triple point in the Fe–O system (at ~ 570°C at 10^5 Pa) should be shifted to higher temperature with increasing depth. An in–situ determination of the wuestite–magnetite phase transition between 0.5 and 5 GPa in the presence of metallic Fe in the MAX80 high pressure device, using white synchrotron radiation, shows that the disproportionation reaction has a negative slope in P–T space. Therefore, to relate the high ferric iron concentrations in upper mantle pyroxene and garnet to pressure–induced FeO disproportionation alone seems a simplistic view.

Oxygen isotopic composition in deep-sea coral, Lophelia pertusa
C. ROLLION-BARD 1, D. BLAMART2, J.-P. CUIF3, A. MEIBOM4, A. JULIET-LECLERC2 AND Y. DAUPHIN3
1CRPG-CNRS, Nancy, France (rollion@crpg.cnrs-nancy.fr)
2LSCE, CEA-CNRS, Gif-sur-Yvette, France
3Univ. Paris XI, Orsay, France
4Museum National d'Histoire Naturelle, Paris, France

The deep-sea coral Lophelia pertusa is a scleractinian coral (azooidaellate) found mainly in Atlantic Ocean. The stable isotopic compositions of their skeleton are frequently used to reconstruct paleocceanographic conditions, including seawater temperature. However, microanalytical techniques, i.e. microdrill and SIMS, have shown that the $\delta^{18}O$ in lines of centres of calcification (LCC) are strongly depleted relative to the surrounding fibrous skeleton. These large amplitude, small length scale isotopic variations cannot be driven by changes in environmental parameters. Several models have been proposed to explain the observed variations, including models based on pH variations of the hypothetical extracellular calcifying fluid (Adkins et al., 2003, Rollion-Bard et al., 2003).

To document clearly the oxygen isotopic behaviour against the structure and the pH, we have performed ion microprobe $\delta^{11}B$ and $\delta^{18}O$ profiles cross-cutting the two main structures of Lophelia pertusa (the $\delta^{11}B$ values are discussed in an abstract by Blamart et al. (this conference)). The $\delta^{18}O$ data range from -2.61 to 3.41 ‰, which is in the range of variation obtained by microsampling. The LCC $\delta^{18}O$ values range from -2.61 to -1.17 ‰, with a mean value of -1.93 ‰ (n=13). The $\delta^{18}O$ values for the surrounding fibres are systematically heavier, ranging from 0.45 to 3.37 ‰, with a mean value at 2.41 ‰ (n=19). So the $\delta^{18}O$ values appear strongly correlated to the microstructure of the coral skeleton.

It was thought that this different behaviour of the $\delta^{18}O$ between fibres and COC was principally driven by variations of pH. The $\delta^{11}B$ data performed in parallel profiles demonstrate that there is no correlation between $\delta^{18}O$ and $\delta^{11}B$, and therefore no correlation with pH. Moreover, it was presumed from $\delta^{16}O$ data that LCC should have a higher pH than surrounding fibres and it is the contrary. This implies that the LCC and surrounding fibres do not derive from the same calcifying fluid. Therefore LCC and surrounding fibres are precipitated by different mechanisms, most likely which are controlled by specialized domains of the calciclastic layer.

Lamproite-hosted xenoliths of Vestfjella: Implications for lithospheric architecture in western Dronning Maud Land, Antarctica
I. ROMU AND A. LUTTINEN
Department of Geology, P.O.Box 64, FI-00014 University of Helsinki, FINLAND (ilona.romu@iki.fi, arto.luttinen@helsinki.fi)

Lamproite-hosted xenoliths from Kjakebeinet (73º47’ S, 14º53’ W), south Vestfjella, represent unique samples of the unexposed continental crust at the rifted margin of western Dronning Maud Land. The xenolith suite indicates 1) heterogeneity of the crust, 2) granulite facies metamorphic conditions, and 3) mainly igneous protoliths. Two leucocratic tonalite gneiss samples yielded U-Pb SHRIMP zircon ages of ~1.0–1.3 Ga (J. Jacobs, personal communication, 2006). Interpretation of mineral–whole-rock Sm-Nd isotope data on mafic granulites is complicated by lamproite overprint. The results imply compositional affinity to Proterozoic lower crustal xenoliths from Lesotho, South Africa (Rogers and Hawkesworth, 1982) and equilibrium of the Sm-Nd system during Grenvillian and Jurassic magmatic events. Overall, the lamproite-hosted xenoliths indicate extension of the Proterozoic Maud Belt crust to Vestfjella. These results and the presence of basalt-hosted Archean xenoliths at the nearby Muren (Luttinen & Furnes, 2000) imply that the Kjakebeinet lamproites erupted probably just at the Archean-Proterozoic lithospheric boundary.

Experimental study of REE behaviour during apatite dissolution in presence of iron and organic matter

T. RONCAL-HERRERO, N. MATHIEU, J. SONKE AND E.H. OELKERS

LMTG, Université de Toulouse, CNRS, IRD, OMP, 14 Av. E. Belin, F-31400 Toulouse, France
(roncal@lmtg.obs-mip.fr; mathieunicholas@yahoo.fr; sonke@lmtg.obs-mip.fr; oelkers@lmtg.obs-mip.fr)

The absolute concentration and distribution of Rare Earth Elements (REE) in many natural aquatic systems is controlled by 1) the dissolution/precipitation rates and 2) the solubility of phosphate minerals (c.f. Poitrasson et al., 2004), which themselves may be influenced by the presence of iron colloids and aqueous organic acids. Taking account of the results of Kohler et al. (2005) the effect of iron colloids and dissolved organic acids on the behaviour of REE in natural fluids were determined by the dissolution of natural apatite (Ca₅(PO₄)₃F) in the presence of a variety of selected aqueous fluids. To best replicate natural system, experiments were performed in closed-system reactors at 25°C and pH 4 and 6. After a short initial period due to the presence of REE in the initial apatite, the reactive solutions become supersaturated with respect to rhabdophane (REE(PO₄)₆H₂O), which buffers total REE concentration and alters the REE spectra. Complimentary synthetic lanthanum rhabdophane (La(PO₄)₆H₂O) dissolution/precipitation experiments were used to determine the steady-state rates of this reaction and to determine aid in the interpretation of the apatite dissolution experiments.

Results to be presented will be used to assess the role of rhabdophane precipitation and the presence of iron colloids and dissolved organic acids during the chemical evolution of surface and near-surface waters. Further analysis of these results is used to access the applicability of aqueous REE speciation models to predict the composition of REE in natural waters.

Hydrochemical characteristics of surface water in two boreal granitoidic settings, Eastern Sweden

PERNILLA RÖNNBACK AND MATS ÅSTRÖM

School of Pure and Applied Natural Sciences,
University of Kalmar, SE-391 82 Kalmar, Sweden
(pernilla.ronnback@hik.se, mats.astrom@hik.se)

The Baltic Sea and its terrestrial surroundings consist of a unique environment due to the brackish water and still active land uplift (up to 8-9 mm/year). Consequently, the near-coastal catchment areas are characterised by young and unweathered soils. The overall aim of this study was to increase the understanding of the chemical dynamics that control water chemistry in small natural catchments in this region, with focus on spatial and temporal trends. The work was done within the Swedish nuclear waste programme and two different areas were studied: Forsmark which has a carbonate-rich till and Laxemar with a carbonate-poor till. One of these will be selected as a deep repository for spent nuclear fuel.

Surface water (lake and stream water) were collected and analysed for major elements, nutrients and trace elements (U and REEs). The water sampling period lasted for nearly four years and continuous flow measurement were carried out over the last two years. Repetitive seasonal cycles in surface water chemistry have been observed each year along with seasonal cycles in stream discharge. The major findings were: (1) the concentrations of elements derived from rock weathering increased in stream water during flow, (2) sporadic intrusions of brackish water from the Baltic Sea resulted in strong increase in salinity (Na, Cl-, Br-, SO₄²⁻), (3) a huge increase in biological activity during summer months resulted in decreased concentrations of NH₄⁺, NO₃⁻ and Si and increased pH and concentrations of chlorophyll a, O₂, DON, POC, PON and POP, (4) the U concentrations were high at both areas and a possible source is reduced U-minerals in the overburden due to the young and unweathered soil and (5) the REE concentrations were low and characterised either by an increase in relative concentrations throughout the lanthanide series (Forsmark) or flat patterns (Simpevarp), and were by speciation modelling predicted to be carried as organic complexes.
Surface charge, ion adsorption and molecular dynamics at the \(\alpha\text{-SnO}_2\)/water interface

\(^3\)Illinois State Water Survey, Champaign IL 61821, USA (machesky@uiuc.edu)

Introduction

It has been hypothesized that the bulk dielectric constant (\(\varepsilon\)) of the oxide solid influences the structure of interfacial water as well as the nature of ion sorption at the interface.\(^1\) To investigate this, we have studied cassiterite (\(\alpha\text{-SnO}_2\), with \(\varepsilon=9\)) using potentiometric titrations, quasielastic neutron scattering (QENS) and molecular dynamics (MD) simulations; and compare the results to previously obtained results for isostructural rutile (\(\alpha\text{-TiO}_2\), with \(\varepsilon=121\)).

Results and discussion

QENS experiments performed on nanosized powders of cassiterite and rutile, predominantly showing the 110 crystal face, indicated considerable differences in the dynamics of water molecules at the interface. Our MD simulation results showed excellent agreement with the measured relaxation times of interfacial water on the 1–100 ps time scale.

Titration showed that the charging of the cassiterite surface is of the same magnitude as for rutile. However, for cassiterite we obtained virtually identical charging curves in RbCl and NaCl media, whereas charging on rutile is clearly different in the different media. Results from MD simulations indicate that the distribution of Rb\(^+\)/Na\(^+\) on the two surfaces is quite different, thus providing an explanation for the observed differences. Significant differences are also observed for Sr\(^2+\) adsorption, while Zn\(^2+\) adsorption is similar on the two mineral surfaces.

Using O-H bond distances obtained in ab initio and MD simulations together with hydrogen bonding schemes obtained from MD, we constructed a surface complexation model based on the MUSIC model\(^2\) that was able to predict the observed charging and distribution of ions.

Phase and melting relations of a residual garnet clinopyroxene

A. ROSENTHAL\(^1\), G.M. YAXLEY\(^1\), D.H.GREEN\(^1\), J. HERMANN\(^1\) and C.S. SPANDLER\(^2\)

\(^1\)Research School of Earth Sciences, Australian National University, Canberra (anja.rosenthal@anu.edu.au)
\(^2\)Institute of Geological Sciences, University of Bern

Melting behaviour and high pressure phase relations of refertilised mantle comprised of mixed lithologies (e.g. discrete bodies of mafic eclogite or pyroxenites and diverse types of metasomatised, re-fertilised or depleted mantle) are poorly constrained, yet this information is essential for understanding the observed geochemical diversity of primitive magmas on Earth.

Our project is designed to explore the melting behaviour of subducted crust in an inhomogeneous, buoyant, upwelling mantle. We track a sequential process in which melts are redistributed from the (initially) low temperature melting of average oceanic crust, and then from the residues (garnet pyroxenite) until the solidus of the latter equals or exceeds the solidus of refertilised peridotite.

Composition Res-2 is the melting residue of an anhydrous altered MORB composition (GA2 of Spandler \textit{et al.}, submitted) at 5 GPa near the point of coesite out, and hence is a model for recycled eclogite which has lost a siliceous melt component during mantle upwelling. It is therefore depleted in incompatible minor elements, with 2.2 wt% Na\(_2\)O and a CaO/Na\(_2\)O ratio of 4.9. Res-3 is identical but has higher CaO/Na\(_2\)O ratio of 12.1.

The subsolidus phases of Res-2 & 3 are grt and cpx with accessory coesite/quartz. The solidus of Res-2 is at 1275°C at 3 GPa, 1400°C at 4 GPa, 1425°C at 5 GPa, and <1450°C? at 6 GPa. The solidus of Res-3 behaves similarly, but is at slightly higher T than that of Res-2 (1300°C at 3 GPa).

Low-degree melting (<10%) is eutectic-like. Once coesite is melted out, the grt-cpx cotectics control melt compositions and proportions with cpx>grt. However, with increasing degree of melting, cpx/grt ratios decrease until cpx is exhausted, leaving grt as the sole liquidus phase. In contrast, coesite-out for Res-3 remains approximately constant at ~50°C above solidus at all pressures. In residues of Res-3 the proportion of grt increases with P, and always exceeds that of cpx.

Melt compositions vary with increasing degree of melting from dacitic to basaltic for Res-2 at 3 GPa. However, at higher P, melts of Res-2 are generally much less silica rich, varying from andesitic to basaltic. This is similar to Res-3 at all pressures.

For both Res-2 & 3, Ti behaves incompletely in cpx at all P-T conditions, but D\(^{30}\)cpx/melt decreases toward higher temperature. Na however, is incompatible at 3 GPa, but compatible at higher pressures.

Late-stage removal of chalcophile elements from the mantle by sulfide liquid extraction to the core

L. ROSE-WESTON¹, D.C. RUBIE¹ and J.M. BRENNAN²
¹Bayerisches Geoinstitut, University of Bayreuth, Germany (lesley.rose@uni-bayreuth.de)
²Department of Geology, University of Toronto, Canada

The U-Pb chronometer reveals a more protracted age of Earth core formation (65-85 Myr; Halliday, 2003) compared to the Hf-W chronometer (30-50 Myr; Kleine et al., 2005). These long-lived isotopic systems are ideal for determining the timescale of core formation because the parent-daughter ratios are fractionated by metal-silicate segregation, with moderately siderophile W and slightly siderophile Pb following metallic liquid into the core. The discrepant timescales suggest that a strong U/Pb fractionation took place sometime during the accretionary history of the Earth, that did not affect the Hf-W system (Wood and Halliday, 2005).

Under reducing conditions in the early Earth, liquid Fe metal separated from liquid silicate to form the core. With oxidation of the lower mantle and the continued accretion of volatile-rich material, it is likely that the later stages of Earth differentiation involved the formation of a FeNi-sulfide liquid (O’Neill, 1991). It has been suggested that because Pb displays chalcophile behaviour (Jones et al., 1993), contrary to W (Chabot and Jones, 2005; Jana and Walker, 1997), removal of a small portion of this sulfide ‘Hadean matte’ to the core may have depleted Pb from the mantle, disrupting the U-Pb chronometer (Hart and Gaetani, 2006). The abundance of other chalcophile elements in the mantle would also have been altered by this process, such as Te and Se, useful in evaluating Earth differentiation processes.

Partitioning of Pb, Te, and Se between liquid metal and liquid silicate are presented at 3 GPa and 2233 K, in which the S content and O₂ are gradually increased. At IW-2, the partition coefficients (D) for Te and Se show a 3-fold increase with the addition of ~10 wt% S to the metallic liquid, with D₂g increasing from 104±18 to 324±68, and D₆e from 30±6 to 90±13. A marked increase in D₆e was observed by Ballhaus et al. (2006) with the addition of S at low pressure. Similar to Se and Te, higher pressures may increase the magnitude of D₆e, suggesting that segregation of some ‘Hadean matte’ equilibrated at high P-T conditions in a magma ocean, may have been a significant factor in disrupting the U-Pb age of core formation on the Earth.

Constraints on atmospheric H₂ from banded iron formations

MINIK T. ROSING¹ AND DENNIS K. BIRD²
¹Nordic Center for Earth Evolution, University of Copenhagen, Oster Voldgade 5-7, 1350 København K, Denmark. (minik@snm.ku.dk)
²Dept. of Earth and Environmental Sciences, Stanford University, Stanford 94305, CA, USA. (bird@pangea.stanford.edu)

Quartz-magnetite banded iron formations are ubiquitous throughout the Archaean geologic record. Models for the composition of the Archaean atmosphere and ocean must therefore be compatible with the widespread precipitation of magnetite from the ocean. At 25°C magnetite is stable relative to siderite only when the partial pressures of H₂ and CO₂ are so low that their reaction to form methane cannot sustain reproduction by methanogenic organisms (Sleep and Bird, 2007).

If we assume ocean temperatures ~ 25°C and a partial pressure of CO₂ in the atmosphere ~ present value, magnetite stability is only possible at H₂ pressures below ~0.0001 bar. At the maximum CO₂ pressures allowed by Precambrian palaeosols (Rye et al., 1995), the hydrogen pressure would be further 5 orders of magnitude lower.

The common presence of magnetite in Archaean sediments is therefore not compatible with models that favour an early Archaean atmosphere characterized by high hydrogen mixing ratios (Tian et al., 2005) or with suggestions that H₂ nourished an extensive biosphere prior to the evolution of oxygenic photosynthesis (e.g. Tice and Lowe, 2004).

Mississippian microbial carbonates: Test for the validation as proxy for marine REE geochemistry

B. ROSLEFF-SÖRENSEN, M. ARETZ AND H.U. KASPER
Universität zu Köln, Institut für Geologie und Mineralogie, Zülpicher Str. 49a, 50674 Köln, Germany
(Beke.Rosleff-Soerensen@gmx.de)

First results suggested that recent microbial carbonates are so far the best proxy material for the record of marine REE-patterns (Webb & Kamber 2000). The results were confirmed by further tests on Archean (Kamber & Webb, 2001, Kamber et al., 2004) and Devonian (Northdurft et al., 2003) microbial carbonates.

To further validate this proxy, REE and some additional trace elements of microbial carbonates were analysed from several locations from the upper Visean (Carboniferous) of England, Morocco, and Spain. Very clean microbial material was chosen by thin-section studies and analysed by ICP-MS. All samples show very smooth REE-patterns that perfectly display the REE-geochemistry characteristics of modern seawater as e.g. LREE depletion, positive La- and Gd- and negative Ce-anomalies. The nearly marine Y/Ho-Ratio as well as the contents of Zr, Sc, Hf and Th suggest very low terrigenous contamination.

While accompanying non-microbial carbonates show the same REE-pattern as the microbial ones, they have a significantly lower absolute REE content and are therefore less readily accessible for analysis.

Slight differences exist in REE content of the different locations. Potential interrelation with the local paleogeographic situation, e.g. by incorporation of variable degrees of terrigenous input require further examination.

Our data confirm the results by Webb & Kamber (2000) that microbial carbonates are so far the most reliable and additionally easiest accessible proxy for fossil marine REE-geochemistry. They do not show the fractionation problems of skeletal carbonates, incorporate high REE content and are overall relatively resistive to diagenetic overprint.

Further investigations to elucidate the possibilities of application to paleogeographic and paleooceanographic reconstructions are necessary.

Carbonate and anhydrite veins from altered gabbroic oceanic crust (Atlantis Massif, MAR 30°N)

M. ROSNER1, W. BACH1, B. PEUCKER-EHRENBRINK 2, J. ERZINGER3 AND B. PLESSEN3
1University Bremen, Germany, (mosner@uni-bremen.de)
2Woods Hole Oceanographic Institution, USA, (behrenbrink@whoi.edu)
3GeoForschungsZentrum Potsdam, Germany, (erz@gfz-potsdam.de, birgit@gfz-potsdam.de)

Atlantis Massif is an Oceanic Core Complex (OCC) that formed in the past 1.5-2.0 Myr at the intersection of the Mid-Atlantic Ridge and the Atlantis fracture zone. IODP Hole U1309D, drilled in the central part of the Atlantis Massif OCC, is the third-deepest hole in oceanic lithosphere with a core recovery of 75%. Gabbros and troctolites are the dominant rock types (92%), followed by ultramafic (~5%) and basicitic (~3%) rocks. The magmatic sequence is metamorphosed and fractured, and fluid flow during uplift resulted in the formation of several generations of late-stage veins that record sub-seafloor water-rock interactions. Below the diabase-dominated top section of U1309D carbonate veins are the most abundant late-stage vein type. Macroscopic anhydrite veins occur only at about 740 mbsf.

Carbon, O and Sr isotope compositions of the calcites do not vary systematically down-hole. The 87Sr/86Sr ratios are relatively unradiogenic and span a limited range between 0.7043 and 0.7051. Oxygen and C isotope ratios are both isotopically light displaying δ18O (VSMOW) values of about 10‰ and δ13C (VPDB) values of about -4‰. Oxygen isotope compositions of calcites yield minimum precipitation temperatures between 150° and 220°C (assuming seawater δ18O for the fluid). The temperature could have been significantly higher, if the fluid had exchanged oxygen with basement. For instance, if the δ18O value of the precipitating fluid was 2‰, like in the Rainbow hydrothermal fluids, calculated formation temperatures would be 30° to 50°C higher. In fact, Sr isotope ratios of the carbonate veins approach values for high-temperature hydrothermal systems such as Rainbow or Logatchev. Unlike in the calcites from detachment fault rocks from the 15°20'N Fracture Zone area, however, the calcites from Site U1309D lack carbon isotope signatures for thermal methanogenesis. Hence, temperatures were likely not higher than 300°-350°C.

Two massive cm-wide single anhydrite veins were recovered at about 740 mbsf at Site U1309D. For the anhydrite veins we obtained 87Sr/86Sr ratios of 0.70774 for core 150R3 and 0.70631 for core 153R3. As the Sr isotope composition of anhydrites from 1309D and 504B are similar we infer that 1309D anhydrites may also have formed in the down-flow limb of a hydrothermal convection cell, from seawater that has been heated to about 150°C and has had limited opportunity to exchange Sr with the basement.
Seismic constraints on deep Earth structure and mantle melts

SEBASTIAN ROST
Institute of Geophysics and Tectonics, School of Earth and Environment, University of Leeds, Leeds LS2 9JT, United Kingdom (s.rost@leeds.ac.uk)

Seismic results of recent years characterize Earth’s lowermost mantle to be highly heterogeneous on many scale lengths. Structures found using seismic means include sharp horizontal discontinuities (although strong topography on these might be present), thin ultra-low velocity zones (thin regions of strongly reduced seismic velocities), anisotropy and large anomalously slow regions with sharp vertical boundaries. Therefore, the lowermost mantle and core-mantle boundary region is a likely location of untapped, “hidden” reservoirs in the Earth which might be detectable by seismic means.

The scales of these heterogeneities span several magnitudes from 1000’s of km to the smallest detected structures with scalelengths of only a few 10’s of km. Smaller structures are likely and their detection depends on increased seismic resolution.

These results indicate a highly dynamic and complicated region that can only be understood by combining seismological, geochemical, geodynamical and mineral-physical results. Current models of the lowermost mantle, the D” region and the core-mantle boundary include the post-perovskite phase transition to explain the D” discontinuity and possibly other regional layers, partial melts to explain ultra-low velocity zones and chemically distinct regions to both explain large-scale and small-scale structures.

This presentation will highlight recent seismological results of the structure of the D” discontinuity focussing on the structure of the structure of the post-perovskite phase transition beneath the Cocos plate (central America). The second part of the presentation will focus on the fine scale structure of ultra-low velocity zones. The seismic data sampling ultra-low velocity zones can be well explained by the existence of dense partial melts in thin layers. Geodynamic modeling shows that ultra-low velocity zones could be the dominant structures at the edges of large-scale thermochemical piles as have been detected beneath the Pacific and Africa. These partial melts could be iron enriched and might be connected to plume genesis.

The Italian contribution to stardust

1Dip. Scienze Applicate, Università degli Studi di Napoli “Parthenope”, Napoli, Italy (rotundi@uniparthenope.it)
2INAF-Osservatorio Astrofisico di Catania, Catania, Italy
3INAF-Oss. Astronomico di Capodimonte, Napoli, Italy
4Novatech s.r.l., Città della Scienza, Napoli, Italy

We report combined micro-infrared, micro-Raman, and Field Emission Scanning Electron Microscope analyses of five particles collected by the Stardust spacecraft during its fly-by of comet 81P/Wild2 on 2 January 2004 and returned back to Earth on January 2006.

The CH2/CH3 ratios inferred from the infrared data are greater than those seen in organics in the diffuse interstellar medium, possibly indicating the presence of longer or less branched aliphatic chains. The micro-Raman data offer insights on the state of order of the carbonaceous component present in the particles. A comparison with spectra of Interplanetary Dust Particles (IDPs) and meteorites yields for most of the particles analyzed that the cometary carbonaceous material span a similar range to those of IDPs and the most primitive meteorites (see Figure 1).

Hydrated minerals seem to be present in one particle which seem to contain also carbonates, but further investigations with other techniques need to be performed to confirm these findings. Analyses interpretation is difficult because of the presence of aerogel mixed with the grain.

The analysed grains result to be: 1) rich in complex organic compounds; 2) compositionally and structurally heterogeneous. Suggesting that cometary particles consist of a mixture of subgrains of various sizes and compositions.

Figure 1: FWHM versus peak position for the G band measured for Stardust particles and IDPs (circles and triangles, LANDS team) compared to several IDPs (Wopenka 1988; Raynal et al. 2001) and Meteorites (Raynal et al. 2001).

Hydrated minerals seem to be present in one particle which seem to contain also carbonates, but further investigations with other techniques need to be performed to confirm these findings. Analyses interpretation is difficult because of the presence of aerogel mixed with the grain.

The analysed grains result to be: 1) rich in complex organic compounds; 2) compositionally and structurally heterogeneous. Suggesting that cometary particles consist of a mixture of subgrains of various sizes and compositions.

Diagenetic evolution of the Hooggenoeg Formation: Implication for Archean seawater composition

VIRGILE ROUCHON¹, BEATE ORBERGER¹,
AXEL HOEFMANN² AND DANIELE L. PINTI³

¹Université Paris Sud, Laboratoire IDIES UMR 8148, 91405 Orsay cedex, France. (virgile.rouchon@u-psud.fr)
²University of KwaZulu-Natal, Durban, South Africa
³UQAM-McGill-Geotop, Montreal, Canada

The reconstruction of the composition of the Archean atmosphere and ocean relies on scarce data and much theoretical modeling. We provide new constraints on this issue by studying the mineralogy and geochemistry of Archean sediments. The low-grade metamorphic Hooggenoeg Formation (HFm) of the Barberton greenstone belt is an extensive low-grade Palearchean volcano-sedimentary sequence, ideal for studying primitive diagenetic processes. The 3.45 Ga Upper HFm comprises a rhyodacitic volcanic complex with associated volcaniclastic sediments that locally overlie pillow basalts and hydrothermal orthochemical carbonaceous cherts. Detrital material was mainly derived from rhyodacites that were affected by an event of K-Si metasomatism prior to erosion. Phenocrysts, matrix and glass fragments were replaced by quartz-sericite-orthoclase and Ti-oxides still co-existing with primary apatite and zircon. After deposition, the detritus was cemented by early diagenetic microquartz. Silicification mainly resulted in SiO₂ dilution, as the trace element signatures (REE, HFSE) of the sedimentary source rocks were preserved.

Sandstones and conglomerates were affected by carbonatization (up to 40% vol.), as carbonate minerals replaced the diagenetic quartz cement and detritus. Three types of carbonate textures were sequentially formed: 1) Oscillatory zoned ankerite rhombs, 2) aggregates of ankerite-pyrite-sericite and 3) ankerite-calcite-albite-kaolinite. EPMA of carbonates revealed Na/Cl molar ratios of ~1 similar to seawater. The bulk δ¹³C_PDB of carbonates ranges from +1.9 to +2.3 ‰, typical of a marine origin. The δ¹⁸O_SMOW is homogeneous at +15 ‰, similar to deep-burial carbonates.

CAIs in Rumuruti chondrites

S. S. ROUT AND A. BISCHOFF

Institut für Planetologie, Wilhelm-Klemm-Str. 10, 48149 Münster, Germany (suryarout@uni-muenster.de)

Rumuruti chondrites (R-chondrites) are a group of chondritic meteorites that are highly oxidised, poor in metals, olivine rich (with high Fe content of ~39 mol%), and have high Δ⁴⁰Ca values. Barely any description of Al-rich objects has been reported till now (Bischoff and Srinivasan, 2003; Berlin, 2003). Here, we present the results of our search and analysis of CAIs and Al-rich objects in the R-chondrites.

We studied 14 R-chondrites (NWA 753, 755, 1472, 1476, 1477, 1478, 3364, Rumuruti, Dhofar 1223, Acfer 217, Dar al Gani 013, Hughes 030, Hammadah al Hamra 119, and Sahara 99537) and found 102 Ca,Al-rich objects (87 CAIs, 13 Al-rich chondrules and 2 spinel-rich fragments). Based on the mineralogical characterisation by SEM and electron microprobe the inclusions can be grouped into seven classes: (1) Concentric spinel-rich inclusions (30). These CAIs have abundant spinel and based on the presence or absence of major Al phases can be subdivided into three groups: (a) 18 CAIs dominantly consist of a spinel core rimmed by Al-rich diopside. (b) Five of the spinel-rich CAIs also contain abundant fassaite. These CAIs have a rim of diopside occasionally including olivine. (c) Within seven inclusions besides spinel abundant Na- and/or Cl-rich alteration products (probably napheline and/or sodalite) were observed within the cores rimmed by diopside and, rarely, by olivine. (2) One concentric hibonite-rich CAI has been found. (3) Concentric fassaite-rich CAIs have no rims and contain either hibonite or spinel and/or olivine and ilmenite as additional phases. (4) Complex spinel-rich CAIs are the most abundant variety of CAIs (30). Based on their mineral abundances these CAIs can be subdivided into four other groups: (a) Two inclusions have also abundant hibonite. (b) 29 inclusions are rich in plagioclase (anorthite and/or oligoclase), and contain either hibonite or spinel and/or olivine. Other CAIs have diopside rims. (d) Complex spinel-rich CAIs with abundant Na-Cl-rich alteration products (probably napheline and/or sodalite) were observed within the cores rimmed by diopside rimmed by olivine.

Constraints on lithospheric enrichment and crustal contamination in the central Rio Grande Rift (New Mexico, U.S.A.): Volatile and trace-element variability in basaltic melt inclusions

M.C. ROWE AND J. C. LASLTER
Department of Geological Sciences, University of Texas at Austin, Austin, TX 78712 (rowem@mail.utexas.edu)

Many basalts erupted during the early stages of rifting throughout the southwestern United States have a preferential enrichment in water-soluble elements relative to insoluble elements, e.g. Ba/Nb, K/Nb, and Sr/Nd. These high ratios are characteristic of “arc-like” or “subduction-related” basalts often found in volcanic arcs. Numerous studies have suggested that these basalts originate from melting of a mantle source that has undergone hydrous metasomatism as a result of shallow subduction of the Farallon Plate beneath western North America during the Laramide orogeny (80-40 Ma).

We have analyzed olivine- and orthopyroxene-hosed melt inclusions from Rio Grande Rift (New Mexico, U.S.A.) tholeiites and alkaline basalts for major-, trace-, and volatile-element concentrations in conjunction with whole rock geochemistry. If prior petrogenetic models requiring melting of hydrous metasomatized mantle are correct, then melt inclusions from lavas with an “arc-like” signature (e.g. elevated Ba/Nb or Sr/Nd) should be enriched in volatile species such as water and Cl.

In melt inclusions from Rio Grande Rift tholeiites and alkaline basalts Cl/K and Cl/Nb ratios broadly correlate with Ba/Nb and Sr/Nd. In melt inclusions with high Ba/Nb and Sr/Nd ratios (up to 32 and 31, respectively), Cl/Nb (~20-35) and Cl/K (0.04-0.08) ratios are also elevated. Similarly, tholeiitic basalts with lower Ba/Nb and Sr/Nd possess low Cl/Nb and Cl/K ratios (Cl/Nb 8-17; Cl/K 0.02-0.04), more consistent with ratios observed in fresh MORB (Cl/Nb 3-8; Cl/K 0.02-0.04). However, at a given Ba/Nb ratio, Cl/Nb ratios are generally low compared to melt inclusions from present day arc and backarc basalts from the Cascade range in western North America.

The observed correlation between Cl enrichment and “arc-like” trace element ratios is consistent with a model for generation of Rio Grande Rift basalts through melting of variably metasomatized mantle. However, partial melting and assimilation of continental crust could potentially produce qualitatively similar trends. No overall systematic variation in Ba/Nb, Sr/Nd or Cl/K is evident relative to the host Mg#, although within an individual sample host phenocryst compositions are restricted. Future in situ water and Pb-isotope analyses of melt inclusions will further constrain the role of crustal contamination and mantle source enrichment in the generation of the Rio Grande Rift basalts.

Sulfate reduction across a salinity gradient in hypersaline coastal pans

ALAKENDRA N ROYCHOWDHURY1 DONOVAN PORTER1 AND DONALD COWAN2
1Department of Geological Sciences, University of Cape Town, Rondebosch, 7700 Cape Town, South Africa (alakendra.roychowdhury@uct.ac.za; dporter@geology.uct.ac.za)
2Department of Biotechnology, University of the Western Cape, Bellville, 7535 Cape Town, South Africa (dcowan@uwc.ac.za)

The impact of salinity on the metabolic activity of sulfate-reducing bacteria in five highly saline to hypersaline coastal pans was studied using a radioactive tracer (35SO42-) technique. We recorded sulfate reduction at the higher in situ porewater salinity (422) than previously reported. The depth-integrated sulphate reduction rates (integrated to 12 cm) varied from 6 to 241 mmol m-2 d-1 and were also among the highest ever reported rates. The reduction rates decreased down-core and, surprisingly, were highest in the winter season when the lowest sediment temperatures were encountered.

High salt concentrations did not inhibit sulfate reduction rates. Rather, higher rates were measured at pans with higher in situ salinities. In laboratory slurry incubation experiments, sediments from the salt pans were treated with increasing salt concentrations. Regression analysis suggested that the short term response of microbial consortia to up-shock was an increase in sulfate reduction activity up to salinities of 350 – 400 and 200 – 300, in hypersaline and highly saline pans, respectively. Beyond these salinities, the cells showed evidence of reduced activities.

Surprisingly, sulfate reduction rates also show an increase with increasing sulfate concentration of up to 600 mM. This is unusual, as for sulfate reduction, the highest reported half-saturation constant values in the literature lie below 10 mM. Does this suggest that there is a third sulfate transport mechanism that becomes active among sulfate reducers thriving in hypersaline environments?
Migmatisation in the Central Alps lasting 10 m.y.

D. Rubatto1, A. Berger2, C. Gregory1, J. Hermann1 and M. Engi2

1Research School of Earth Sciences, ANU, Canberra 0200 Australia (daniela.rubatto@anu.edu.au; joerg.hermann@anu.edu.au; courtney.gregory@anu.edu.au)
2Institut für Geologie, Universität Bern, Switzerland (berger@geo.unibe.ch; engi@geo.unibe.ch)

The southern part of the Central Alps underwent Barrovian style metamorphism that reached partial melting at upper amphibolite facies conditions. Previous geochronological constraints indicated that melting occurred in the Oligocene, around 29-32 Ma, with cooling extending into the Miocene.

SHRIMP U-Pb dating of zircons from migmatite suite from the southern Central Alps yielded variable and distinct ages between circa 31 and 22 Ma. A similar age range is recorded by the U-Th-Pb system of allanite. This range in ages is found not only across different samples, but also within single samples. For example, a leucosome from the locality of Bellinzona contains zircon grains with inherited Permian cores remnants of the magmatic protolith. The cores are overgrown by three zircon rims with different internal zoning and chemical composition, which yield distinguishable ages at circa 31, 26 and 23 Ma. In the locality of Valle Arbedo (25 km to the E) similar migmatites show distinct zircon overgrowths at circa 31, 28, 23, and 22 Ma. For all of the zircon overgrowths the inclusions, trace element composition and Ti-in-zircon thermometry indicate growth in the presence of melt at similar temperatures between 600 and 700 °C. Therefore, we conclude that this region of the Central Alps repeatedly underwent melting at similar conditions over an extended period of at least 10 Ma.

These geochronological constraints support a model where episodic melting is controlled by the availability of aqueous fluids (Berger et al., 2007). Local infiltration of aqueous fluid in rocks of different composition thus produced diachronous melting episodes. The southernmost part of the Central Alps evidently remained at temperatures above the wet granite solidus for at least 10 million years.

New constraints on conditions of core formation and the light element content of the Earth’s core

D.C. Rubie and D.J. Frost

Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany, (dave.rubie@uni-bayreuth.de)

The concentrations of light elements in the Earth’s core must have been set by metal-silicate equilibration during core formation, as was likely the case for the moderately siderophile elements. It has been shown recently that equilibration conditions of core formation can be constrained by the partitioning of FeO between liquid Fe-alloy and silicate melt in a magma ocean, based on the mantle composition and the light element content of the core (Rubie et al., 2004; Asahara et al., 2007). This is because the partitioning of FeO into liquid iron increases strongly with increasing temperature (and therefore magma ocean depth), thus decreasing the FeO content of the mantle and increasing the O content of the core. Based on a simple core formation model, Asahara et al. (2007) estimated that the maximum depth of metal-silicate equilibration was ~1700 km, which would have resulted in a maximum of ~8 wt% oxygen in the core. However, lower limits could not be constrained because the oxygen content of the starting (chondritic) composition is poorly constrained.

Traditionally, experimental data on the metal-silicate partitioning of siderophile elements have been used to constrain the conditions of core formation, for which an estimate of the prevailing oxygen fugacity is required. However, for a given metal-silicate bulk composition, the oxygen fugacity is fixed by the partitioning of FeO, which is a function of pressure and temperature only. Therefore we are developing core formation models based on the combination of FeO and moderately siderophile element partitioning. The model bulk composition is chondritic with an initial oxygen content that can be varied. Liquid metal and liquid silicate are assumed to equilibrate near the base of a magma ocean (defined by the peridotite solidus) and the compositions and relative proportions of the two phases are calculated using mass balance combined with formulations describing the partitioning of FeO and siderophile elements as a function of P and T. The results enable new constraints to be placed on (i) conditions of metal-silicate equilibration and therefore magma ocean depth, (ii) the bulk oxygen content of the Earth and (iii) the oxygen content of the Earth’s core.

Fluid-rock interactions recorded by kinetic fractionation of Li isotopes

ROBERTA L. RUDNICK1, WILLIAM F. MCDONOUGH1, FANG-ZHEN TENG2 AND MICHAEL A. W. MARKS3

1Department of Geology, University of Maryland, College Park, MD, 20742, USA
2Department of the Geophysical Sciences, The University of Chicago, Chicago, IL, 60637, USA
3Universität Tübingen, AB Mineralogie und Geodynamik, D-72074 Tübingen, Germany

Li diffuses relatively rapidly through minerals and fluids and this, coupled with the large differences in diffusivities between its two isotopes (Richter et al., 2003), can lead to large kinetic isotopic fractionations parallel to the diffusion pathways. Thus, Li isotopes can be used to trace fluid-rock interaction. Here we summarize three different pluton-country rock settings that illustrate the controls and limits on kinetic Li isotopic fractionation. Lithium diffused over distances of >30 m from the Li-rich Tin Mt. pegmatite into metamorphic country rocks along fluid-filled grain boundaries accompanied by large, kinetically induced isotopic fractionations (>30‰, Teng et al., 2006). Li diffused over an order of magnitude further into the country rocks than other fluid-mobile trace elements (e.g., Na, Rb, Cs and Sb), making Li perhaps the most sensitive tracer of fluid-rock interaction among the lithophile elements. In contrast, metapelitic country rocks surrounding the Onawa granodiorite are not enriched in Li, reflecting the low Li content of the intrusion (45 ppm) relative to the country rocks (130 ppm) and hence the lack of a chemical potential gradient to drive diffusion. Indeed, Li content of the metapelites decreases by a factor of two adjacent to the pluton, reflecting the loss of Li during metamorphic devolatilization (Teng et al., 2007). The constant δ6Li in the country rocks is consistent with equilibrium fractionation during Li loss via Rayleigh distillation at the temperatures of metamorphism (>500°C). Finally, large, kinetic Li isotopic fractionations are observed perpendicular to the contact between an alkali syenite and granitic country rocks of the Ilímaussaq Complex, Greenland (Marks et al., 2007). Here, however, the syenite is barely enriched in Li relative to the country rocks (25 vs. 14 ppm, respectively), and this concentration difference is not large enough to account for the large isotopic fractionations observed over distances of up to 150 m (δ6Li ≥ −9 in the granite country rocks and ≤ +16 in the syenite). These large fractionations reflect the circulation of isotopically heavy, Li-bearing fluids adjacent to the syenite-granite contact.

Studies of continent stability using joint petrological and geodynamical models

L.H. RUPKE, N.S.C. SIMON AND Y.Y. PODLADCHIKOV

Physics of Geological Processes, University of Oslo, P.O.Box 1048 Blindern, N-0316 Oslo, Norway, (lars.rupke@fys.uio.no)

Continents are remarkably stable features of our dynamic Earth. Extreme examples of this are Archean cratons, which have resisted erosion by lithosphere delamination and mantle convection for billions of years. However, continents are not stable under all conditions. In fact, delamination of continental lithosphere has been related to intra-plate volcanism and uplift in the absence of shortening. The main goal of this study is to identify and quantifying the key factors that control the stability of continental lithosphere.

To simplify this task we regard lithosphere delamination as a Rayleigh-Taylor instability. Rayleigh-Taylor instabilities have been extensively studied analytically, numerically and experimentally - also with regard to continent stability. It is clear from these studies, that the growth rate of the instability is primarily controlled by the density and viscosity contrast. The density (and viscosity) contrast between the lithosphere and asthenosphere is a complex function of temperature, pressure and, often neglected, chemical and mineralogical composition. Chemical composition can vary significantly among different continents and it may well be that chemical and mineralogical variations determine if the lithosphere is gravitationally stable or not. To test this hypothesis, we use a joint petrological and geodynamical approach. The petrological model is based on a companion study (Simon et al. 2007 – this volume), which explores the dependence of mantle density on chemical composition using thermodynamics. The key metamorphic reaction for continental stability is the garnet-in reaction. The location of this reaction in p-T space is strongly dependent on the Cr2O3/Al2O3 ratio, while the amount of formed garnet mainly depends on the Al2O3 content. This suggests that relatively fertile mantle compositions rich in aluminum will tend to destabilize continental roots. To quantify the effect of mantle composition on continent stability, we will integrate thermodynamically computed densities for various mantle compositions into a geodynamic flow model. Using this joint petrological and geodynamical model, we will explore for which mantle composition continents are stable over geological time and define a critical enrichment for which continental lithosphere becomes gravitationally unstable.
Prebiotic chemistry in iron-rich water medium: Fixation of cyanide as Prussian Blue

M. RUIZ BERMEJO, C. MENOR SALVÁN, S. OSUNA ESTEBAN AND S. VEINTEMILLAS VERDAGUER
Centro de Astrobiología (CSIC-INTA). Ctra. Torrejón-Ajalvir km 4.2, Torrejón de Ardoz E-28850, Spain (ruizbm@inta.es)

Water based aerosols are ubiquitous in the actual troposphere and it has been suggested that they could play an important role as prebiotic micro-reactors in the origin of life. The salinity and pH of the aqueous phase may have an important influence in the gas-liquid interfaces, which are expected to be special sites for relevant prebiotic reactions (1). The presence of the Archean banded iron formations strongly suggests that dissolved iron (ferrous ion) was present in high quantities in the ancient sea and it has been postulated that the ancient sea had a salinity of the 1.5 to 2 times the modern value and its pH ranged between 4 to 10 (depending of the author).

In this work, we explore the effects of pH (between 5.8 to 9.8) in the generation of biomolecules in prebiotic simulation experiments using aqueous aerosols of saline iron rich solutions and spark discharges in a suitable prebiotic atmosphere.

In all experiments, we observed that the presence of ferrous iron leads the formation of Prussian Blue, a strongly reduction the final pH of the aqueous pool and the lack of small molecules in the raw of reaction. Under the assayed conditions the Strecker reaction is inhibited and the formation of heterocycles is stopped but a rich mixture of carboxylic acids is obtained (Fig. 1). Therefore, independently of the pH, in the studied range, the ferrous ion seems to have an important influence in the formation of the organics and their precursors.

Formation of high alumina phases in sediments and soils of different ages without inherited weathering products

HANS RUPPERT1 AND GEORG GRATHOFF1,2
1Geosciences Centre, University of Goettingen, Germany, (hruppert@gwdg.de)
2Department of Geology, Portland State University, USA, (GrathoffFG@pdx.edu)

We investigated the mineralogy and geochemistry of moraine forest soils in the former ice-covered granitic areas in Kings Canyon and Yosemite National Parks (Sierra Nevada, California), soils on sand dunes at the Pacific coast in Oregon (USA), as well as moraine profiles in the Dry Valley (Antarctica). The profiles did not contain any inherited weathered phases. So the neoformed phases represent the weathering products and help us decipher the weathering processes. Grain sizes of <0.2µm and 0.2-2µm were separated by plant debris. This trend is more pronounced in the 0-90cm section by plant roots and accumulation in the humic rich upper soil horizon. Inverse to that is the trend of the Al/Si ratios close to 1, which are approximately factor 5 higher than the ratios of the source material. Vermiculite is the main clay minerals formed during the last 10-20ky. The 60-80ky old soils in Kings Canyon additionally may contain gibbsite. Mobile nutrient elements such as K, Mn, Mg, and Ca are enriched in the uppermost horizons, because of mobilization by plant roots and accumulation in the humic rich upper soil section by plant debris. This trend is more pronounced in the older profile.

2. In the 120ka old soil profile of the sand dune in Oregon (pH around 5), the 0.2-2µm fractions in the 0-90cm section show Al2O3/SiO2 ratios close to 1, which are approximately factor 5 higher than the ratios of the source material. Vermiculite is the main clay minerals formed during the last 10-20ky. The 60-80ky old soils in Kings Canyon additionally may contain gibbsite. Mobile nutrient elements such as K, Mn, Mg, and Ca are enriched in the uppermost horizons, because of mobilization by plant roots and accumulation in the humic rich upper soil section by plant debris. This trend is more pronounced in the older profile.

Results:

1. In the soils of the Sierra Nevada with soil solution pHs around 6, the fraction 0.2-2µm has fairly high Al2O3/SiO2 ratios close to 1, which are approximately factor 5 higher than the ratios of the source material. Vermiculite is the main clay minerals formed during the last 10-20ky. The 60-80ky old soils in Kings Canyon additionally may contain gibbsite. Mobile nutrient elements such as K, Mn, Mg, and Ca are enriched in the uppermost horizons, because of mobilization by plant roots and accumulation in the humic rich upper soil section by plant debris. This trend is more pronounced in the older profile.

2. In the 120ka old soil profile of the sand dune in Oregon (pH around 5), the 0.2-2µm fractions in the 0-90cm section show Al2O3/SiO2 ratios close to 1, 20 times higher than that of the bulk material. In the section below 90cm, the Al2O3/SiO2 ratios increases to 4. Inverse to that is the trend of the Al/Si ratio in the separation solutions (0-90cm: Al2O3/SiO2 ratio of ~11, below 90cm: ~3). We suppose, that this dissolved or colloidal organic complexes extremely enriched in alumina are translocated from the upper soil horizon into the deeper profile facilitated by the enormous pore space. On the way down the organic ligands are oxidized leading to precipitation of Al-rich phases such as allophane and gibbsite.

3. The composition of the clay fraction of the profile from Dry Valley has low Al2O3/SiO2 ratios close to 0.3, which are close to that of the parent rock. The separation solution is higher in Si (0.7-5.1ppm SiO2) and lower in Al (0.0-0.7ppm Al2O3). No trends of the element contents with age (20ka, 200ka, 2000ka) are discernible. Although the soil solution has pH-values between 8.8 and 10.2, the chemical weathering is insignificant, presumably because of lacking plant material which promotes chemical weathering.

238U-230Th and 226Ra-230Th crystal ages at Volcán Quizapu: A prime location for studying magma mixing processes on short time scales

P. RUPRECHT1, K. M. COOPER2 AND G. W. BERGANTZ1
1Department of Earth and Space Sciences, University of Washington, Box 351310, Seattle, WA 98195-1310, USA (ruprecht@u.washington.edu; bergantz@u.washington.edu)
2Department of Geology, University of California, One Shields Avenue, Davis, CA 95616-8605, USA (kmcooper@geology.ucdavis.edu)

Despite significant innovation in textural, crystal-chemical analysis as well as U-series and diffusion age dating of igneous materials, the physical processes associated with measured time scales are unclear. For example, there is often discordance between diffusion ages and absolute ages of mineral separates derived from U-series (238U-230Th and 226Ra-230Th) disequilibria, and the two techniques may be measuring different processes. A simple system with well defined boundary conditions is necessary to understanding the information contained in ages measured by different techniques. We present U-series data for the historic eruptions of Volcán Quizapu, Chile, (5 km3 of lava in 1846/47 and 4 km3 of pumice in 1932). Both dacitic eruptions of Volcán Quizapu were accompanied by andesitic recharge magma. The lavas of the earlier eruption show extensive but incomplete mixing and mingling, while the plinian eruption of 1932 displays less interaction between the recharge and host magmas. 238U-230Th ages indistinguishable from the eruption age and Ra-Th ages of 2-3.5 ka for plagioclase and hornblende separates indicate a relatively short and simple magmatic evolution of Volcán Quizapu that stresses the dominance of short time scales processes associated with the magma mixing. This simplicity, along with the well-constrained repose time between the two major eruptions, makes Volcán Quizapu a perfect location to further investigate the information provided by diffusion and short-lived radioactive isotopic clocks. 226Ra-230Th dating of selected populations from the recharge and host magmas will allow us to integrate textural and crystal-chemical information with crystal ages. In addition, tracking changes in phenocrysts from recharge magma that were not evacuated during the first eruption, but remained in the reservoir and subsequently erupted in the second pulse has the potential to unravel the interplay between diffusion, crystal growth and resorption during a simple magma overturn.
Photoluminescence recovery upon annealing of fergusonite

K. RUSCHEL1, L. NASDALA1, M. GAFT2, C. SCHNIER3 AND J. SCHLÜTER4

1Institut für Mineralogie und Kristallographie, Universität Wien, Austria (katja.ruschel@univie.ac.at; lutz.nasdala@univie.ac.at)
2Physics Group, The Open University of Israel, Raanana, Israel (michael_g@itlasers.com)
3GKSS, Geesthacht, Germany (christian.schnier@gkss.de)
4Mineralogisch-Petrographisches Institut, Universität Hamburg, Germany (jochen.schlueter@uni-hamburg.de)

Fergusonite [general formula YNbO 4], due to its actinide content, is commonly found in the metamict state. In dry annealing experiments, the majority of structural recovery occurs at temperatures of >800 °C (Tomašić et al., 2006). This process involves intermediate formation of tetragonal α-fergusonite below ∼1000 °C and monoclinic β-fergusonite above this temperature.

We have studied changes in laser-induced photoluminescence (PL) spectra, which are dominated by emissions of centres related to rare-earth elements (REE), upon gradual reconstitution of the crystallinity. For this, a metamict fergusonite sample from Madagascar (Th 1.9 wt%, U 4.3 wt%) was subjected to dry annealing for 100 h at different temperatures. Analogous to observations on annealed zircon (Nasdala et al., 2002), annealed fergusonite yields considerably intensified PL (Fig. 1). General sharpening of bands at higher annealing temperatures is due to increasing crystal field effects and indicates recovery of the fine structure.

Figure 1: Photoluminescence spectra of natural and annealed fergusonite, dominated by trivalent REE (Nd, Er, Pr, Ho, Tm) emissions.

Worlds frozen in time:
Dawn explores 1 Ceres and 4 Vesta

C. T. RUSSELL

Institute of geophysics and planetary physics and department of earth and space sciences, university of california, los angeles, USA (ctrussell@igpp.ucla.edu)

Dawn is a low-cost planetary mission that uses ion propulsion to rendezvous with and orbit the two most massive members of the asteroid belt, 1 Ceres and 4 Vesta. Our current understanding of Ceres is based almost entirely on remote sensing while our understanding of Vesta is based predominantly on cosmochemical evidence obtained from the Howardite-Eucrite and Diogenite meteorites. These data suggest that these two bodies are quite dissimilar: Ceres being wet with perhaps a 100 km thick ice mantle covered with dust and Vesta being dry with a basaltic surface similar to the moon. Both bodies have clearly undergone thermal evolution to reach their current state but, we believe, did so rapidly in the first 1 – 3 million years of the early solar system well before the larger terrestrial planets were formed. The surfaces of these two survivors of the collisional environment established with the formation of the gas giants have remained frozen in time allowing the Dawn mission to effectively travel not only in space but also take us backward in time to learn the conditions at the earliest epoch of our solar system. Dawn carries redundant framing cameras, a visible infrared mapping spectrometer and a gamma ray and neutron detector. These instruments together with radiometric data provide geologic context, mineralogical data, elemental composition and internal structure. Vesta will be orbited in 2011 and Ceres in 2015.
Site-specific, size-dependent reactivity of Al-oxide nanoparticle surfaces

JAMES R. RUSTAD1, JIANWEI WANG1
AND WILLIAM H. CASEY1,2

1Department of Geology, University of California, Davis, One Shields Avenue, Davis, CA 95616
2Department of Chemistry, University of California, Davis, One Shields Avenue, Davis, CA 95616

We use molecular dynamics calculations to estimate water-exchange rates for a series of aluminum (oxy)hydroxide compounds. These include the Al(OH)64+ monomer; the ε-Keggin ion [AlO4Al12(OH)24(H2O)12]3+/8+ (Al13); the [Al2O2Al26(OH)26(H2O)26]18+ (Al30) aqueous polynoxocation; the surfaces of Al-oxyhydroxide minerals boehmite (AlOOH) and gibbsite (Al(OH)3); and the aluminosilicate mineral kaolinite (Al2Si2O5(OH)4). X-ray structural data can be used in conjunction with rate data from 17O NMR studies2 to test predictions of reactivity trends at a site-specific level. The molecular dynamics calculations here tie these structurally diverse systems together into a simple structure-reactivity trend based on Al-water bond lengths, and highlight the role of the Al13 and Al30 ions in systematically bridging the structural gap between the hexaaquo ion and the oxide surfaces.

Water-exchange rates were calculated for each species using the reactive-flux method. The rate constant is taken as k = kTST where kTST is the transition state rate constant and κ is the transmission coefficient. κ is highly variable across the spectrum of reactive sites, ranging from 0.1 to 0.001.

Overall, the estimates of τ298 for the aluminous minerals are surprisingly short, falling within the range of ~10−5–10−10 s, close to those for alkali and alkaline-earth metal ions. Waters bound at the edges of the minerals will exchange rapidly with bulk waters and with other ligands. The fast rates for these surface sites are consistent with the long Al-water bond lengths and also follow the general trend that rates increase, and ΔH‡ values decrease, with increasing size and decreasing charge/Al ion of the complex.

This framework provides, for the first time, a means for estimating kinetic parameters for individual sites at aqueous polynuclear ions and oxyhydroxide surfaces. This result is enormously important for environmental chemistry where treatment of reactions at the aqueous-mineral interface is a long-standing problem. The structure-reactivity relation presented here places the ligand-exchange properties of extended interfacial systems on a new site-specific, quantitative footing.

Potential temperature and volatile contents in mantle plume of Siberian trap province

I.D. RYABCHIKOV

Institute for Geology of Ore Deposits, Russian Academy of Sciences, 119017, Moscow, Russia, (iryab@igem.ru)

Magmatism in the Siberian CFB province is mainly represented by the voluminous lava flows of tholeiitic plateau basalts and subordinate amounts of highly magnesian volcanics and dyke rocks. These highly magnesian rocks are strongly enriched in incompatible trace elements and are characterized by high LREE/HREE ratios. It suggests that their primary magmas were near solidus melts formed at high pressures. P-T conditions of the generation of these hi-Mg melts must be nearly identical with the P-T parameters characterizing magma-generating mantle plume.

To assess the formation conditions of hi-Mg Siberian magmas we investigated melt and fluid inclusions in the phenocrysts of these rocks, which were analyzed for major and trace elements (EMPA and SIMS methods). High Ti/Na ratios and high normative olivine contents in the melt compositions recalculated to the condition of equilibrium with mantle peridotites imply, that initial pressure of magma-generation is in the range of 7–9 GPa.

Ion microprobe data for reheated melt inclusions in phenocrysts from Siberian rocks show low concentrations of volatile and fluid-mobile components. H2O/Ce ratios in melt inclusions from picrobasalts and meimechites are significantly lower than from MORBs and many OIBs. This implies that the source of Siberian magmas was even poorer in water by comparison with convecting mantle peridotites. The same relations are observed for the ratios of a number of other volatile and fluid-mobile components to their non-volatile geochemical analogues, like B/Ce, Pb/Nd etc.

Low levels of volatiles contents imply that the estimates of near-solidus transition temperatures based on comparison with volatile-free systems would not be changed significantly. Comparison of the estimated from melt inclusion data pressures with experimental data shows that the temperature of rising plume material was ca 400°C higher by comparison with convecting upper mantle at the same depth. This proves that plume material arrived from deep levels in the mantle.
Tracking subduction zone fluxes off slabs, across arcs, and into the mantle: B-Li isotopic evidence

JEFFREY G. RYAN

Department of Geology, University of South Florida, 4202 East Fowler Ave., Tampa, FL, 33620; (ryan@shell.cas.usf.edu)

New light element abundance and B and Li isotopic results from forearc settings and samples reflecting deep recycled mantle sources have begun to complete the picture of subduction zone chemical cycling for the fluid-mobile elements (FME). Progressive boron and FME declines with increasing metamorphic grade in forearc “subduction complex” massifs (i.e., Bebout et al 1999), are complemented by signatures observed in diapiric serpentinites and associated fluids erupting in the Mariana forearc, which preserve dramatic enrichments in B and select FME, but are not elevated in most large-ion lithophiles (Savov et al 2005). Declines in B and $\delta^{11}$B across volcanic arcs point to continued removal from slabs by metamorphism, and depleted B and $\delta^{11}$B in ocean island lavas suggest deeply recycled slabs are stripped of boron. B isotopic variations in forearcos point to extensive boron removal at low temperatures, as the $\delta^{11}$B of slab materials (~0 to -3‰ on average) are substantially lower than that of Mariana forearc serpentinites (+13 - +18‰; Benton et al 2004) or of B-enriched arc lavas. High $\delta^{11}$B releases at shallow depths indicate isotopic “lightening” of the slab, such that the $\delta^{11}$B systematics in arc lavas require inputs both of downdrugged forearc mantle materials with high B and $\delta^{11}$B, and of a B depleted, low $\delta^{11}$B slab component.

Li isotopic variations in the forearc mantle are divergent, with serpentinite muds showing uniform $\delta^7$Li indicating equilibrium with high $\delta^7$Li porefluids, while entrained ultramafic clasts record highly variable $\delta^7$Li. Relatively high $D_{Li}$ for mafic minerals (especially Mg-rich sheet silicates) combined with high Li diffusion rates result in exceptionally diverse $\delta^7$Li in mantle-derived ultramafic samples. However, $\delta^7$Li in young volcanic rocks from all tectonic settings are remarkably uniform, ranging from +3‰ to +6‰, indicating buffering by a uniform, Li-rich upper mantle reservoir, and/or limited Li isotopic change due to subduction zone chemical processing, despite evidence for Li and $\delta^7$Li depletion in eclogitic rocks (Zack et al 2003). Interestingly, substantial $\delta^7$Li changes can occur over time in lavas from “dying” subduction systems, suggesting that such changes may only be observed when processes that homogenize the mantle (i.e., wedge convection) shut down.

Chemical weathering in the Han River Basin, South Korea: Carbonate and silicate weathering

J.-S. RYU1, 2, K.-S. LEE1, H.S. SHIN1 AND H.-W. CHANG2

1Division of Isotope Geoscience, Korea Basic Science Institute (jsryu@kbsi.re.kr; kslee@kbsi.re.kr; h2shin@kbsi.re.kr)
2SEES, Seoul National University (changhow@smu.ac.kr)

This study focuses on the fluvial geochemistry of the Han River, South Korea to determine its chemical weathering rate and associated CO2 consumption rate. The Han River draining approximately 26,000 km$^2$ is the largest river in South Korea in terms of water discharge and the total river length, and consists of two major tributaries: the North Han River (NHR) and the South Han River (SHR). A remarkable difference in basin geology (silicate vs. carbonate) between the NHR and the SHR provides a good natural example to understand the processes of weathering and the influence of basin geology on water quality.

In this paper we report dissolved major elements and Sr isotopic compositions of a total of 58 samples collected seasonally from the Han River system for two years (2000 and 2006). A big difference in the concentration of dissolved loads is observed between the NHR and the SHR: the NHR is much lower in total dissolved solids (TDS), Sr, and major ion concentrations relative to the SHR, while higher in Si concentration and $\delta^{87}$Sr/$\delta^{86}$Sr ratios.

Using the forward model, it is calculated that the dissolved loads of the NHR are primarily from silicate weathering (55±11%) with relatively smaller portion of carbonate weathering (30±14%), whereas those of the SHR mainly from carbonate weathering (82±3%) with minor portion of silicate weathering (11±4%). These results are consistent with geological characteristics of their drainage basin: silicate rocks in the NHR vs. carbonate rocks in the SHR. Unlike the NHR basin, sulfuric acids derived from sulfide dissolution play an important role in carbonate weathering in the SHR basin because of widely distributed coal-containing sedimentary strata. Silicate weathering rate (SWR) of the NHR basin is much higher than that of the SHR basin, indicating higher CO2 consumption rate in the NHR basin.
U$^{4+}$ and Pu$^{4+}$ incorporation in zircon and their effect upon helium diffusion in the host lattice

I. SAADOUNE AND N.H. DE LEEUW

Department of Chemistry, University College London, 20 Gordon Street, London, UK, WC1H 0AJ
(i.saadoune@ucl.ac.uk, n.h.deleeuw@ucl.ac.uk)

Zircon mineral (ZrSiO$_4$) is a potential host matrix for the encapsulation of highly radioactive materials, such as dismantled weapons and nuclear waste from power stations (Ewing, 2001).

We report a detailed computer modelling study, based on interatomic potentials, to address two fundamental issues concerning radiation processes in the zircon mineral: first, the physics and chemistry of U$^{4+}$ and Pu$^{4+}$ inclusion in the crystalline matrix of zircon and, second, the effect of U$^{4+}$/Pu$^{4+}$ dopants on the incorporation and diffusion behaviour of helium in zircon.

Our results show that U$^{4+}$ and Pu$^{4+}$ can incorporate isomorphously in zirconium sites (Zr$^{4+}$). The solution energies of U$^{4+}$ and Pu$^{4+}$ are 0.18 eV and 0.03 eV respectively, which indicates that Pu$^{4+}$ is more readily incorporated as a dopant than U$^{4+}$. However, the positive solution energies show that the inclusion of the two species in the crystalline matrix would occur only under high temperature conditions.

Interstitial incorporation of helium in zircon is an energetically unfavourable process, which causes strong deformation in the host lattice due to movement of atoms in the channel walls to accommodate He. Moreover, the presence of Pu$^{4+}$ and U$^{4+}$ dopants in the zircon lattice has a direct effect upon the energetics of helium diffusion between interstitial sites. For instance, activation energies calculated for He diffusion are dependent upon the distribution of U$^{4+}$ and Pu$^{4+}$ in the lattice, and can differ by as much as 0.2 eV from those calculated for the perfect zircon.

Short-lived naturally occurring radioisotopes ($^{234}$Th, $^{7}$Be, $^{210}$Pb) as a tracer for particle transport in the Gironde fluvial-estuarine system (France)

H.-K. SAARI, S. SCHMIDT AND G. BLANC

UMR CNRS 5805 EPOC, Université Bordeaux1, Avenue des Facultés, 33405 Talence Cedex, France
(hk.saari@epoc.u-bordeaux1.fr,
s.schmidt@epoc.u-bordeaux1.fr,
g.blanc@epoc.u-bordeaux1.fr)

Human activities release various chemical species to the environment. Many of these substances bind strongly to sediments, which are then delivered to rivers. Thereafter the fate of pollutants in fluvial environments is linked to particle transport. The short-lived, naturally occurring radioisotopes, $^{234}$Th ($T_{1/2} = 24.1$ days), $^{7}$Be ($T_{1/2} = 53.3$ days) and $^{210}$Pb ($T_{1/2} = 22.3$ years), can be used as potential tracers to investigate particle transport from land to sea. However, up to now, their use is still rare and for $^{234}$Th mainly devoted to marine environments. Uranium ($^{238}$U) forms $^{234}$Th through radioactive decay in the dissolved phase. However, due to the typically low and invariable concentrations of $^{238}$U in riverine environments, the formation of $^{234}$Th is often insufficient to be used as a tracer.

The programme ARTTE “Application Radioisotopes as Tracers of particle transport in environment”, has been carried out to develop the application of $^{234}$Th, $^{7}$Be and $^{210}$Pb in the polluted (e.g. Cd, Hg (e.g. Schäfer et al., 2006)) Gironde fluvial-estuarine system (South-West France). A preliminary investigation in 2005 has revealed adequately elevated and spatiotemporally stable dissolved $^{238}$U activities within this system (Saari et al., submitted), allowing the $^{234}$Th application.

$^{234}$Th, $^{7}$Be and $^{210}$Pb activities in suspended materials were measured monthly (2006-2007) by $\gamma$-spectrometry within the Garonne and Lot Rivers, and the Gironde estuary. The first results reveal: (1) $^{7}$Be/$^{210}$Pb activity ratios decrease from river to estuary, due to aging of sediments and/or to resuspension of old bottom sediments (2) $^{234}$Th$_{ds}$ activities show large variabilities with time, from negligible values up to about 300 mBq g$^{-1}$, probably due to differences of particle residence time in the river channels.

The Formation of the Fe skarn deposit between Camibogazi and Arnastal (Gumushane, NE Turkey): Evidence from mineral chemistry

M. B. SADIKLAR1, F. SIPAHI2, H.-J. BERNHARDT3 and I. UYSAL1

1Jeoloji Müh., KTU, MF, Tr-61080, Trabzon; (sadiklar@ktu.edu.tr)
2Jeoloji Müh., KTU, GMF, Tr-29000, Gumushane; (sipahi@ktu.edu.tr)
3Zentrale Elektronen-Mikrosonde, Ruhr University, D-4801, Bochum

The Fe skarn deposit in the Camibogazi and Arnastal area is located about 50 km north of Gumushane in NE Turkey. The deposit is hosted by Late Cretaceous Carbonate rocks which comprise dolomitic and sandy limestone, and limestone, adjacent to the Eocene Zigana Granitoid [1]. Petrographically, granitoid consists of syenogranite, monzogranite, quartz-monzonite and granite. Fe skarn deposit has mineral paragenesis of vesuvianite (idocrase), phlogopite, diopside, andradite, actinolite, tremolite, epidote, quartz, magnetite, hematite and less pyrrhotite and pyrite. Vesuvianite, diopside and phlogopite mineralization are only seen in a very narrow field of the Camibogazi Plateau (altitude of c. a. 2450 m). Magnetite, hematite, andradite, actinolite, tremolite, epidote, quartz and less parroting and pyrite are seen in Aransas Plateau.

Microprobe analyses indicate that majority of the skarn minerals are calcic and have high Mg/(Mg+Fe). Clinopyroxene consists of diopside (Di0.66,99.04 Hd0.67-2.80 Jo0.29-0.55). Vesuvianite is mostly Mg-rich, and has very low MnO content (< 0.1 %). Phlogopite has high and nearly constant Mg/ (Mg+Fe) ratios, 0.93 to 0.94. The Ba content of phlogopite is low. Magnetite is generally massive, and some of them are martitization. According to vesuvianite-diopside geothermometry, the formation temperatures of skarn minerals in Camibogazi range from 329 to 558 °C.

The Fe exoskarn skarn deposit was characterized by early, high-temperature mineral assemblages dominated by anhydrous minerals diopside and garnet, and late low-temperature assemblages with hydrous minerals vesuvianite, phlogopite and epidote. Types of clinopyroxene and garnet, the abundance of magnetite with minor pyrite, and widespread occurrence of epidote suggest that the Fe skarn deposit between Camibogazi and Arnastal Plateau was formed under relativized oxidized conditions.

Modelling pore water B and $\delta^{11}B$ signatures in the shallow subduction zone forearc: Examples from Barbados, Costa Rica and N. Japan

DEMIAN SAFFER1 AND ACHIM KOPF2

1Pennsylvania State University, 310 Deike Building, University Park, PA 16802, USA – (dsaffer@geosc.psu.edu)
2Research Center Ocean Margins, Univ. Bremen, P.O.Box 330440, 28334 Bremen, Germany (akopf@uni-bremen.de)

At many subduction zones, pore water geochemistry from boreholes and mud volcanoes indicate a contribution from deep sources. These observations include pore water freshening, but enrichment in volatiles such as B and Li, and decreased $\delta^{11}B$, $\delta^6Li$, and $\delta^{37}Cl$. Identifying the location and distribution of source regions for these tracers is one critical step toward characterizing subduction zone fluid transport. Here, we present a simple model to combine (1) heating and compaction that accompany progressive burial of sediment in subduction zones with (2) previously published laboratory experimental data that constrain the distribution coefficient ($K_d$) for B in marine sediments as a function of temperature, to quantify the expected distribution of [B] $\delta^{11}B$ within bulk mudstones in subduction zones. In a generic subduction zone with a taper angle of 8º, we evaluate two end-member cases: a “cold” (60 mW m⁻²) and a “warm” (120 mW m⁻²) scenario. For the first, simulated values of [B] within the subducted sediment at 30 km from the trench range from 650–1200 µM and values of $\delta^{11}B$ range from 23.4-30.6‰. At 60 km from the trench, [B] ranges from 1010-3340 µM and $\delta^{11}B$ from 18.0-25‰. For the warm scenario, simulated [B] is 970-2400 µM at 30 km and 2250-11480 µM at 60 km; $\delta^{11}B$ ranges from 19.2-25.2‰ at 30 km and 15.92-19.5‰ at 60 km. These signatures are generally stronger than those observed in pore fluids at shallow depths, as would be expected due to probable re-adsorption of some B during updip or vertical advection. Ultimately, our results can be used for hydrologic models to quantitatively assess the fluid flow rates and permeabilities required to transport B at rates high enough to produce the observed signature.
The formation of calcium perovskite from majoritic garnet – Implications for splitting of the 520 km seismic discontinuity

A. SAIKIA, D.J. FROST AND D.C. RUBIE
Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Germany, (ashima.saikia@uni-bayreuth.de)

Global seismic observations show complexity in the region of the 520 km seismic discontinuity (Deuss and Woodhouse 2001). In some regions of the mantle this discontinuity seems to be split into two discontinuities at approximately 500 km and 560 km. In addition to the wadsleyite to ringwoodite transition, the exsolution of calcium perovskite (Ca-Pv) from majoritic garnet (gt) may be capable of producing a seismic discontinuity. This, however, would require the reaction to occur over a sufficiently narrow depth interval and to cause a significant change in elastic properties.

We have experimentally studied the calcium perovskite forming reaction in high pressure and temperature multi anvil experiments to determine if it is likely to cause an observable discontinuity. Experiments were performed by equilibrating Ca-free majorite gt with Ca-Pv to determine the saturation level as a function of pressure, temperature and garnet majorite content i.e. (Al/Mg+Si).

Experimental results show that because the reaction results in a strongly non-linear yield of Ca-Pv with pressure, a significant portion of the reaction is completed over a quite narrow initial depth interval. The sound velocity changes over this interval for a fertile peridotite composition are smaller but of a similar magnitude to those of the wadsleyite-ringwoodite transition and would likely cause a weak discontinuity at approximately 560 km in line with seismic observations. If, however, the mantle contained a significant component of recycled basaltic crust the higher mantle Ca contents would result in a much stronger discontinuity. For this reason the feature observed at 560 km will be sensitive to the proportion of basaltic components in the mantle at transition zone conditions and is therefore an indicator of chemical heterogeneity.

Fulgurites from Garuamukh, Assam, India – FTIR spectroscopic study

BHASKAR J. SAIKIA1, G. PARTHASARATHY2, N.C. SARMAR1 AND G.D. BARUAH1
1 Department of Physics, Dibrugarh University, Dibrugarh-786004, India: (vaskar_r@rediffmail.com)
2National Geophysical Research Institute, Uppal Road, Hyderabad-500 007, India (gpsarathy@ngri.res.in)

There are two phenomena that are responsible for making natural glass on Earth: meteorites and lightning. Glass that is made as a result of the collision of a meteorite with the Earth's surface is called meteoritic glass or tektite. Glass (a glassy object, to be exact) that is made as a result of a cloud-to-ground lightning discharge is called a fulgurite (from the Latin "fulgur" which means lightning). Fulgurites come in a great variety of forms and can be viewed as nature's own works of art. It is worth noting that lechatelierite (natural silica glass) is not present in obsidian, a glass-like material associated with volcanic activity. On the other hand, volcanic activity is known to generate lightning which, if it strikes sandy soil, may produce a fulgurite. The black-brown natural glass found at Garuamukh near Nagaon town (Lat.26°19´N, Long. 94°30´E, Assam, India) is due to the fourth category of formation. The colloidal material comes out from the earth's surface making a number of branching with fire and foul odour smoke and the upper part of it is gradually solidified to natural glass within a few hours. The solid material have been found to have a temperature of about 80 ºC even after a lapse of two days after occurrence of the event whereas the room temperature during that period was 28 ºC. The increasing of temperature is observed on the spot with the increasing of depth. In order to understand the possible meteoritic or fulgurite origin of the glassy materials, we made an attempt to characterize the sample by using FTIR spectroscopy, and powder x-ray diffraction. The present investigation of the naturally occurring glass sample reveals the characteristic features of amorphous silica with some other minerals as trace. As the structural change taking place in the octahedral symmetry in the formation of the sample so, the possibility of producing this silicate glass is by ultra high-temperature that is higher than the corresponding fusion point of the crystalline state, indicating the nature of a fulgurite.

On March 2, 2001, at 16:40 local time (GMT+5:30hrs), four fragments of a meteorite fell near Dergaon town (Lat. 16° 41’ N, long. 93° 52’E, Assam, India. Based on the petrography and chemical composition of the stony iron Dergaon meteorite has been classified as H5 chondrite. But from the chemical composition, the previous workers reported that the meteorite is an unusual H chondrite. In this present work we analysed the sample with the help of FTIR and Diffused Reflection Spectroscopy and found the SiO4 tetrahedron at 800-1100 cm⁻¹ and aliphatic functional CH₂ and CH₃ groups in the spectral region around 2800-3000 cm⁻¹. In 2800 – 3000 cm⁻¹ region (3.4 µm region), the hydrated and anhydrous interstellar dust particles attribute CH₃ and CH₂ stretching vibrations of aliphatic hydro carbons which is similar to the spectra found from the meteorite in this frequency region. The silicate grain in the interstellar medium and meteorites consist predominantly of olivine [(Mg,Fe)SiO₄] or of non-crystalline silicates of intermediate compositions associated with organic matter. The organic matter can extract the poly atomic carbon based molecules by crushing the MgO and (Mg,Fe)SiO₄ crystals. Generally four peaks are observed in this region. The symmetric CH₂ stretching vibration at 2850 cm⁻¹, symmetric CH₃ stretching vibration at 2865 cm⁻¹, asymmetric CH₂ stretching vibration at 2922 cm⁻¹ and asymmetric CH₃ stretching vibration found at 2958 cm⁻¹. The spectral features in the mid infrared region were found to be identical to that of the interstellar dust gain particles. Most of the strong IR absorption bands are due to olivine. Few weak absorption bands observed in the Dergaon meteorite are due to organic compounds present in the meteorite, the features observed in other H-chondrites by Lawless et al. (1972).

Experimental study on gas emission using fault rock core penetrating Atotsugawa fault, central Japan

TOMOHIKO SAITO AND HIDEMI TANAKA

Department of Earth and Planetary Science, University of Tokyo, Bunkyoku Hongo 7-3-1, Tokyo, Japan (tomohiko-s@eps.s.u-tokyo.ac.jp, tanaka@eps.s.u-tokyo.ac.jp)

Crustal gas-anomalies with earthquakes have been observed around active faults. However few experimentel studis have been done for this problem. Therefore fundamental processes are largely unknown. In order to examine the processes, grinding experiments were carried out under wet condition using two types of rocks taken from drilled core penetrating Atotsugawa fault: (1) Weakly Pulverized and Altered Rock (WPAR) and (2) Fault Gouge.

Result of the experiments show that positive relationships between surface area (ΔS) and amount of gas (n) (Fig.1). For hydrogen, the relationships can be expressed as: n = kΔS, which is in good agreement with those reported by Kameda et al., (2003). For methane, the relationships can be expressed as: n = A(1 - EXP[-kΔS]). The equation corresponds to solution: dn/dΔS = k(A - n). A will be max amount of methane contained in a sample and k shows degree of evolution of gas when samples are crushed. This diferencial equation indites that methane gas contained in the rock sample were released by fracturing and release ratio( dn/dΔS ) is proportional to (A - n), which means the amount of methane gas remains in the rocks.

Figure 1. Amount of released gases (methane and hydrogen) during wet grinding experiment.

Microstructural observation of thin sections clarified that fluid inclusions are abundant in quartz or calcite in granitic rocks, metasediments, and less in calcareous rock, which released methane gas by grinding. On the contrary, no fluid inclusion is observed in the minerals of andesite that did not released methane gas by grinding.

Combining experiment results and microstructural observations, we conclced that methane gases were included in fluid inclusion and released by fracturung minerals.

Adsorption behavior of gold (I and III) complexes on manganese dioxide

S. SAKOMOTO1, K. YONEZU1, T. YOKOYAMA2, Y. OKAUE3, A. IMAI4, and K. WATANABE1

1Dep. of Earth Resources Engineering, Kyushu University. 744 Motooka, Nishi-ku, Fukuoka 819-0395, Japan. sakomoto-sachihiro@mine.kyushu-u.ac.jp
2Dep. of Chemistry, Kyushu University, 4-2-1 Ropponmatsu, Chuo-ku, Fukuoka 810-8560, Japan.

It is essential in geochemistry to elucidate the uptake mechanism of trace elements into manganese nodules. It is well known that transition metals such as Co, Cu and Zn are concentrated in manganese nodules. However, only a few investigations have conducted on the uptake of noble metals such as Au, Pd and Pt. It is recognized that adsorption of metal ions on manganese dioxide was investigated to explore their uptake mechanism into marine manganese nodules.

In this study, a model compound of manganese nodule was manganese dioxide. As model compounds of gold, [Au(S2O3)2]3- and [AuCl4-n(OH)n]- complexes were selected for convenience because gold(I) and gold(III) ions present in hydrosphere.

The adsorption behavior of [Au(S2O3)2]3- and [AuCl4-n(OH)n]- complexes on the surface of manganese dioxide was investigated with pH. The adsorption behaviors were quite different. The percentage of [Au(S2O3)2]3- adsorbed increased with decreasing pH (from 8 to 4). Above pH 8, which is the same pH of ocean water, no [Au(S2O3)2]3- was adsorbed on manganese dioxide. Since the isoelectric point of the manganese dioxide was around pH 4-5, the surface negative charges increase with increasing pH above pH 4-5. This opposite correlation between the surface charge and percentage of [Au(S2O3)2]3- adsorbed suggests that the adsorption of [Au(S2O3)2]3- may be controlled by electrostatic force. On the other hand, the percentage of [AuCl4-n(OH)n]- adsorbed increased from pH 4 to 6 and showed a maximum at pH 6-8. This result indicates that the adsorption of [AuCl4-n(OH)n]- occurred by overcoming the electrostatic repulsion.

In addition, the chemical state of gold adsorbed on manganese dioxide was examined by XPS. The results showed that [Au(S2O3)2]3- and [AuCl4-n(OH)n]- complexes adsorbed on manganese dioxide were spontaneously reduced to elemental gold. [AuCl4-n(OH)n]- may be specifically adsorbed by condensation reaction (the formation of Au-O-Mn bond) between two OH groups in the [AuCl4-n(OH)n]- and two OH groups on manganese dioxide. The adsorbed [AuCl4-n(OH)n]- may be distorted due to the regulation by the two OH groups on the manganese dioxide, and then its redox potential may be changed and reduced by water molecules. In contrast, the adsorbed [Au(S2O3)2]3- may disproportionate to form Au(0) and Au(III) species. The resulting Au(III) may be reduced to Au(0) by the above same mechanism.

Based on the results of this study, the chemical state of gold in marine manganese nodules should be investigated spectroscopically.

Dissolution and precipitation kinetics of magnesite at conditions relevant for CO2 geologic sequestration

GIUSEPPE D. SALDI, ERIC H. OELKERS, OLEG S. POKROVSKY AND JACQUES SCHOTT

Géochimie et Biogéochimie Experimentale, LMTG, Université de Toulouse, CNRS, IRD,OMP. 14 ave. Edouard Belin, F-31400 Toulouse, FRANCE.
(saldi@lmtg.obs-mip.fr)

Understanding carbonate mineral reactivity is of critical importance to assessing and optimizing potential CO2 storage sites (c.f. Oelkers and Schott, 2005). In particular, carbonate dissolution and precipitation rates play a fundamental role in CO2 mineral fixation. To address this need, the dissolution and precipitation rates of magnesite (MgCO3) have been studied as a function of pH (2<pH<10), solution composition and P CO2. Experiments have been performed using both open and closed-system reactors at temperatures from 100°C to 200°C and reactive fluid concentrations having ionic strengths varying from 0.01 to 1 M.

Measured dissolution rates decrease strongly with decreasing chemical affinity and increasing HCO3- concentration. The last observation is in agreement with the magnesite surface speciation model of Pokrovsky et al. (1999). Within this model all aqueous species able to form complexes with Mg surface hydrated sites, and thus decreasing >MgOH2+ concentration, inhibits magnesite dissolution. In addition, a significant increase in dissolution rates is observed with increasing reactive solution ionic strength: rates measured in 1 mol/kg NaCl solutions are on average 5 times faster than those observed in < 0.1 mol/kg NaCl solutions at a pH of ~ 7.

Magnesite is observed to precipitate at 150°C only at relatively high degrees of supersaturation. For example measured magnesite precipitation rates are found to be 2x10^-12 only at a saturation index > of ~ 30, when the CO2 pressure is at atmospheric or lower values. Moreover, the degree of supersaturation required for magnesite precipitation is observed to decrease with increasing temperature.

Natural and experimental multiscale F diffusion profiles in biotites from the Seridó micaschists, Northeastern Brazil

R. Sallet1, J.D. Price2, R. Moritz3 and D.A. Wark2

1Federal University of Rio Grande do Norte, Brazil, (sallet@geologia.ufrn.br)
2Earth and Environmental Sciences, Rensselaer Polytechnic Institute, USA, (pricej@rpi.edu, warkd@rpi.edu)
3University of Geneva, Department of Mineralogy, Switzerland, (robert.moritz@terre.unige.ch)

We examined the F distribution in Seridó Fold Belt biotite at the regional, contact, and grain scale through electron probe microanalysis. At the regional scale biotites show largely homogeneous F contents varying from 0.30 to 0.40wt%. The uniform concentration suggests the biotites equilibrated with F-poor fluids (log[H2O]/[HF] = 4.5 to 5.0) at upper amphibolite metamorphic conditions. At the contact with pegmatoid intrusions, schist biotites are enriched at different levels F = 0.5 to 2.5wt%, similar to those observed for biotites in the pegmatoid biotites. This suggest that schist biotites were locally reequilibrated at 600-700°C by pegmatoid related F-rich fluids (log[H2O]/[HF] = 3.8 to 4.3).

At pegmatoid contacts the F contents of schist biotites decrease to background contents in metric and centimetric diffusion profiles. At the Areias pegmatoid sill the F content of biotites decrease from 0.95wt% to the regional background F = 0.03wt% in 5.2m. In the same distance the F contents of amphiboles decrease from 0.47 to 0.32wt% and apatites show a near constant content F = 0.2-0.3wt%. At the Pedra Lavrada pegmatoid stock the F content from biotites in a schist enclave decrease from F = 0.43 to 0.37wt% in the narrow range 20 cm. The obtained diffusion profiles can be related to the interplay of three major factors: (i) fluid [H2O]/[HF] chemical gradient, (ii) thermal gradient and (iii) fluid advection into micaschists.

AFSQ-buffered experiments on a mixture of two Seridó biotites (F = 0.3 and 2.5wt%) at 750°C, 0.4 GPa produced strong F zonation. X-ray maps show zontations from F-rich borders to F-poor cores, with F-rich incursions along the c-perpendicular direction. A 4 micron profile perpendicular to the c-axis from F = 3.0wt% on the border to F = 0.5wt% in the core was fitted using $C(x) = 1 - C_0 \exp[-(4Dx)^{1/2}]$ to produce an F diffusivity in biotite $D = 2.75 \times 10^{-15}$ m$^2$/s. The value is larger order of magnitude higher than F diffusion in apatite and four orders higher than F diffusion on tremolite. The constant F contents of apatites at the Areias sill should be related to its poor cleaved non-permeable structure.

The Geochemical Atlas of Europe – Continent-wide distribution patterns of elements

R. Salminen

Geological Survey of Finland, P.O. Box 96, 02151 Espoo Finland, (reijo.salminen@gtk.fi)

The European geochemical baseline survey covers 26 countries, and provides invaluable information about the natural and human-induced concentrations of chemical elements in different sample media of the near-surface environment (topsoil, subsoil, humus, stream sediment, stream water and floodplain sediment). This is the first multi-national project of its kind – performed using harmonised sampling, sample preparation and analytical methodologies, and producing high quality compatible data sets across national borders. Over 60 determinands were studied, most for both total and aqua regia extractable concentrations. The results of the project are published in a two-volume set, which is freely available for viewing and downloading from www.gtk.fi/publ/foregsatlas together with the analytical data and photograph archive.

Over 400 maps were plotted and interpreted. The geochemical distribution maps show distinct geographical differences in the levels of potentially harmful elements, for example, arising from natural geogenic sources, including lithology and mineralisation, and from natural processes, such as climate, which influence the original concentrations.

The data from minerogenic samples reflect mostly geological variation in element distribution throughout Europe. In contrast, stream water data tends to reflect both the results of exogenic processes and the anthropogenic input of elements to the surficial deposits, although some elements give a direct signal related to the chemical composition of the bedrock. In central Europe, nitrate concentrations in stream water form a large anomalous area due to intensive agricultural practices. In northern Europe, stream water is more acidic than in central and southern Europe due to the low base cation capacity of the metamorphosed bedrock and the high concentration of humic and fulvic acids typical of the boreal climate. These low pH waters result in higher solubility of aluminium and some transition metals. Another striking feature is a relatively large anomaly of REEs detected in stream water in the area of southern Fennoscandia extending to northern Germany and Scotland. Reasons for this regional anomaly are unknown.

The geochemical maps may be used to delineate areas of ore potential interest across Europe. They may also be used to identify potential geohazard and health risks in particular regions that may warrant more detailed investigation. The observed geochemical variations do, however, illustrate the difficulty in defining a single guideline value for ‘water’, ‘soil’ and ‘sediment’ to be applied throughout Europe.
Coupled biological, geochemical and physical processes in acidic mine lakes: Model development and application.

S.U. SALMON1, C.E. OLDHAM2 AND M. HIPSEY3

1School of Environmental Systems Engineering, University of Western Australia, (ursula.salmon@uwa.edu.au)
2School of Environmental Systems Engineering, University of Western Australia, (carolyn.oldham@uwa.edu.au)
3Centre for Water Research, University of Western Australia, (hipsey@cwr.uwa.edu.au)

Existing water quality models for aquatic ecology and hydrodynamics have been extended to include representation of (bio)geochemical processes of relevance for acidic lakes and their sediments. The developed model allows quantitative investigation of biological, geochemical, and physical processes and their interactions, to assess controls on key water quality parameters, such as acidity.

The initial case study for model development was acidic Lake Kepwari, a decommissioned and flooded coal mine pit in Collie, southern Western Australia. Largely without calibration, the numerical model prediction of Lake Kepwari water quality over an annual cycle closely reproduced the patterns of stratification and overturn observed in the lake, as well as evapoconcentration. The model also reproduced major temporal and spatial patterns for non-conservative species, such as NH4, DOC, pH and Al. A sensitivity analysis indicated that even though the lake is now at full capacity, surface and groundwater inflows may still be important factors in the long-term evolution of the lake water quality. The model also allowed us to test the importance of geochemical processes for lake water quality, for example solubility equilibrium control of pH by Al hydroxide phases.

The modelling study of Lake Kepwari demonstrated the capability of the model to reproduce the main features of the current water quality in the lake, and highlighted the need for testing against data sets which include e.g. well-constrained water and mass balances over the lake.

It should be noted that the generic process descriptions in the developed model can be applied to almost any aquatic system. While the initial field site was a coal mine pit lake, the model is based on sophisticated process description and parameterisation; this allows immediate application to mine lakes of widely varying water quality.

We now require a comprehensive validation exercise of model predictions against high quality datasets from acidic water bodies; it is essential to increase our confidence in the simulation results. In particular, there is a need for testing model performance against long-term data sets from acidic systems with well constrained groundwater inflow, sediment fluxes and aquatic food web data, as well as hydrodynamic and geochemical state variables. The result will be an improved tool for management and remediation of acidic water bodies, including design optimisation for future field and laboratory sampling campaigns.

U-Pb age and REE data (SHRIMP II) on zircons in mantle xenoliths from alkaline basalts (Vitim area, Transbaikalia): Implication for the upper mantle partial melting

A. K. SALTYKOVA1, L. P. NIKITINA2 AND D.I. MATUKOV1

1Centre of Isotopic Research, VSEGEI, St.Petersburg, Russia; (Anna_Saltykova@vsegei.ru)
2IPGG RAS, St-Petersburg, Russia; (PN@LN10839.spb.edu)

Isotope dating of the upper mantle ultramafic rocks is difficult because their isotope systems are disturbed and mineral isochrones yield volcanic episode age. We report the U-Pb age and REE pattern of zircons from peridotite nodules in Cenozoic alkaline basalts of the Vitim volcanic area to display complicated evolution of the upper mantle.

The zircons 0.06 – 012 mm size were separated from nonmagnetic heavy concentrate. U-Pb and REE analyses have been carried out using SHRIMP-II in the CIR VSEGEI.

The protogranular spinel-garnet peridotite formed at P-T conditions of 45-50 kbar and 1400-1500 °C (data on Gar – Opx equilibria, Nikitina, 2000) bears prismatic or rounded zircons, colorless, with abundant fluid-melt and mineral inclusions. CL – images show their oscillatory and sectorial growth zoning and convoluted recrystallization domains.

The dating results are grouped in four age-spans with concordant 206Pb/238U ages of 1462±19 – 1506±4.0 (PR 1), 264.0±7.3- 295.7±0.76 Ma (P 1), 164.6±1.6 – 183.4±2.0 (J 1) and 135.5±2.7 to 141±3 Ma (K 1). Regression through two discordant data points has lower intercept of 138,0±5,7 Ma falling within K 1 age group. Its upper intercept of 1891±26 overlaps with other Proterozoic 207Pb/206Pb ages, ranging 1835 -1955 Ma. No volcanic episode age (48 – 28 Ma, Ionov et al. 1992) was noticed.

Chondrite-normalized REE distribution patterns in zircons show a LREE and HREE enrichment up to 100 and 1000 normalized units respectively. They are complicated by Ce and Eu minimum. Total REE content and Eu anomaly increase with the age.

The ages obtained are in agreement with main Phanerozoic intraplate magmatic events in the Central Asia region (Yarmoljuk et al., 2000). The studied zircons crystallized during partial melting of the peridotites initiated by gas-saturated fluid. Variation of the REE pattern with the zircon age indicates the multiple partial melting.

The Dynamics of Core Formation in Terrestrial Planets by Negative Diapirism: Timescales, Heat Distribution and Metal-Silicate Equilibration

H. SAMUEL AND P. J. TACKLEY
Department of Geophysical Fluid Dynamics, Institut für Geophysik, ETH Zürich, Switzerland (henri.samuel@erdw.ethz.ch)

Geochemical constraints on core formation provided by Hf/W systematics suggest it is a relatively fast process which may have been completed within less than 100 Myrs for the Earth or Mars. In addition, the overabundance of siderophile elements in the Earth’s mantle suggests that metal silicate equilibration occurred during core formation processes.

We investigate dynamically the timing and metal-silicate equilibration processes during core formation by negative diapirism. Using numerical modeling, we follow the sinking of iron-rich diapirs through a viscous silicate mantle, in 3D axisymmetric geometry. We carried a parameter study in which shear heating as well as several viscous rheologies were considered and systematically varied. General scaling laws are derived for the diapir sinking velocity as well as for the heat distribution. These scaling laws are subsequently used to investigate the ability of negative diapirism to explain core formation in Terrestrial planets within the timing and metal-silicate equilibration constraints provided by geochemistry and mineral physics.

Different types of hydrochemical stratification in the acidic mine pit lakes of the Iberian Pyrite Belt

JAVIER SÁNCHEZ ESPAÑA, ENRIQUE LÓPEZ PAMO, ESTHER SANTOFIMIA AND MARTA DIEZ
Instituto Geológico y Minero de España (IGME), Ríos Rosas, 23, 28003 Madrid, Spain (j.sanchez@igme.es)

Meromixis in pit lakes of the Iberian Pyrite Belt

Many acidic pit lakes formed in the abandoned mines of the IPB during the last decades are meromictic, showing a bottom, anoxic water body (called monimolimnion) which is permanently isolated from the rest of the water column, and an upper, oxygenic mixolimnion that periodically circulates.

Results and Discussion

On-going research in pit lakes of the IPB has revealed different types of perennial hydrochemical stratification, which ranges from a simple model with two internally homogeneous layers separated by a well defined chemocline, to a more complex, multi-layer model that display numerous steep salinity gradients and different strata with continuously increasing dissolved solids content with depth (Figure 1).

Figure 1: Vertical profiles of electric conductivity (EC) and dissolved oxygen (DO) in the pit lakes of San Telmo (left) and Cueva de la Mora (right).

These different models of chemical stratification do not correlate with the age of the pit lakes (15-100 years), their relative depths (13-45%) or the geometry of their pit basins. It is hypothesized that the different vertical trends are the result of the interplay between different types of processes, including (i) physical mixing (e.g., wind-induced advection, heat-driven convection) in the mixolimnion, (ii) geochemical and microbiological reactions (bacterial oxidation of Fe(II), photoreduction of Fe(III), precipitation of Fe(III) phases, metal sorption) in the mixolimnion, (iii) bacterial reduction of Fe(III) and SO$_4^{2-}$ coupled with fermentation in “reactive” lake bottoms (water/sediment interfaces), (iv) groundwater input at depth, and (v) warm salt-laden water descending into the basin along the pit contours.
**Interaction between barite and celestite cleavage surfaces and carbonate bearing aqueous solutions**

N. SÁNCHEZ-PASTOR, C.M. PINA AND L. FERNÁNDEZ-DÍAZ

Dpto. Cristalografía y Mineralogía. Universidad Complutense de Madrid. E-28040 Madrid, Spain
(nsanchez@geo.ucm.es; cmpina@geo.ucm.es; lfdiaz@geo.ucm.es)

In nature, crystals of the witherite-strontianite solid solution series often show a significant chemical bimodality, i.e. intermediate compositions in this solid solution are very rare. Such a chemical bimodality can not be easily justified by invoking thermodynamic arguments. However, it has been suggested that witherite-strontianite crystals can result from the replacement of crystals of the barite-celestite solid solution which act as precursors. Consequently, the chemical bimodality in the carbonates might be a compositional feature inherited from the original sulphates. In this case, the replacement implies the coupling of dissolution and crystallisation reactions occurring on the interface between the $\text{Ba}_x\text{Sr}_{1-x}\text{SO}_4$ crystal surfaces and carbonate bearing aqueous solutions.

In this work, we present in situ Atomic Force Microscopy (AFM) observations of the interaction between barite and celestite (001) and (210) faces with static $\text{Na}_2\text{CO}_3$ aqueous solutions at room temperature. The concentrations of the solutions used were in the range between 0.001 mol/l and 0.1 mol/l. Typically, such interaction is characterised by the dissolution of the original faces and the rapid nucleation and spreading of islands (~3 nm in height). The coalescence of the islands leads to the formation of a homogeneous epitaxial layer. Measurements on series of AFM images provide quantitative information about coupled dissolution-growth rates. On the basis of our results, we discuss the viability of the transfer of chemical information at a nanoscale during the replacement of the barite-celestite crystals by witherite-strontianite.
