Aerobic culture experiments with two strains of moderately halophytic bacteria grown in solid medium have been used to determine the $\text{Sr}^{2+}$ partition coefficient for dolomite at different temperatures and chemistries. The $\text{Sr}^{2+}$, $\text{Ca}^{2+}$ and $\text{Mg}^{2+}$ data and results from XRD studies indicate that $\text{Sr}^{2+}$ incorporation into dolomite crystals is not by substitution of $\text{Ca}^{2+}$, but instead, in our experiments, $\text{Ca}^{2+}$ is replaced by $\text{Mg}^{2+}$. $\text{Sr}^{2+}$ enrichment is probably via surface adsorption or occlusion. Thus, the experimental $\text{Sr}^{2+}$ partition coefficient between dolomite and fluid is represented here by the ratio of the $\text{Sr}^{2+}$ concentration in the solid phase (dolomite, “dol”) over that in the fluid (site of dolomite precipitation = bacteria-medium interface, “bmi”), $D_{\text{Sr}}^{\text{dol}} = \frac{\text{Sr}_{\text{dol}}}{\text{Sr}_{\text{bmi}}}$. Together, our observations suggest that $D_{\text{Sr}}^{\text{dol}}$ is apparently related to microbial activity, temperature and sulfate concentration. Therefore, the highest values calculated in the experiments, in comparison with the theoretical values, have implications for interpretation of depositional environment of ancient dolomite. The results of our cultures experiments show that high very high $\text{Sr}^{2+}$ concentrations in ancient dolomite could reflect microbial mediation.
Equation of state of fluids from sound velocity measurements in the diamond anvil cell using Brillouin scattering spectroscopy

CARMEN SANCHEZ-VALLE1,2 AND JAY D. BASS2

1Inst. for Mineralogy and Petrology, ETH Zurich, CH-8092 Zurich, Switzerland (carmen.sanchez@erdw.ethz.ch)
2Dept. of Geology University of Illinois, 61801 Urbana, USA (jbass@uiuc.edu)

Saline-rich aqueous fluids play an important role in metamorphic reactions and chemical transport in a wide range of geological environments. In subduction zones, aqueous fluids expelled from subducting slabs lead to the important geochemical phenomena of mantle wedge metasomatism and arc magmatism and mediate the recycling of elements in the Earth. Reconizing the role of deep fluid in these processes a number of significant but unanswered questions arise as to their chemical composition, the extent of mass transfer, or the mechanism of elemental transport from the slab to the mantle wedge. Answers to these questions depend on quantitative thermodynamic modelling of fluid-mineral interactions, that is greatly limited by the lack of thermodynamic data of complex aqueous fluids at high pressure and temperature conditions [1].

To address this problem, we conducted sound velocity measurements in the diamond anvil cell using Brillouin scattering spectroscopy to determine the equation of state (EoS) of H2O and chlorine-bearing solutions (1m and 3m NaCl) up to 400 ºC and 7 GPa. Sound velocities measured in H2O are in excellent agreement with previous measurements using the Impulsive Stimulated Brillouin Scattering technique [2]. The newly determined equation of state is used to evaluate the pressure and temperature dependences of thermodynamic properties of water and NaCl solutions, including thermal expansion coefficients, isothermal and adiabatic compressibilities and heat capacities. The results are combined with previous experimental and theoretical EoS of H2O-NaCl mixtures to provide an internally consistent dataset for the thermodynamical properties of the most relevant aqueous systems involved in subduction process.

Effect of Al3+ on the elastic properties of ferropericlase at high pressure

CARMEN SANCHEZ-VALLE1, KOSTANTIN D. LITASOV2, EIJII OHTANI3 AND JAY D. BASS3

1Inst. for Mineralogy and Petrology, ETH Zurich, CH-8092 Zurich, Switzerland (carmen.sanchez@erdw.ethz.ch).
2Inst. of Mineralogy, Petrology and Economic Geology, Tohoku University, Sendai, 980-8578 Japan (klitasov@ganko.tohoku.ac.jp; ohtani@mail.tains.tohoku.ac.jp)
3Dept. of Geology University of Illinois, 61801 Urbana, USA (jbass@uiuc.edu)

Main features of the Earth’s mantle structure revealed by seismic observations, including the radial profile, lateral heterogeneity, and anisotropy are largely determined by the elasticity of the materials present in this region [1]. Mineralogical models indicate that the lower mantle consists of approximately 20% ferropericlase (Mg,Fe)O and more than 70% of silicate perovskite [(Mg,Fe)SiO3], containing minor amounts of aluminium. Although the effect of Al3+ incorporation on the elastic properties of MgSiO3 perovskite has been constrained from several studies [2,3], nothing is known about how this element can affect the sound velocities and elasticity of (Mg,Fe)O.

In this contribution we present high-pressure measurements on the sound velocities and single-crystal elastic properties of aluminium-bearing ferropericlase (containing 2.4 atom% Al3+ and 8.7 atom% Fe2+) to 25 GPa at room temperature. Measurements were performed by Brillouin scattering in samples compressed in the diamond-anvil cell using alcohol-water mixtures as pressure transmitting media. The pressure-dependence of the aggregate compressional (Vp) and shear (Vs) wave velocities, as well as, the adiabatic bulk (Ks), shear (µ) moduli and elastic anisotropy were obtained. In view of these results and previous elastic data for (Mg,Fe)O [4], the effect of Al3+ incorporation on the elastic properties ferropericlase and the implications for the chemical composition of the Earth’s lower mantle will be discussed.

Comparative study of organic Cd and Zn complexation in lake waters

SYLVIA SANDER1, LÉTICIA GINON1, BARRY ANDERSON1 and KEITH A. HUNTER1

1University of Otago, NZ; (sylvias@alkali.otago.ac.nz)

The complexing capacity and associated stability constants of Zn and Cd in three alpine lakes in New Zealand has been determined using Competitive Ligand Equilibration-Cathodic Stripping Voltammetry (CLE-CSV) with ammonium pyrrolidine dithiocarbamate (APDC) [1] as competing ligand for Zn and Anodic Stripping Voltammetry (ASV) was used to measure the complexing parameters for Cd [2].

We compared depth profiles, seasonal variability, pH dependence and selectivity of the natural organic ligands for both elements and took a view to similarities and differences with Cu speciation in the same lakes.

Probably the most noticeable and interesting result of our study on the speciation of Cd an Zn in three freshwater lakes in southern New Zealand is the apparent difference of the Cd-binding ligand composition with depth, but also differences in summer and winter. While our data gives evidence for a rather unspecified binding affinity towards Cd in winter and in deep water, the specificity seems to be increased at the surface in summer. Both the higher stability constant and selectivity against competing elements could indicate towards a compound of recent biological origin. Ligands with a lower stability found in winter at the surface and all year around in the deep water samples are probably non-specific degradation products.

The chemistry of Zn is much more uniform throughout the depth profiles and seasons, with Zn speciation being dominated by strong organic complexes. On average 95%±5% of Zn is present as organic complex, compared to only 70% ± 22% of Cd being organically complexes. Zn binding ligands also seem to be very selective towards Zn, and thus, probably produced in response to the presence of this element on the water. The pH dependence of the complexation of both metal ions is indicating that the composition of ligands is not uniform and functional groups may consist potentially of carboxylic groups (pKₐ 3-5) and groups being incompletely deprotonated at pHs as high as 8.2 (e.g. phenolic and amino groups).

Comparing the speciation of Cd and Zn with that of Cu in the same lakes, it strikes that the concentrations of all ligands for all three elements is very similar with an over all average of 6.8 nM ± 3.1 nM (SD) although the total metal concentration vary in the range of two orders of magnitude, with Cd being the least prevalent element. However, the different complex stability constants, inorganic speciation and ligand selectivities for Cd, Zn and Cu in combination with their concentration is leading to the fact, that probably the highest risk of toxicity for organisms is coming from cadmium.

Interactions of uranium with Fe(III)-(hydr)oxides under sulfate reducing conditions

R.K. SANI1, B.M. PEYTON2, T. GINN3 and A. DOHNALKOVA4

1South Dakota School of Mines and Technology, 501 East St. Joseph Street, Rapid City, SD 57701-3995 USA (rajesh.sani@sdsmt.edu)

4PNNL, Richland, WA, USA (Alice.Dohnalkova@pnl.gov)

Uranium (U) contamination is a global problem in water supply and related ecosystem health, and it is the primary radioactive metal contaminating subsurface environments at many sites and is of particular concern because of its carcinogenicity. The high solubility of its hexavalent form can result in U transport to sensitive receptors such as drinking water sources. One potential method of treating U contamination is by using natural dissimilatory metal reducing bacteria including sulfate reducing bacteria (SRB) to reduce soluble U(VI) to insoluble U(IV) (as uraninite, UO₂). This reduction can lead to in situ U immobilization; however, it is vital to understand the reactivity and stability of microbially-mediated uraninite. Our recent published HR-TEM, SAED, and EDS analysis data showed that SRB transformed U(VI) into colloidal uraninite with particle diameters of 3–5 nm. Further, we recently showed that under lactate-limited sulfate-reducing conditions, this biogenic uraninite can be oxidized by common Fe(III)-(hydr)oxides such as hematite, goethite, and ferrihydrite. In addition to the oxidation of biogenic uranium under biotic conditions, in this paper we review the oxidation of aqueous phase biogenic uraninite by Fe(III)-(hydr)oxides under abiotic conditions. These aqueous uraninite particles were separated from SRB using 0.2 µm membrane filter, and treated with hematite and ferrihydrite under strict anaerobic conditions. Our results suggest that Fe(III)-(hydr)oxides oxidized uraninite; however, the reactivity of biogenic uraninite was greater with ferrihydrite as compared to the more crystalline structure of hematite. Thermodynamic calculations also indicate congruent favorability of these reoxidation reactions. The results have strong implications for field application of in situ biological reduction of U(VI) since oxidation of bioreduced uraninite by Fe(III)-(hydr)oxides in situ may limit U immobilization even under reducing conditions.
Reactivity of heavy rare gases with silicates at deep Earth conditions

C. SANLOUP 1,2, B. SCHMIDT 3, A. DEWAEL 4, G. GUDFINNSSON 5 AND M. MEZOUAR 6

1Université Pierre et Marie Curie, Paris-6, France (sanloup@ccr.jussieu.fr)

6European Synchrotron Radiation Facility, Grenoble, France (mezouar@esrf.fr)

The incompatible [1-3] and inert [4-5] character of atmospheric rare gases varies with pressure and temperature. This variation is poorly understood, yet it challenges our current appreciation of the formation of Earth’s atmosphere and mantle dynamics. The levels of the noble gas Xe in the atmospheres of Earth, and Mars are much lower than those of other noble gases, a puzzle known as the “missing Xe problem” [6]. One solution would be that Xe is hidden in other phases in a deep Earth reservoir. From a geochemical point of view, not only Xe, but all rare gases could be partly hiding in the deep Earth [7].

X-ray diffraction were conducted in situ on the SiO2-Xe and San Carlos Olivine-Xe systems, and completed by chemical analysis and Raman spectroscopy on quenched samples. We have shown that at high T and P, the normally unreactive Xe can bond covalently with oxygen in quartz 5, displacing Si atoms in the crystal lattice. A similar behavior of Xe is observed in the olivine lattice. Xe could therefore be trapped in deep Earth silicates. The results provide an answer to the paradox of "missing Xe" in the atmospheres of the Earth and Mars. Preliminary results will be shown on silicate-Ar systems, and discussed in relationship with the observed solubility drop of Ar observed at high pressure in silicate melts 1,3.

Geographical distribution of helium isotope ratios and seismic tomography in Japan

Y. SANO1 AND J. NAKAJIMA2

1Center for Advanced Marine Research, Ocean Research Institute, the University of Tokyo, Tokyo 164-8639, Japan (ysano@ori.u-tokyo.ac.jp)
2Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, Sendai 980-8578, Japan

The 3He/4He ratios (Ra) of natural gas, volcanic fluid, and groundwater are compiled in the Japanese Islands and their geographical distributions are discussed in the tectonic frame work of subduction zone together with precisely-determined seismic velocity structures. In Northeastern (NE) Japan where typical island arc signatures are developed, there is a clear contrast of 3He/4He ratios perpendicular to the trench axis, low-Ra in the frontal arc and high-Ra in the volcanic arc. This may reflect the presence or absence of magma with high-Ra in the shallow crust [1]. As a carrier of primordial helium, source melt may be generated in low-V zone of the wedge mantle by dehydration of Pacific slab at about 150 km deep and may flow upward sub-parallel to the slab, which is well constrained by S-wave velocity perturbation [2]. In the Chugoku and Shikoku districts of Southwestern (SW) Japan, there is a geographical contrast of Ra similar to NE Japan except for the region at about 100 km from the volcanic front where medium-Ra was found. High-Ra observed in volcanic arc of the Chugoku district may be attributable to the mantle helium derived from the magma source generated below the Philippine Sea slab [3]. Medium-Ra in the Shikoku district is explained by dehydration of the young slab with a moderate aging effect [4]. These features are again consistent with the results of seismic tomography [5]. In the Kinki district of SW Japan, anomalously high-Ra was observed in the frontal arc region that was called by “Kinki Spot”[6]. Since the high-Ra is located at much wider region from the volcanic front when compared with NE Japan, the melt generated below the Philippine Sea slab may penetrate into the fissure of the slab tear and may arrive at the shallow crust by upwellling flow.

D/H ratios in n-alkanes as a proxy for paleoclimatic changes in a Brazilian lacustrine rift sequence

E.V. Santos Neto, A.A. Ferreira and A.L.D. Spigolon

Petrobras R&D Center, 950, Horácio Macedo Ave, 21941-915, Rio de Janeiro, RJ, Brazil (eugenioneto@petrobras.com.br)

Meteoric water is considered the main hydrogen source for primary producers (Schimmelmann and Vogel; 1970), and fossil hydrocarbons can preserve most of their source D/H signature throughout geologic time (Santos Neto and Hayes, 1999; Li et al., 2001, Dawson et al., 2004), and even during catagenesis (Schimmelmann et al., 2006).

Examination of n-alkanes from organic extracts of representative core samples of an early Brazilian Cretaceous paleolake sediments showed that $\delta D_{DSMOW}$ of n-C20 to n-C32 varied mostly between $\approx -60\%$ to $-100\%$ (Fig. 1). Spikes up to $-125\%$ probably are related to coelution of compounds. The cyclic fluctuations of $\delta D$ in n-alkanes are significant, correlative to inorganic indicators of environment changes, and largely independent of secondary exchanges. This suggests that D/H ratios are reflecting periods of more and less water evaporation, during the lake evolution, and can be an useful proxy for paleoclimatic studies.

Figure 1: Graph showing the $\delta D$ (%) variation for the n-paraffins ranging from 20 to 32 carbon atoms

Emplacement of the Monchique alkaline massif (SW Portugal): Microstructures and magnetic fabric constraints

H. Sant’Ovaia1, C.R. Gomes2 and L.G. Pereira2

1GIMEF, Dep. de Geologia FCUP, Centro de Geologia Univ. Porto, Portugal (hsantov@fc.up.pt)  
2CGUC, Dep. de Ciências da Terra, Univ. Coimbra, Portugal

The Monchique massif aged of Upper Cretaceous ($^{40}$Ar/$^{39}$Ar 72.7±2.7 Ma, Valadares et al., 2005) covers an area of 80 km² and has an east-west elongate shape. This massif is composed by two principal units: the central one corresponding to a coarse grained nepheline syenite and a marginal unit represented by a heterogeneous syenite. The central unit contains large crystals of alkali feldspars, nepheline (25% to 40%), pyroxene, biotite and plagioclase. The marginal unit has a variable granulometry and is poorer on nepheline (10 to 20%) (Gonzalez-Clavijo & Valadares 2003). Gomes & Pereira (2004) considered this massif as an intrusion in an antiform structure and controlled by a NE-SW shear zone.

All the thin sections display microstructures typical of magmatic or submagmatic state and no microstructures indicate of strain developed under near-solidus conditions were observed. Preliminary studies of Anisotropy of Magnetic Susceptibility (AMS) were carried out measuring 102 oriented core samples from 12 sites, using an Agico Kappabridge (KLY-4S), at the Geology Dep., Porto University. The high average bulk susceptibility (23.83E $^{-3}$ SI) together with previous paleomagnetic works (Gomes & Pereira, 2004) indicates that magnetite controls the magnetic behaviour. Magnetic anisotropy magnitude (Kmax/Kmin) is quite low, 1.065 on average. AMS fabric patterns show subvertical magnetic foliations associated with subhorizontal magnetic lineations. They have both a tendency to display NE-SW trends on the east and west sectors of the massif, passing to an E-W trend on the centre of the massif, drawing a sigmoid shape. Considering the AMS fabric as magma flow indicators, we propose that Monchique massif is a subvertical intrusion and that the steeply dipping magnetic foliations related to gentle dipping lineations represent an E-W trending of the magmatic flow controlled by a NE-SW left strike slip fault.

Sr isotopic composition in Variscan granitoids, Silurian metasediments and waters from the Boticas area (Northern Portugal)

M. SARAIVA1, M. E. P. GOMES1 AND M. R. AZEVEDO2

1Department of Geology, University of Trás-os-Montes e Alto Douro, Apartado 1013, 5001-801 Vila Real, Portugal (marlenesarai@gmail.com, mgomes@utad.pt)
2Dep. of Geosciences, University of Aveiro, Campus Universitário de Santiago, 3810-193 Aveiro, Portugal (mrosario@geo.ua.pt)

The processes of water-rock interaction controlling the Sr isotopic composition of superficial and groundwaters from the Boticas sanitary landfill and the Carvalhelhos mineral waters are investigated in this work. The Boticas region is composed of several intrusions of Variscan granitoids emplaced into Silurian metasediments. The granitoids, consisting of quartz, K-feldspar, plagioclase (albite - oligoclase) and micas show Sr content, and present-day 87Sr/86Sr isotopic ratios varying between 37-105 ppm and 0.749238-0.886953, respectively. In the Silurian metasediments, quartz and mica are modally important mineral phases and plagioclase is absent. Their Sr contents range from 41-60 ppm and their 87Sr/86Sr ratios from 0.760103-0.782684. The surface and groundwaters from the Boticas sanitary landfill have bicarbonate compositions with relatively high calcium and magnesium contents (mixed-type), whilst the Carvalhelhos mineral waters show sodium bicarbonate compositions. The range of Sr and 87Sr/86Sr values in the Boticas waters (Sr = 0.0042-0.056 ppm; 87Sr/86Sr = 0.718106-0.726322) is much wider than those of the Carvalhelhos mineral waters (Sr = 0.072-0.076 ppm; 87Sr/86Sr = 0.718106-0.732276) and micas show Sr content, and present-day 87Sr/86Sr isotopic ratios varying between 37-105 ppm and 0.749238-0.886953, respectively. In the Silurian metasediments, quartz and mica are modally important mineral phases and plagioclase is absent. Their Sr contents range from 41-60 ppm and their 87Sr/86Sr ratios from 0.760103-0.782684. The surface and groundwaters from the Boticas sanitary landfill have bicarbonate compositions with relatively high calcium and magnesium contents (mixed-type), whilst the Carvalhelhos mineral waters show sodium bicarbonate compositions. The range of Sr and 87Sr/86Sr values in the Boticas waters (Sr = 0.0042-0.056 ppm; 87Sr/86Sr = 0.718106-0.726322) is much wider than those of the Carvalhelhos mineral waters (Sr = 0.072-0.076 ppm; 87Sr/86Sr = 0.718106-0.732276).

Adsorbed soil gas and microbial studies for Hydrocarbon prospecting: Jamnagar sub-basin, Gujarat, India

T. SATISH KUMAR, M.A. RASHEED, G. KALPANA, D.J. PATIL AND A.M. DAYAL

Stable Isotope and Surface Geochemical Prospecting Lab, National Geophysical Research Institute, Hyderabad 500 007, India (satishthadoju@gmail.com)

This study was designed to combine and compare adsorbed gas (acid released gas) and Microbial methods with sub-surface geology. These techniques provides to understand the hydrocarbon generation, migration and accumulation processes within a basin prior to drilling. Sub-surface soil samples were collected on a detailed grid over the Jamnagar sub-basin, India. The area is largely covered and prominently exposed by the Deccan Trap (basaltic rocks), whose thickness varies from few hundreds to thousands of meters. Traps are underlain by thick Mesozoic sediments (100-4000 m), which can form potential source rock for hydrocarbon. Deccan Trap volcanoclasty during Late Cretaceous may have generated the requisite thermal conditions and acted as a catalysis in Mesozoic hydrocarbon-generation process. Sedimentation in marine intertonguing environments is considered to have been favorable phenomena for hydrocarbon generation and entrapment (Kumar et al., 2004).

Adsorbed soil gas of light hydrocarbons (C1 to C3) shows variations in concentrations of Jamnagar sub-basin. The C1, C2, and C3 concentration range from 3-518 ppb, 0-977 ppb and 0 – 331 ppb, respectively. Correlation factor is more than 0.9 between C1 - C2, C1 - C3, C2 - C3 and C1 - C2, which indicates that light hydrocarbon components are generated from a thermogenic source. The compositional ratio of C2/C1 varies from 60 – 68600 CFU/gm. Adsorbed soil gas and microbes intensities indicate that this is warm area for hydrocarbon. The adsorbed soil gas data and microbial population are concordant and coincide with major structural features in basin. This study clearly demonstrates that adsorbed soil gas and microbial methods with geology can be applied sucessfully to demarcate the hydrocarbon reservoir zone for future exploration.

Radiometric age is defined as a cooling age or a closure age of a particular mineral or of minerals. With determination, quantitative analysis of thermal history of a rock or a geologic event (fault movement) could be performed with comparison of various minerals of radiometric age. Contrastingly, other method, e.g. ESR, FT and U-He age, the closure temperature of K-Ar system is rather high, a kind of melted-rocks under high temperature, such as pseudotachylytes, are widely applied to evaluation of fault activity with K-Ar dating method. To obtain reliable ages of fault activities, it is a key issue whether the ages were initialized by re-equilibrating their Ar isotopes with atmospheric Ar besides to be rejuvenesced, and other noble gas isotopes are re-equilibrating from original rock ratio to atmospheric ratio. In the case that such a rejuvenescence can explicate one of a geochemical phenomena of field observation, analyses of apparent K-Ar ages could be applied for fault rocks for thermal history.

Here we report a preliminary experiment that effectuates high temperature frictional melting experiments with using a high-velocity friction apparatus in Kyoto Univ. in order to test whether age is reset by frictional heating of fault or not. A pair of gabbro chunks cut into hollowed cylinder was slid at a slip velocity of 1.3 m/s and a normal stress of 1.4 MPa. Under this condition, local frictional melting started into 5 sec. and temperature around an artificial fault reached around 1100 C in ca. 20 sec., then fault plane is well above the closure temperature of K-Ar system. Due to rapid equilibrium of volatiles during frictional melting of rocks, we expect that the K-Ar age should be reseted. This age-reset is only observed in glass completely melted. In natural field observation, such completely melted glassy materials, are faced on fault planes. Such glassy materials age are regarded to be reset during fast fault movement by re-equilibirating of Ar isotopes to atmospheric one at the event. An apparent incomplete initialize was observed in the part including some un-melted gabbro fragments. In the part, mechanically fractured pieces are mixed in the glass matrices in frictional zones. That’s why the Ar isotope ratios might not be re-equilibirated in the experiments. However, U-He age is also initialized as for re-equilibrating of He isotopes, which is more sensitive and degassed earlier than Ar isotopes such as low speed frictional and low temperature (un-melted), just crushed rock.

Sulfur/Selenium ratios in Bushveld Complex, South Africa

D. SAVARD, S.-J. BARNES, L.P. BÉDARD AND R. COX

¹,²,³,⁴University of Quebec at Chicoutimi, Qc., Canada, (ddsavard@uqac.ca; sjbarnes@uqac.ca; pbedard@uqac.ca; richard_cox@uqac.ca)

Introduction

Over the past decade S/Se ratios have been used in modeling the processes leading to magmatic ore deposits. Sulfur and selenium have many chemical similarities but the use of S/Se ratio is based on the idea that Se is less mobile. Thus, magmatic sulfides ore deposits have S/Se ratio close to mantle values (~2500-4000). If sulfides are altered S may be preferentially removed resulting in rocks with low S/Se.

It has been suggested that the Pt-rich Merensky Reef in the Bushveld Complex formed when Pt-bearing disseminated sulfides in the underlying cumulate rocks were dissolved by Cl-rich fluids. The S and Pt were deposited at the level of the reef when this fluid dissolved into the intercumulate silicate liquid. An alternative model for the formation of the reef is that sulfides segregated from the mafic magma a little above the reef then collected on the cumulate pile. We have investigated these models with the idea that if the Pt and S were collected from bellow the reef then the S/Se ratios of the cumulate pile should be less than normal magmatic values and S/Se ratios in the reef should be higher than magmatic values. Alternatively if the sulfides in the reef segregated from a mafic magmaw have S/Se ratios close to mantle.

Results and conclusion

The S/Se ratios of the reef rocks is approximately 2000 and the S/Se ratios of the rocks below the reef are in most case >2000, within or close to S/Se mantle range (Fig. 1). Therefore S/Se ratios are consistent with the magmatic model for the formation of the reef.

Figure 1: Statigraphic distribution of S/Se ratios in Bushveld (Union section)
Sorption removal influence on the transformation of dissolved uranium (VI) runoff in the river water – seawater mixing zone

ALLA V. SAVENKO
Department of Geology, Moscow M.V. Lomonosov State University, Moscow, Russia, (Alla_Savenko@rambler.ru)

Special attention is paid to radio ecologic research, when studying chemical transformation of continental runoff in river mouth areas. Sorption-desorption processes are especially important for trace elements characterized with low coefficients of biologic accumulation. Experimental simulation of interaction between waters of various salinity which contain uranium (VI) and terrigenic clay minerals was provided aimed at revealing the role of sorption-desorption processes in transformation of runoff of dissolved uranium in the river water – seawater mixing zone.

The resultant action of sorption-desorption processes was estimated based on experimental parameters of isotherms of uranium sorption at natural clays of different composition. Calculations showed that sorption removal of essential amounts of dissolved uranium occurs when river suspended solids interact with salinous waters. These amounts approach amounts of dissolved uranium occurs when river suspended solids for rivers of the world, with only exception for montmorillonite. When accounting of correction coefficient for difference in total amounts of clay minerals in the Gzhel clay (53%) and in the global solid runoff (67%), the value of specific sorption of uranium at the Gzhel clay rises from 0.13–0.16 nmole/g up to 0.16–0.20 nmole/g or 39–48 ng/g at transition from river water to seawater. The total amount of suspended solids removed to the Ocean was estimated varying from 15.7 to 18.5 billion ton per year [Walling, Webb, 1987; Lisitsiyn, 1978]. Consequently, the amount of sorption removal of uranium values 610–890 ton per year at the river–sea barrier, when applying the Gzhel clay as the analog of suspended solids in continental runoff.

Values of uranium sorption at montmorillonite clay are an order of magnitude higher than values for the Gzhel clay (1.5–2.9 nmole/g). As the result the presence of montmorillonite in suspended solids causes essential increase of uranium removal from solutions. River suspended solids contain ~3% of montmorillonite, thus additional removal of uranium was estimated at 170–380 ton per year. Hence the total amount of uranium removed by sorption at terrigenic solids is equal to 780–1270 ton per year. The amount of dissolved uranium entering seawater with river runoff was estimated at 20 000 ton per year. Considering this estimation the sorption removal of uranium is insignificant (4–6%).

This work was supported by Russian Fond of Fundamental Investigations (project 05–05–66810).

Li-Sr-Lu-Hf isotope and trace element systematics of eclogites from Bulgaria

IVAN P. SAVENOV1, MICHAEL BIZIMIS2, RAFAL HALAMA3, STEVEN SHIREY1, ERIK HAURI4 AND IVAN HAYDOUTOV4
1DTM-Carnegie Institution, Washington DC, USA. (savov@dtm.ciw.edu)
2NHFML-Florida State University, Tallahassee, FL, USA.
3University of Maryland, College Park, MD, USA.
4Geological Institute, B.A.S., Sofia, Bulgaria.

Ecl ogites from the Sredna Gora Terrane and the Rhodope (UHP) Massif lie in southern Bulgaria and northern Greece and are part of the Alp-Himalayan orogenic belt. Two groups of eclogites were studied. Group 1 eclogites (Verila Mts., Ograzden Mts., E. Rhodope Mts.) have 1-10 x chondrite (CI) HREE concentrations and [La/Sm]N = 0.2-1 and variable 87Sr/86Sr (0.7035-0.7098). This group also shows MORB-like trace element systematics and Nb/Zr (0.07-0.26), Nd/Pb (~1), Hf/Yb (~0.22-0.48) and Nb/U (~29) ratios. Group 2 eclogites (Central Rhodope Mts.) have 30 x (CI) chondrite HREE abundances, 87Sr/86Sr ratios between 0.7057 and 0.7077; enriched LREE ([La/Sm]N = 1.1-2.5), elevated LILE contents and Nb/Zr (0.25-0.94), Nd/Pb (~9.5) and Nb/U (~32) ratios, but relatively low Hf/Yb (0.17-0.20). One interpretation of the data is that group 1 eclogites represent metamorphosed altered oceanic crust and group 2 eclogites record interaction with crustal melts/fluids possibly in an arc crust environment. In situ analyses by SIMS (Cameca 6f) of garnets and omphacites show depleted LREE and little core to rim trace element variations. The Li abundances of all garnets (1-2.5 ppm) and omphacites (45-56 ppm) are in the typical range for eclogites [1]. Mineral separates and bulk rocks from group 1 have extremely light Li-Sr-Lu-Hf isotope and trace elements ratios (δ7Li = +1.2 and –12.9 ‰) compared to group 2 (δ7Li = –0.26 to + 5.7 ‰). Our data confirm earlier studies reporting very light δ7Li in eclogites from the Alps[1].

The Lu/Hf isotope systematics of omphacite-garnet pairs suggest that eclogites from Central Rhodope Massif are of Late Proterozoic (Pan African) age [Beden eclogite = 567 Ma], almost identical to ophiolite successions throughout the basement of the Balkan Terrane to the north. Eclogites from Ograzden Mts. and Verila Mts. record Carboniferous metamorphic overprint [Gega eclogite = 293 Ma; Krainitsi eclogite = 320 Ma]. The Variscan orogeny in Bulgaria was established based on stratigraphy and abundant 300-315 Ma granitic intrusions [2]. The reported Lu/Hf age of eclogites from the Ograzden and Verila Mts. (in addition to zircon metamorphic rim geochronology [2]), implies the existence of previously not known high-grade metamorphic event similar to the one recorded in western and central Europe. These results on well-preserved Bulgarian eclogites provide a sensitive record of the pre-Mesozoic subduction events in the southern margin of the European continent.

Effects of cations and pressure on the structure of aqueous solutions as evidenced by IR OH bands

T. SAWAI AND S. NAKASHIMA

Department of Earth and Space Science, Graduate School of Science, Osaka University, 1-1 Machikaneyama-cho, Toyonaka-shi, Osaka 560-0043, Japan.
(tsawai@ess.sci.osaka-u.ac.jp)

In order to study effects of cations and pressure/temperatures on the st ructure of aqueous solutions, infrared (IR) spectra were measured for salt solutions under different pressures/temperatures.

IR spectra of synthetic salt solutions (LiCl, NaCl, KCl, RbCl, CsCl, MgCl₂, CaCl₂, SrCl₂, BaCl₂ ) were measured by attenuated total reflection (ATR)-IR spectroscopy at room temperature under atmospheric pressure. The peak positions of OH stretching bands shifted to higher wavenumbers with increasing salt concentrations.

**Figure 1:** The peak positions of OH stretching bands.

By taking difference spectra from the pure water, the higher wavenumber component (3430 cm⁻¹) increases, while the lower wavenumber component (3170 cm⁻¹) decreases for most of the salt solutions. The addition of these salts to pure water resulted in the increase of water molecular clusters with longer H-bond distances.

In order to measure IR transmission spectra of fluids at different pressure/temperature conditions, a high pressure/temperature IR transmission cell has been developed to be used under an IR microscope.

First, IR spectra of pure water was measured at different pressures from 0.1 to 15.6 MPa. The OH stretching peak position did not change significantly upto 15.6 MPa. The above salt solutions are now being examined at different pressure/temperature conditions.

Geochemistry of Kairouan plain, Tunisia

RIM SAYADI¹, RACHIDA BOUHLILA² and MUSTAPHA BESBES³

¹Ecole Nationale d’Ingénieurs de Tunis, Tunisie-rim_sayadi@hotmail.com
²Ecole nationale d’Ingénieurs de Tunis, Tunisie-bouhlila.rachida@enit.rnu.tn
³Ecole nationale d’Ingénieurs de Tunis, Tunisie-mbf.besbes@gnet.tn

The aquifer of Kairouan, located in the central part of Tunisia, is the main water resource for drinking supply, agriculture and industrial use in the region. It is composed of a shallow and a deep units and its main feeding comes from natural recharge in wadis. Because of the demographic, agricultural and industrial development in the region, the aquifer knows an increasing exploitation with more than 5000 wells and 400 drillings. The actual exploitation volume exceeds the aquifer capacity and thus can threaten the water quality there. The main risks are dealing with deep saline water upcoming and Sebkha water intrusion. Another risk can come from irrigation water recycling which can only be very saline because of the climate aridity in the region.

In this work, we present the main results of a geochemical study of Kairouan aquifer. Major elements were used to identify the water types and a statistical study was performed to determine the salinity origin as well as the inter connection between the surface water and the two aquifer layers.

The richness of the mineralization by different major elements has been explained by the probability of rocks alteration, meteoric contribution and salt migration in the atmosphere from Sebkhas that constitute the Kairouan groundwater outlet.

Palaeoweathering chemistry of some flood basalt hosted fossil soils and their palaeoclimatic significance

M. R. G. SAYYED
Department of Geology, Poona College, Camp, Pune 411 001, India (mrgsayyed@yahoo.com)

Ancient soils have been largely used to understand the palaeoclimates because the chemical weathering was in response to the contemporaneous reactions between the meteoric water equilibrated with the atmospheric gases and the protoliths. The present paper attempts to compare chemical weathering patterns of the fossil interbasaltic soils (from the published geochemical data) from some flood basalt provinces. These include from Late Triassic Ischigualasto basin (NW Argentina), end-Cretaceous Deccan Traps (India), British Tertiary Basaltic Province and Tertiary lavas of Northern Ireland. The published geochemical data of the basalts and modern soils (Mumbai) developed upon them from Deccan Traps have been used for comparison. In general the CIA values do not show many variations from the Deccan boles but if studied from two spatially separated areas they have appreciable differences; the Ischigualasto palaeosols, however, show a wide range of CIA values. The higher CIA values in the Skye and Mull boles from British Tertiary basaltic province, than the Deccan boles, indicate their quite intensive weathering conditions while Tertiary interbasaltic formation of Northern Ireland conspicuously shows very high CIA values, indicating highly intense and/or prolong chemical weathering. Hydrolysis show good correlation with MAP and CIA but the Tertiary interbasaltic formation shows exceptionally higher hydrolysis. When plotted on the triangular diagrams the Deccan boles and the Tertiary interbasaltic formation show distinctive fields. The Skye and Mull boles, Ischigualasto palaeosols and Mumbai modern soils plot close together. Thus from the fossil interbasaltic soil geochemistry it is evident that the palaeoweathering characteristics are different in different flood basalt provinces and the different chemical weathering characteristics should be correlated with the time gap (quiescence periods) between the successive lava flow eruptions and the palaeolatitudinal positions influencing the palaeoclimates.

Age evolution of Gold concentrations in metamorphic rocks

A.M. SAZONOV1 AND E.A. ZVIAGUINA2
1Siberian Federal University, Krasnoyarsk, Russia (sazonov_am@mail.ru)
2Siberian Federal University, Krasnoyarsk, Russia (elena_zv@mail.ru)

The results of examination of gold-bearing rocks in Achaean, Proterozoic and Oligocene metamorphic complexes are presented below. The territories under study are located within the blocks of the basement and the folded frame of old platforms (the Siberian platform, the East–European platform) and the Oligocene folded structure of the Eastern Pamir (Central Asia). The distribution of gold in metamorphic rocks depends on the next regularities.

The oldest super-crustal metamorphic rocks of the granulite facies are characterized with higher concentrations of gold in comparison with clark (12.18 – 55.3 ppb). Charnokites formation, granitization, migmatization and diaphthorezis in the granulite series lead to gold carrying out – 20-55 ton / km³. These series could be one of the sources of metal for Proterozoic and Phanerozoic mineral deposits.

Gold concentration in the Proterozoic and Phanerozoic metamorphic complexes is 2-5 times more than concentration in the surrounding aleuropelite sedimentary rocks. Gold is introduced with deep fluids into the metamorphism area.

Rocks of the amphibolite facies of zoning metamorphic belts are characterized with the lowest concentration of gold (2.92-4.5 ppb). Double exceeding of gold grades is typical for the greenschist facies (4.25-6.19 ppb) and epidote-amphibolite facies (4.4-6.7 ppb) in comparison with the amphibolite facies. Accumulation of gold takes place under marginal P-T conditions of metamorphism, in the rocks near the boundaries between facies or subfacies (8.21-24.00 ppb).

The distribution of gold in the zoning metamorphic Oligocene rocks of the S-E Pamir is similar to Proterozoic rocks, but gold grades in these units are more than 20% higher in comparison with Proterozoic series.
Patterns and processes of long-term drainage exports from a pine chronosequence on restored lignite-mining dumps in Lusatia, Germany

WOLFGANG SCHAAF
Chair of Soil Protection and Recultivation, Brandenburg University of Technology, P. O. Box 101344, D-03013 Cottbus, Germany; (schaaf@tu-cottbus.de)

Open cast lignite mining results in severe multiple disturbances of ecosystem functions. In the Lusatian lignite mining district (E-Germany), an area of 80.000 ha is characterized by overburden dumps, tailings and mining lakes due to intensive lignite mining. Pyrite oxidation and AMD result in initially phytotoxic site conditions. On 60% of this area pine forests have been restored after intensive amelioration measures.

Characteristic features of the soils developing at these sites are sandy texture, poor water and nutrient storage capacity, high acidity and salinity, secondary mineral formation, and a high content of geogenic organic matter in various forms and spatial distribution (Schaaf and Hützl 2006). We studied the relevant soil structures and processes along a chronosequence of mine sites as well as the effects of its specific properties on element budgets and drainage exports at various scales using intensive field measurements, small-scale monolith sampling, and soil column experiments.

Pyrite oxidation itself and labile secondary minerals as well as the content and distribution of geogenic organic matter and its related physico-chemical properties affects water and element transport, element transformation and release processes, nutrient cycling, and soil development. The disturbance effect on element exports is declining over time, but can be clearly identified over a period of at least 60 years with considerably increased leaching rates from the restored ecosystems (Schaaf 2001).

Numerical study on shock effects in impact-rocks due to porosity

S. SCHADE AND K. WÜNNEMANN
Museum für Naturkunde, Invalidenstr. 43a, 10115 Berlin, sara.schade@museum.hu-berlin.de (kai.wuennemann@museum.hu-berlin.de)

Motivation and method
The heterogeneous distribution of crystalline shock polymorphs is commonly observed in impact rocks, and results from impedance contrasts between different minerals (e.g. Heider and Kenkmann, 2003) and pore spaces (e.g. Kieffer, 1976, Steward, 2007). We present numerical simulations of pore collapse due to shock wave loading to analyse the dependency of pre-shock internal rock structure on the resulting variety of shock features. We use the 2D hydrocode iSALE (e.g. Wünemann et al., 2006) and the analytic EOS (ANEOS) for dunite and quartzite. Pore spaces are represented by simple geometries, aligned by varying their sizes, distances and numbers.

Results
Significantly enhanced high temperatures and pressures occur when the collapse of a pore is completed. The maximum and distribution of peak pressures dependents on the geometry (Fig. 1), number and alignment of pores.

Results will be furthermore compared analytically with impacted terrestrial and meteoritic rocks.

Terrestrial cosmogenic isotope techniques have been revolutionizing earth sciences over the last decade and the methodological progress is accelerating. Related to the US/EU framework of the CRONUS initiative, substantial advances have been made over the last two years in developing new cosmogenic isotope systems and in sharpening existing cosmogenic tools.

We present analysis and production rate calibrations of several cosmogenic isotope systems focusing on terrestrial $^{53}\text{Mn}$, a long-lived radio isotope previously limited to extraterrestrial applications. This novel tool will allow new insights into landscape dynamics in arid regions on the million year time scale. On the other end, we present recent progress in the $^{10}\text{Be}$ technique allowing precise and accurate dating of Holocene climate changes including processes less than two hundred years in age.

Weathering rates determined on eroding moraine crests using cosmogenic $^{10}\text{Be}$ and base cation depletion

M. SCHALLER, J.D. BLUM, AND T.A. EHLERS

Department of Geological Sciences, University of Michigan, 1100 N, University Ave., Ann Arbor, MI 48109-1005; USA (mirjam@umich.edu; jdblum@umich.edu; tehlers@umich.edu)

Quantification of weathering rates is important for the understanding of landscape evolution and soil formation. Chemical weathering rates are influenced by many factors such as climate, vegetation, physical erosion, parent material composition, and soil age. Weathering rates of soils are typically calculated from non-eroding surfaces of known deposition age (e.g. Bain et al., 1993; Taylor and Blum, 1995) or surfaces assumed to erode at steady-state (e.g. Green et al., 2006; Riebe et al., 2001). Unfortunately, the assumption of non-eroding or steady-state landscapes is not always justified (e.g. moraine crests). In this study we integrate cosmogenic radionuclides ($^{10}\text{Be}$) and base cation depletion in two ~2 m depth profiles from moraines of different age to quantify soil mixing, denudation, and chemical weathering.

Depth profiles were sampled from terminal moraines in the Wind River Mountains, Wyoming. The two profiles were collected on the crests of the Pinedale (~21 ka) and Bull Lake (~140 ka) moraines. Calculations of weathering rates are based on base cations (Ca, K, Mg, Na) and reported as g(oxide) cm$^{-2}$ yr$^{-1}$. Weathering rates assuming no physical erosion of the moraine surfaces are 1.0 x 10$^{-5}$ and 3.1 x 10$^{-5}$ g(oxide) cm$^{-2}$ yr$^{-1}$ for the Pinedale and Bull Lake moraines, respectively. Measurement of in situ-produced cosmogenic $^{10}\text{Be}$ in each depth profile suggest denudation rates of 0.01 mm yr$^{-1}$, and soil mixing depths of 40 to 60 cm. Results to date suggest the assumption of steady-state denudation is not applicable to the investigated moraines due to their young age. Calculation of weathering rates based on transient denudation of the moraines needs to be investigated further.

Preliminary Results suggest that weathering rates accounting for physical erosion are higher than rates based on the assumption of no erosion. The increase in weathering rates might be larger for older surfaces as more weathered material has been eroded. Taking into account physical erosion, the decrease of weathering rates over time might be less than previously determined by assuming no erosion (e.g. Taylor and Blum, 1995).

3Université de Lausanne, Département de Géologie et Paléontologie, Lausanne, Switzerland (jean.guex@unil.ch)

The end-Triassic extinction is considered to be one of the most important biotic crises our planet has experienced, involving the disappearance of about 80% of the known species. Flood basalt volcanism of the Central Atlantic Magmatic Province (CAMP) has repeatedly been invoked to have caused this catastrophic event. New precise zircon U-Pb ages are proposed for the Triassic-Jurassic and the Hettangian-Sinemurian boundaries. The ages were obtained with ID-TIMS techniques from single chemical-abraded zircons from volcanic ash layers within the Pucara Group, Aramachay Formation, in the Utcubamba valley, northern Peru. Ammonite biostratigraphy is combined with U-Pb dating to indicate 206Pb/238U ages of c. 201.5 Ma for the Triassic-Jurassic and of c. 199.5 Ma for the Hettangian-Sinemurian boundaries. The former is established on a tuff located 1 m above the last local occurrence of the topmost Triassic genus Choristoceras and the latter was obtained from a tuff collected within the Badouxia canadensis beds. Our new ages document total duration of the Hettangian of c. 2 Ma, which has fundamental implications for the interpretation and significance of the ammonite recovery after the end-Triassic extinction.

The new zircon 206Pb/238U age for the T/J boundary is 2 Myr older than the currently accepted 206Pb/238U date for this boundary, and is in agreement with the published database of 40Ar/39Ar ages, taking into account the systematic 0.6-1.0% age difference between the two isotopic systems. The most precisely dated CAMP rock – the North Mountain Basalt in Eastern United States – is slightly younger than our date for the T/J boundary, with a 206Pb/238U date of 201.27 ± 0.06 Ma (Schoene et al., 2006). Resolving the question of synchronicity between CAMP volcanism and the T/J extinction, and thereby supporting a causal relationship between these two events, requires further high-precision U-Pb dating of potentially older basaltic units within the CAMP.

Estimating magnesium and silicon isotope fractionation with first-principles lattice dynamics

E A Schauble1, E Tonui1, R B Georg2, E D Young1 and A N Halliday2

1Dept. of Earth and Space Sciences, UCLA, CA 90095, USA (schauble@ucla.edu)
2Earth Sciences, Oxford University, OX1 3PR, UK

Silicon and magnesium are major elements that undergo differentiation in a variety of igneous, metamorphic, and low-temperature environments. In this study first-principles methods are used to calculate equilibrium isotopic fractionations involving these elements, in order to assess potential applications of isotope measurements to understanding geochemical processes. Calculations focus on silicate and oxide minerals, and aqueous Mg2+ (by analogy to crystalline Mg(H2O)6•SO4).

Isotopic fractionations are calculated using density functional perturbation theory (DFPT), with norm-conserving pseudopotentials and a gradient-corrected functional (PBE). The energies driving fractionation are determined from changes in the density of states of vibrational (phonon) frequencies when isotopes are substituted into each crystal structure. Comparison with measured infrared and Raman spectra suggests that the DFPT-PBE method underestimates frequency changes in the density of states of vibrational (phonon) spectra. Comparison with measured infrared and Raman frequencies when isotopes are substituted into each crystal structure suggests that the DFPT-PBE method underestimates frequency changes in the density of states of vibrational (phonon) spectra. Comparison with measured infrared and Raman frequencies when isotopes are substituted into each crystal structure suggests that the DFPT-PBE method underestimates frequency changes in the density of states of vibrational (phonon) spectra. Comparison with measured infrared and Raman frequencies when isotopes are substituted into each crystal structure suggests that the DFPT-PBE method underestimates frequency changes in the density of states of vibrational (phonon) spectra. Comparison with measured infrared and Raman frequencies when isotopes are substituted into each crystal structure suggests that the DFPT-PBE method underestimates frequency changes in the density of states of vibrational (phonon) spectra. Comparison with measured infrared and Raman frequencies when isotopes are substituted into each crystal structure suggests that the DFPT-PBE method underestimates frequency changes in the density of states of vibrational (phonon) frequencies by 3-5%, and a fitted scale factor is used to adjust model frequencies. 1-5 phonon wave vectors appear to give a sufficiently large sample of the phonon density of states for each crystal.

The models predict measurable equilibrium isotopic fractionation of both magnesium and silicon in common minerals at metamorphic and igneous temperatures. At 1000°C, 26Mg/24Mg will be higher in spinel than silicates (0.6% for spinel-forsterite). This agrees with preliminary measurements of peridotite mineral separates (Tonui et al., this meeting). Silicates will have higher 26Mg/24Mg than carbonates (0.5% for diopside-dolomite at 600°C). Aquous Mg2+ will also have higher 26Mg/24Mg than coexisting carbonates (by ~2-3% at 25°C), in qualitative agreement with speleothem data [1]. There may be a small (0.1% at 1000°C) fractionation between forsterite and diopside, with diopside tending to be heavy.

30Si/28Si will also vary, tending to be highest in quartz. This agrees with previous Si-isotope fractionation models [2]. Quartz-zircon fractionation is expected to be ~0.5% at 800°C, compared with 0.3% observed in a granodiorite. Forsterite-diopside fractionation is small (~0.1% at 1000°C, diopside being light), consistent with xenolith data. Our results indicate that processes of igneous and metamorphic differentiation and metasomatism are likely to cause detectable Si- and Mg-isotope signatures.

Molecular and geochemical investigation of sediments covered with white mats at the Logatchev hydrothermal vent field

R. SCHAUER¹, H. ROY¹, H.-H. GENNERICH², A. MEYERDIERKS¹ AND R. AMANN ¹

¹Max Planck Institute for Marine Microbiology, Germany (rschauer@mpi-bremen.de)
²University of Bremen, Germany (hherm@uni-bremen.de)

Microbial mats have been described for different hydrothermal vent sites, e.g. along the East Pacific Rise (Taylor et al., 1999), in the Western Pacific (Takai et al., 2003), and at the Loihi Seamount (Moyer et al., 1995). In our study, we investigated the microbial community of two different sediments covered with white mats at the Logatchev hydrothermal vent area on the Mid-Atlantic Ridge (14°45’N). The white areas were occasionally interspersed with mussels at diffuse venting sites.

Temperature measurements showed 2-3 °C in the surface layer of both sediments increasing to up to 99°C in 28 cm depth. The corresponding temperature profiles revealed a linear temperature gradient indicating a high convective heat flux and no fluid flow. In contrast, the temperature of the sediments outside of the white-covered areas increased from 2-3°C to a maximum of only 8°C in 28 cm depth. To investigate the microbial diversity within the sediment surface layer (0-1 cm) of the white-covered areas 16S rRNA clone libraries were constructed. The analysis of about 100 clones per site resulted in 10-13 detected phyla. Using operational taxonomic units (OTUs), members of the Gamma-, Delta-, and Epsilonproteobacteria as well as of the phylum Bacteroidetes were identified as mat specific. CARD-FISH experiments confirmed that members of these four phylogenetic groups constitute the majority of microorganisms in the surface sediment layer of the “white mat” community. Typical filamentous sulphur-oxidizing bacteria of the genera Beggiatoa and Thiothrix were not detected.

In conclusion, the microbial community of the white mats was found to be highly diverse. However, mat specific groups were identified, which phylogenetically affiliated mainly with cultured sulphur-oxidizing bacteria. The high temperature in the deeper sediment layers correlates with the appearance of the white mats on the sediments. This suggests that a high subsurface temperature could cause processes supporting the formation of white mats on hydrothermal sediments.

U-Th magma residence times of the Plinian Mercato eruption at Mt. Somma-Vesuvius (Southern Italy)

B. SCHEIBNER¹, G. WÖRNER¹, A. HEUMANN¹ AND L. CIVETTA²

¹Geowissenschaftliches Zentrum Göttingen (GZG) – Universität Göttingen, Goldschmidtstr. 1, D-37077 Göttingen, Germany (B.Scheibner@fz-juelich.de)
²Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuviano and Dept. Scienze Fisiche, Università di Napoli Federico II, Via Diocleziano 328, I-80124 Naples, Italy

Plinian phonolite eruptions are a permanent dangerous threat for the population close-by to explosive volcanoes and have an effect on global climate changes. Hence, phonolite residence times in the crust are critical for assessing the potential hazard and frequencies of such explosive phonolite volcanic systems. So far, previous U-Th-studies on phonolites suggest time scales for the whole differentiation process forming a basanite to a phonolite of hundred of years up to hundred of thousand years. However, it is still unclear how long an differentiated phonolite and potentially explosive magma can reside in the crust without eruption or solidifying. Our combined petrological, geochemical and isotope study on late-stage phenocrystic unzoned phonolite Ca-garnets from a phonolite sample of the Pomici di Mercato eruption from Mt. Somma-Vesuvius (Southern Italy) permit for the first time the precise determination of the residence time of a differentiated phonolite magma in the shallow crust: These Ca-garnets, glass and whole-rock from the 8.1 ka-old phonolite Pomici di Mercato eruption define an U-Th-isochrone age of 14.4 ± 1.1 ka (2σ). It follows that explosive phonolite magma resided for more than 5 ka before eruption beneath Mt. Somma-Vesuvius in the shallow crust. In addition, given the recorded frequencies of eruptions from this volcano over the time, the Pomici di Mercato eruption was preceded by an exceptionnel long repose time. This could be explained by the closed-system behaviour of the Mercato reservoir, that was not refilled since Ca-garnet crystallisation and was not triggered by an input of new volatile-rich, less-differentiated magma.
Noble gases in fluid inclusions in speleothems

Y. SCHEIDEGGER1,2, R. KIPFER1, R. WIELER3, S. BADERTSCHER3 AND M. LEUENBERGER4

1Water Ressources and Drinking Water, Eawag, Switzerland
2Isotope Geochemistry and Mineral Resources, ETH, Zürich, Switzerland
3Geological Institute, University of Bern, Switzerland
4Climate and Environmental Physics, University of Bern, Switzerland

Speleothems contain various paleoenvironmental proxy records on long time scales with high temporal resolution. Air and water inclusions formed during speleothem growth both represent potentially valuable archives of past climate conditions. First semi-quantitative analyses of air inclusions indicate that the major components (N2, O2, Ar) are present in near-atmospheric abundances. In contrast, trace gases (CO2, N2O, CH4) are enriched in the inclusions and hence the cave air. Therefore, similar to air trapped in ice cores, air inclusions in speleothems have the potential to reconstruct past climate conditions from regions where no ice is available. The concentrations of dissolved noble gases in water inclusions directly reflect the atmospheric pressure as well as the trace gas abundances from air inclusions. Moreover, the noble gas signature after heating is dominated by noble gases from water inclusions. However, the noble gas signature after heating is dominated by noble gases from water inclusions. Therefore, similar to air trapped in ice cores, air inclusions in speleothems have the potential to reconstruct past climate conditions from regions where no ice is available. The concentrations of dissolved noble gases in water inclusions directly reflect the atmospheric pressure as well as the temperature and salinity of the water at the time of formation of the inclusions. To infer past climate conditions, the parameters T, p, S and “excess air” have to be determined from four measured noble gas concentrations (Ne, Ar, Kr, Xe), analogous to the noble-gas thermometer employed in lakes and groundwater. The separation of noble gases from air and water inclusions is crucial to determine paleotemperatures from noble gases is water inclusions. Microscopical investigations show that air and water inclusions differ in size and position within the speleothem. Hence, a sufficient separation should be achievable by extracting noble gases in two subsequent steps (crushing and heating). First results show that crushing mainly opens inter-granular air inclusions whereas heating cracks intra-granular water and air inclusions. However, the noble gas signature after heating is dominated by noble gases from water inclusions.

The salinity of the drip water before incorporation into the speleothem - determined by microthermometry - ranges from 7 – 15 ‰ and therefore can be assumed to be equal to that of freshwater. Since tritogenic and radiogenic 3He in the water inclusions are probably negligible, 3He is purely atmospheric, in contrast to 4He. This would allow 3He to be used as an additional constraint to reconstruct the paleoenvironmental conditions.

With the potential of a quantitative separation of noble gases from air and water inclusions before analysis and additional measurements of 3He, the determination of paleotemperatures from noble gases in fluid inclusions seems to be possible.

In summary, dissolved noble gases from water inclusions, as well as the trace gas abundance from air inclusions are emerging proxies that will complete the available methods to reconstruct past climate conditions from speleothems.

Selenite reduction by nano-crystalline green rust, magnetite, siderite and mackinawite: EXAFS identification of Se species

A. C. SCHEINOST1 AND L. CHARLET2

1Institute of Radiochemistry, FZD, Dresden, Germany, and The Rossendorf Beamline, ESRF, Grenoble, France
2Geochemistry Group, LGIT, Grenoble, France

Selenium oxoanions are abiotically reduced on Fe(II/III) hydroxide (green rust) and Fe(0) metal surfaces to Se oxidation states of 0, -I or –II with relatively slow reaction kinetics [1, 2]. The unequivocal phase characterization by EXAFS spectroscopy, which is a key for the determination/prediction of Se solubility, was hindered by incomplete reduction, insufficient spectral data ranges and the similarity in short-range structures of the potential mineral phases. In a recent study [3], however, we were able to clearly identify the reduction product of selenite co-sorbed with FeII to montmorillonite as nano-particulate, trigonal Se(0) by collecting low-noise EXAFS spectra at 15 K (Rossendorf Beamline at ESRF, Grenoble, France) and by employing advanced data analysis methods [4, 5].

Here, we present data on the reduction of selenite by green rust, magnetite, siderite and mackinawite. In the presence of green rust, selenite was completely reduced to trigonal Se(0) within one day, which was further converted to ferroselite (orthorombic FeSe2) within one month. The associated Fe(II) oxidation and magnetite formation quantified by Moessbauer spectroscopy allowed us to establish the following reaction scheme: 32 [FeII3FeIII4(OH)12 Cl] + nH2O(s) + 38 SeIVO3(s) ⇌ 19 [FeIVSeI2](s) + 175 [FeIIIFeII3O4](s) + 160 Cl - + 502 H2O + 84 H±

Similar to green rust, mackinawite and magnetite reduced all selenite within one day, whereas reduction by siderite was incomplete. Depending on type of mineral and Se-to-mineral ratio, trigonal Se(0), ferroselite or achavalite (hexagonal FeSe) formed. The observed differences in reaction end products and reduction kinetics may significantly affect Se bioavailability and Se migration.

Formation of Liesegang rings in borosilicate glass during experimental alteration

D. SCHEITER, A. JANSSSEN AND T. GEISLER
Institut für Mineralogie, University of Münster, 48149 Germany (ajanssen@uni-muenster.de)

Borosilicate glasses are currently the standard material for the immobilization of high-level nuclear waste. Numerous studies have been carried out to study the aqueous durability of such glasses, which have indicated that under ambient conditions the corosion of the glass is initially controlled by ion exchange and later by hydrolysis of the glass network, forming a so-called “leached layer”, before the glass dissolves. For the present study we have synthesized a borosilicate glass with a complex composition, including network modifiers such as Na, Ce, Al, Mn, Li, Ca, Mg, and Ti (WAK glass), from which we cut cuboids with edge lengths of about 2.6 mm. These cuboids were treated in a 1 M HCl solution at temperatures between 100 and 220 °C for 4 days. For one experiment (at 150°C) the solution was enriched with 47.5 at.% 18O. After the experiments, the formerly translucent, yellowish glass cuboids showed a milky-white color, but their external shape has not changed, as in pseudomorphism. Interestingly, the measured weight and elemental loss values increase regularly from 100 to 150°C, and then decrease towards a local minimum between 170 to 190°C before they increase again. Backscattered electron images on cut glass samples revealed reaction rims (“leached layers”) with complex oscillatory banding structures and bifurcations (Liesegang rings), which form a layer between the unaltered glass and an unpatterned outer rim. Whereas the outer rim consists of almost pure SiO₂, the patterned layer retained some Ce, Ti, and Al, located now within distinct bands. The occurrence of Liesegang-like banding structures suggests, at first glance, a diffusion-controlled alteration process. However, infrared spectroscopic measurements on the alteration rim formed in the 18O-enriched solution show a large mass shift of the Si-O vibrational modes (even close to the interface between the unaltered glass and the alteration layer) when compared with measurements on the alteration layer formed in “normal” 16O-enriched solution. This indicates a high concentration of 18O throughout the alteration rim. Furthermore, the chemical interface between the unaltered glass and the alteration rim is sharp on a micrometre scale with no apparent chemical diffusion profiles. Such features are not compatible with a process that is solely controlled by diffusion of cations and hydrogen species. Here we suggest that during the first step the borosilicate glass dissolved congruently followed immediately by the precipitation of amorphous SiO₂ at an inward moving interface. Once the SiO₂ layer became too thick, the communication between fluid and the reaction interface ceased and the SiO₂ layer increasingly incorporated Ce, Ti, and Al. In a second step the Liesegang bands were formed by a diffusion-controlled process.

Metamorphic reworking of the Congo Craton in Uganda

VOLKER SCHENK, PETER APPEL, NIELS JÖNS, DENNY LOOSE, ANDREAS SCHUMANN AND HEIKE WEGNER
Institut für Geowissenschaften, Universität Kiel, Germany (vs@min.uni-kiel.de; pa@min.uni-kiel.de; nj@min.uni-kiel.de; dl@min.uni-kiel.de)

The Basement Complex of Uganda (BC) forms the NE corner of the Archean Congo craton bordering the Pan-African Central African Fold Belt (CAFB) in the N and the East African Orogen (EAO) in the E. We studied the tectonic history of the Archean basement and of its Neoproterozoic cover series by means of metamorphic P-T paths and metamorphic ages (SHRIMP dating of zircon and U-Th-total Pb chemical dating of monazite).

A clockwise P-T evolution during a first metamorphism (M1) along the northern craton border is constrained by prograde sillimanite and later formed kyanite included in garnet, peak-metamorphic Grt-Sil-Bt assemblages and the late-stage formation of cordierite rims around garnet. Peak conditions (9-10 kbar; ca. 940 °C) were followed by decompression to about 8 kbar and subsequent near-isobaric cooling. A second metamorphism (ca. 750°C at 7 kbar) is evident from new garnet overgrowing Bt-Sil/Ky-Crd symplectites formed during retrogression after M1. Dating revealed ca. 2.6 Ga for M1 and ca. 650 Ma for the reworking, indicating that the granulites formed the deep cratonic crust for about 2 Ga prior to their Pan-African uplift.

At the eastern craton border, aluminous Opx (up to 11.5 wt% Al₂O₃ when coexisting with Grt) and assemblages with Spl-Spr-Qtz-Grt-Osumilite (pseudomorph), Opx-Sil-Grt or inverted pigeonite point to extreme metamorphic temperatures (>1000°C) at 8-10 kbar in a very large area (including the Labwor Hills). In contrast, late-stage Grt-Cpx-Qtz coronas in charnockitic and metabasitic rocks were formed at 6-7.6 kbar only after near-isobaric cooling to temperatures of 650-680°C. The reaction history in metapelites points to an anti-clockwise P-T evolution. UHT metamorphism and magmatism of high-temperature A type granitoids are spatially and timely associated and lasted for about 70 Ma between 700 and 630 Ma. The intrusion of the magmas is interpreted as the cause of the UHT metamorphism.

Neoproterozoic cover series (NW Uganda) have not experienced granulite facies metamorphism unlike the basement rocks on which they are resting. They are Grt-Ky-Ms-Bt-Pl-Qtz bearing micaschists metamorphosed at 8 kbar and 650-680°C during a clockwise P-T path. Monazites show a one-stage growth history and give ages of 621±26 and 633±27 Ma for the metamorphic event that was caused by thickening of the cratonic crust.
The Lu-Hf systematics of meteorites: Consistent or not?

E.E. SCHERER\textsuperscript{1}, C. MÜNKER\textsuperscript{2}, AND K. MEZGER\textsuperscript{1}

\textsuperscript{1}Universität Münster, Germany (escherer@uni-muenster.de)
\textsuperscript{2}Universität Bonn, Germany

The discrepancy between the $\lambda_{176}^{176}\text{Lu}$ value determined from terrestrial minerals ($1.867 \pm 0.011 \times 10^{-11}\text{yr}^{-1}$; [1-3]) and those derived from meteorite WR isochrons (1.93-1.98 $\times 10^{-11}\text{yr}^{-1}$; [2,4-8]) remains unsolved. Meteorites that violate isochron assumptions are not ideally suited for $\lambda_{176}^{176}\text{Lu}$ measurements [9]. Nevertheless, some internal (mineral) isochrons may yield valuable insights about the early solar system. Amelin [9] compared the Lu-Hf and U-Pb systematics isochrons may yield valuable insights about the early solar system. Amelin [9] compared the Lu-Hf and U-Pb systematics isochrons may yield valuable insights about the early solar system. Lipid biomarkers as indicators for environmental stress in cyanobacterial mats of Abu Dhabi, United Arab Emirates

A.-K. SCHERF\textsuperscript{1}, R.M.M. ABED\textsuperscript{2} AND J. RULLKÖTTER\textsuperscript{1}

\textsuperscript{1} Institute of Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, Oldenburg, Germany (annka.scherf@icbm.de)
\textsuperscript{2} Max Planck Institute for Marine Microbiology, Bremen, Germany

Intertidal cyanobacterial mats in the coastal flats of the Arabian Gulf in Abu Dhabi (United Arab Emirates) grow under locally different conditions. Salinity ranges from 60 to 200 due to the high evaporation rates of the tidal waters caused by shadowless sunshine exposure for nearly 12 hours a day.

We compared the phospholipid fatty acid profiles of six mats from lower, middle and upper tidal zones. The analysed mats show differences in their texture and horizontal layering. As the species of the layers are attributed to the activity of physiologically different bacterial populations we sliced the mats accordingly and compared the results of single-layer analyses with the data for the whole mats. Phospholipids are main constituents of cell membranes and are easy to extract and identify. Differences in concentrations and distributions will reflect changes in microbial populations and reactions on environmental stress, e.g. desiccation.

Former studies had shown that lipids may be involved in the protection against environmental stress as they maintain the membrane fluidity. In our mats, increased ratios of saturated to unsaturated fatty acids, cyclopropyl to monounsaturated fatty acids and trans- to cis-monounsaturated fatty acids are interpreted as response to environmental stress in the region. The trans- to cis-monounsaturated fatty acid ratios reached up to 1.6, e.g. for elaidic acid in our mats.

What governs the transition from miaskitic to agpaitic assemblages in peralkaline rocks?

JULIAN SCHILLING, MICHAEL A.W. MARKS AND GREGOR MARKL

University of Tuebingen, Wilhelmstr. 56, 72074 Tuebingen, (julian.schilling@student.uni-tuebingen.de)

Peralkaline igneous rocks (molar (Na+K)/Al>1) are characterized by exceptionally high contents of generally incompatible elements like Na, Li, Be, Rb, REE and HFSE (Ti, Zr, Hf, Nb, Ta). However, based on their mineral assemblages, they can be subdivided into two groups: In the case of peralkaline miaskitic rocks, HFSE are incorporated in minerals like zircon, titanite and ilmenite, whereas in agpaitic varieties, these elements occur in complex Na-(Zr,Ti)-silicates such as eudialyte, rinkite and lävenite (Sørensen, 1997). Commonly, peralkaline igneous complexes worldwide show either a miaskitic or an agpaitic character, or at least distinct melt batches within the same complex tend to develop to either miaskitic or agpaitic assemblages. Still, it is not clear, which processes cause either miaskitic or agpaitic assemblages to crystallize.

In the special case of the Eocene Tamazeght complex (Moroccan High Atlas mountains), a continuous transition from miaskitic nepheline syenites to agpaitic ones, including late-stage agpaitic pegmatites and veins, is observed. The earlier miaskitic rocks are characterized by nepheline, K-feldspar, aegirine-rich clinopyroxene, sodalite, titanite and rarely developed zircon. In contrast, the agpaitic varieties bear eudialyte instead of titanite and zircon, without showing any replacement textures between these minerals. However, the major mineral assemblages in the agpaites show no obvious difference compared to their miaskitic counterparts.

In this study, we compare electron microprobe data for nepheline, sodalite and clinopyroxene as well as mineral stable isotope data (O, H) of both miaskitic and agpaitic samples. Additionally, eudialyte from agpaitic samples was analyzed by electron microprobe. Preliminary fluid inclusion investigations indicate two types of inclusions in both nepheline and eudialyte, including a methane- and hydrogen-bearing population, which is known to be typical of peralkaline rocks (Potter & Konnerup-Madsen, 2003).

Based on this, we will try to shed light on the relevant changes of parameters being responsible for the transition from miaskites to agpaites.

Werner Schreyer and the MASH-system: Results from investigations on natural rocks and experiments

HANS-PETER SCHERTL1, THOMAS FOCKENBERG1 AND MICHAEL BURCHARD2

1Ruhr-Universität Bochum, Institut für Geologie, Mineralogie und Geophysik, D-44780 Bochum; Germany.
2Universität Heidelberg, Mineralogisches Institut, Im Neuenheimer Feld 236, 69120 Heidelberg, Germany.

Nearly iron-free metamorphic rocks of sedimentary and metasomatic origin are found in several parts of the world (e.g. Sar-e-Sang/Afghanistan, Dora-Maira-Massif/Western Alps, Eastern Alps/Austria). All these rocks have experienced metamorphic conditions at moderate temperatures and relatively high to ultrahigh pressures. Chemically, these rocks can be well described with the MgO-Al2O3-SiO2-H2O (MASH) experimental model system, and thus provide an excellent independent check on it. In so-called leucophyllites from the Eastern Alps the assemblage chlorite + quartz is found which is stable to only 600°C (Chopin and Schreyer, 1983). Towards higher pressures these phases react to the "whiteschist" assemblage talc + kyanite (Sar-e-Sang) with a temperature of 750 - 800°C this is replaced by the ultra-high-pressure assemblage pyrope + coesite (Schreyer and Yoder, 1988). At all times, Werner Schreyer recognized the significance and interaction of nature and experiment. From experimental studies in the MASH-system he and his working group mapped out petrogenetic grids which allow HP-metamorphic sequences in natural rocks to be seen in a geodynamic context, while at the same time these natural occurrences also served as a template for delineating stability/compatibility fields of the observed nearly iron-free phases and assemblages in the laboratory (e.g. Fockenberg, 1995).

Recent geological and geophysical observations from the Galileo spacecraft indicate that Europa, one of the icy moons of Jupiter, harbors a salty ocean of liquid water beneath its icy surface. Magnetic field perturbations observed by the Galileo spacecraft at Europa, are consistent with induced magnetic fields from the interior of the moon. These magnetic fields are very likely caused by electromagnetic induction in a subsurface water ocean with high electrolytical conductivity. An additional process, which also generates magnetic field perturbations at Europa and therefore competes with induction, is the interaction of Europa’s oxygen atmosphere with the magnetospheric plasma in which the moon is embedded. We have developed a time dependent 3D model to study simultaneously the electrical conductivity distribution inside Europa and the time-varying interaction of Jupiter’s magnetosphere with Europa’s atmosphere. By comparing our simulation results to the Galileo spacecraft measurements by Europa, we place the so far strongest constraints on the conductivity and the thickness of Europa’s subsurface ocean. We find an internal ocean close to the surface with a conductance of 50,000 S or larger to be most suitable to explain the magnetic flyby data. These results suggest that a global subsurface ocean at Europa with terrestrial “sea water” would have to be thicker than 10 km.

In situ cosmogenic $^{36}$Cl production rate calibration on basaltic flows of Mount Etna (Sicily, 38°N)

I. SCHIMMELPFENNIG1, L. BENEDETTI1, R. PIK2, P. BURNARD2, P.H. BLARD3 AND D. BOURLÈS1

1CEREGE, UMR 6635 CNRS, Aix en Provence, France (schimmel@cerege.fr)
2CRPG, UPR 2300 CNRS, Vandoeuvre-lès-Nancy, France
3CALTECH, Pasadena, CA 91125, USA

One of the CRONUS-EU goals is to provide high quality calibration sites from independently dated surfaces. Several previous studies have been conducted on $^{36}$Cl production rate calibration (e.g. Stone et al. 1996, Phillips et al. 2001), which, however, used different protocols and yielded $^{36}$Cl production rates with up to 40% discrepancies. The objectives of this study are 1- to understand the source of these discrepancies and 2- to calibrate $^{36}$Cl production rates from its most abundant target elements $^{40}$Ca, $^{39}$K and $^{35}$Cl.

As a first step we focused on testing the chemical protocol by performing a sequential $^{36}$Cl extraction experiment on whole rock grains and Ca rich plagioclase from the same sample. The sample was collected at Mt. Etna on a pahoehoe flow which has a K-Ar fossil exposure time of 10±3 kyr. Cosmogenic $^4$He of this sample was also precisely measured within cogenetic olivine phenocrysts (Blard et al. 2005) and yields an exposure time of 10.4±1.5 kyr.

Both, total Cl and $^{36}$Cl concentrations from the first dissolution steps are high, 5800 ppm (whole rock) and 450 ppm (plagioclase) Cl, and $10^7$ - $10^8$ atoms $^{36}$Cl/g of rock dissolved. After about 20% dissolution of the plagioclase sample, Cl is almost completely removed (1-3ppm) and $^{36}$Cl concentrations reach a plateau value of $2*10^5$ atoms/g of rock. Using the Stone et al. (1996) and Evans et al. (1997) $^{36}$Cl production rates for the target elements Ca and K, respectively, this plateau concentration yields an exposure age which is in agreement, within uncertainty, both with K-Ar dating and cosmogenic $^4$He ages. On the contrary, in the whole rock sample total Cl concentrations remain high ($>330$ppm) resulting in a considerable $^{36}$Cl production from capture of low-energy neutrons by $^{35}$Cl, an additional and still not well-constrained $^{36}$Cl production mechanism. The resulting exposure ages from the whole rock are 20-30% higher than the independent $^4$He ages.

To better constrain the different sources of $^{36}$Cl in basaltic rocks and their production rates we will perform a similar experiment on separated sanidine (K-rich feldspar) from an independently dated basaltic flow of another volcano.

Simultaneous determination of Se and Te in different geological matrices with DRC-ICP-MS

THOMAS SCHIRMER, ANDREA KOSCHINSKY AND MICHAEL BAU

Jacobs University Bremen gGmbH, Campus Ring 8, D-28759, Bremen, Germany (t.schirmer@iu-bremen.de, a.koschinsky@iu-bremen.de, m.bau@iu-bremen.de)

An investigation of ferro-manganese crusts conducted by Hein, Koschinsky et al. (2003) had shown an extreme enrichment of tellurium, but no comparable concentrations of the geochemically very similar element selenium. This Te enrichment was related to a surface oxidation process of Te(IV) to Te(VI) on the Fe-Mn oxide surfaces, which apparently does not take place for Se(IV). Therefore the element pair Se and Te seems to have an interesting potential as paleo-proxy to investigate in situ redox conditions. In a next step Se and Te are investigated in more detail in different geological matrices to gain knowledge of the usability of this element pair to describe geopaleontogical redox processes.

Very little Te data of different geological materials have been available so far. A first challenge to be addressed is the precise determination of these two elements with quadrupole DRC-ICP-MS. In this context an analytical approach was developed, using different methods for sample digestion, enrichment and analysis.

Two well known problems connected with the determination of Se and Te with standard quadrupole ICP mass spectrometry are low sensitivities (max. ~3 kcps and ~15 kcps for 10 ppb Se and Te respectively) and severe interferences, especially on Se (e.g. $^{40}$Ar$^{+}$ on $^{80}$Se). This fact is accompanied by the overall low concentrations in the different matrices, especially in water. Another problem with respect to the acid pressure digestion is the instability of Se in chloride matrix and at temperatures above 80 °C.

All these analytical problems where addressed by optimizing the ICP-MS conditions, the digestion procedure and by the use of thiol cotton separation for samples with very low Te and Se concentrations, first described by Mu-Qing and Gui-Qin (1983). Data for Te and Se in various sample types including marine ferromanganese crusts, weathered basalt and dolomites will be presented.

Influence of Hydrogen on electrical conductivity in enstatite

E. SCHLECHTER¹, R. STALDER¹ AND H. BEHRENS²

¹Dept. of Geoscience, University of Göttingen, (elke.schlechter@geo.uni-goettingen.de), (rstalde@gwdg.de)
²Institute of Mineralogy, University of Hannover, (h.behrens@mineralogie.uni-hannover.de)

Hydrogen has a significant influence on several physical properties of upper mantle rocks. Models for electrical conductivity, for instance, are mainly based on conductivity data for olivine. Therefore, systematic laboratory data on electrical conductivity of other H-bearing nominally anhydrous minerals (e.g. enstatite, MgSiO$_3$) are needed. An important mechanism for electrical conduction in enstatite requires the presence of protons, because they are the major mobile charge carriers. Key factors for this conduction mechanism are concentration and mobility of protons. In this study, we measured electrical conductivity and H-diffusivity in pure, Al-, and Fe-doped synthetic enstatite. As incorporation of additional cations, such as Al and Fe, create new point-defects in the crystal lattice, transport mechanisms might depend on the defect chemistry.

Diffusion experiments were conducted at 1 bar and 1000°C to 1000°C in air. Electrical conductivity was measured at same conditions with an impedance analyzer (0.1 - 10000 Hz), and H-concentration was monitored by FTIR-spectroscopy.

Initial results show that H-diffusivity from dehydration experiments in Fe-bearing enstatite is about one order of magnitude faster than in pure enstatite, whereas it is slower in Al-bearing enstatite. A similar behaviour was observed for electrical conductivity.

Application of the Nernst-Einstein equation to the diffusivity results for pure enstatite are in good agreement with our preliminary conductivity data; this supports the hypothesis that H is the major mobile charge carrier.
Cation sorption at the smectite edges: From transition metals to Y and Lu

M.L. SCHLEGEL

CEA, DANS/DPC/SCP/Laboratory for the Reactivity of Surfaces and Interfaces, F-91191 Gif-sur-Yvette, France (michiel.schlegel@cea.fr)

Introduction

Clay minerals can adsorb trace elements in soils and weathering formations, a sorption property which is also a key-point for the use of clay materials in nuclear waste repositories. Retention can occur either by adsorption on the clay basal plane or at the layer edges, depending on physico-chemical conditions. Building on previous identification of sorption sites of transition metals [1-3], this study shows how the geometry of Y and Lu surface complexes on layer edges of clay minerals can be identified.

Materials and methods

Suspensions of purified clay minerals (hectorite or Al-montmorillonite, 2 and 1 g/L, respectively) were reacted in 0.5 M NaCl at pH 6 (Al-montmorillonite) and 7 (hectorite) with sorbates at concentrations of 50 μM (Y) and 100 μM (Lu). Self-supporting films of reacted clay minerals were obtained by slowly filtering suspension aliquots on cellulose nitrate filters. Yttrium K-edge and Lu L3-edge polarized EXAFS (P-EXAFS) spectra of the self-supporting films were collected in fluorescence mode on the FAME beamline (ESRF, France). P-EXAFS data were reduced, and analyzed using standard procedures.

Results and interpretation

Small but significant angular dependences were observed for all P-EXAFS data, meaning that the Y and Lu binding environments are anisotropic. Coordination spheres of 7 O at 2.36 Å and 8 O at 2.27 Å, were observed for Y and Lu, respectively, comparable with d(Ln-O) distances measured by EXAFS spectroscopy [4]. Lutetium sorbed on Al-montmorillonite was surrounded by an Al-shell at 3.35 Å, consistent with Lu sharing edges with Al octahedra and partially incorporated in a gibbsite-like interlayer. Both Y and Lu sorbed on hectorite were surrounded by cationic silicates. Modelling of these cationic contributions yielded one out-of-plane Si/Mg shell at 3.16 Å (Y) or 3.04 Å (Lu), and two in-plane (Mg/Si) shells at 3.50, and 3.97 Å for Y, or 3.33 and 3.91 Å for Lu. These distances and angular orientations collectively suggest that Y and Lu form inner-sphere surface complexes at the edges of hectorite platelets, but slightly above/below the hectorite octahedral plane, and tend to share edges with silicate groups of the clay tetrahedral sheet.

Interaction between colloidal and organically complexed Iron (III) species in seawater by ultrafiltration

C. SCHLOSSER AND P. CROOT

IFM-Geomar, Kiel, Germany (eschlosser@ifm-geomar.de, pcroot@ifm-geomar.de)

Method and Theory

Ultrafiltration experiments (Viavflow 50 - 10kDa filter) were performed using 55Fe in combination with artificial and natural organic ligands (in excess) in seawater. The activity of the 55Fe in the permeate and retentate was measured using standard liquid scintillation methods. The permeation (Pc) and retention coefficient (Rc) were calculated as follows:

\[ P_c = 1 - \frac{\log c_p}{\log CF} \]
\[ R_c = 1 - \frac{\log c_R}{\log CF} \]

Where CF = concentration factor (CF). Some results are shown in the Table below:

Table 1: P_c and R_c values of the Fe (III) species

Discussion

These 2 parameters allow us to differentiate between very strong, strong and weak ligands based on their ultrafiltration properties. Pc=Re=1 are significant for very strong ligands (e.g. DFO_B), where all added Fe is organically complexed. Strong ligands (e.g. TAC, EDTA) have additionally a colloidal fraction, but no interaction between both species (Pc=1, Rc<1). Pc=Re<1 are observable for weaker ligands (e.g. Protophorphyrin IX) with an identifiable interaction between both species.

Conclusion

Using this approach helps us better understand the relationship between colloidal and dissolved Fe concentrations in natural seawater and how to quantify the interconnections between natural organic complexes and colloidal iron. The results strongly suggest that information on colloidal Fe concentrations is dependent on CF and this needs to be taken into account when reporting ultrafiltration data. This approach is particularly useful for assessing the bioavailability of iron in natural seawater as most colloidal iron is believed to be weakly bioavailable.
Hydrothermal AFM and mixed-flow reactor studies of ZnS dissolution

C. SCHLUETER¹, G. JORDAN¹, O. POKROVSKY² AND W.W. SCHMAHL¹

¹Sektion Kristallographie, Departement für Geo- und Umweltwissenschaften, Theresienstr.41, 80333 München, Germany, (schlueter.christoph@googlemail.com, jordan@lmu.de, wolfgang.schmahl@lrz.uni-muenchen.de)
²LMTG-OMP CNRS, Univ. P. Sabatier, Toulouse, France, (oleg@lmtg.obs-mip.fr)

Sulfide minerals are the major contributors to acid mine drainage (AMD) and heavy metal release. While the weathering of iron sulfides has been studied intensively only little attention has been paid to the zinc sulfides. To understand the mechanisms and kinetics of sphalerite reactions in aqueous solutions, a combination of high resolution microscopy methods and chemical analytical methods proved to be perfect as it correlates nano-scale observations with macro-scale data.

Here, in situ hydrothermal AFM (HAFM) measurements and mixed-flow reactor experiments were conducted at pH 1-2 and a temperature of 125 °C. While HAFM measurements were performed on the (110) surfaces, sphalerite powder was used for mixed-flow reactor experiments.

Mixed-flow reactor experiments showed an initial maximum of zinc and sulfur release. This initial maximum in dissolution was followed by an exponentially decreasing part, which converted into a steady state after ca. 10,000-15,000 min. Within the accuracy of the data, the mixed-flow experiments revealed no incongruent or not stoichiometric dissolution. in situ HAFM measurements showed the formation of a thin altered layer on the surface during the initial state of dissolution followed by a development of facets.

From the mixed-flow reactor experiments it can be concluded that the leached layer observed in HAFM experiments can only be caused by a minimal shift in the chemical composition of the surface.

The HAFM experiments further showed the decomposition of the cleavage morphology into facets with three prominent orientations. These observations indicate that the observed initial maximum in zinc and sulfur concentration was caused by a change of the surface morphology from one morphology with high dissolution rates to another morphology with lower dissolution rates. As proved by SEM investigations, small particles on the crystals can be excluded as a reason for the observed rate maximum. Until now tip-surface convolution disabled crystallographic indexing of the facets by AFM. Indexing the facets via LEED remained difficult because the facets were not persistent while LEED sample conditioning. Further experiments are in progress.

In summary, the two different experimental approaches yielded complementary information which in combination allowed one to obtain a significantly more comprehensive understanding of the mechanisms and kinetics of sphalerite dissolution.

Architecture of phosphatic and calcitic brachiopod shell materials – A comparison.

W. W. SCHMAHL¹, C. MÉRKEL¹, E. GRIESSHABER¹, K. KELM² AND C. LUETER³

¹Department for Earth and Environment, LMU Munich, Munich, Germany, (W.Schmahl@lrz.uni-muenchen.de)
²CAESAR Research Institute, Bonn, Germany, (K.Kelm@caesar.de)
³Museum für Naturkunde der Humboldt-Universität, Berlin, Germany, (Carsten.Lueter@museum.hu-berlin.de)

Brachiopods have developed shell materials employing the two principal mineral groups of hard biologic tissue: calcium carbonate and calcium phosphate, each with distinct hierarchical architecture. The “phosphatic” shells consist of a predominantly chitin fibrous matrix, which is reinforced by isometric hydroxyapatite or similarly sized amorphous Ca-phosphate particles attached to the fibres [1]. The fibre composit is not unlike vertebrate bone. A laminated structure is created by changing volume ratios of chitin and reinforcing particles. In contrast, the composit structure of calcitic brachiopod shells employs inorganic single-crystal fibres reinforced by thin intercrystalline and extremely thin intracrystalline organic membranes [2, 3]. The pronounced crystallographic texture of the fibres [2, 4] appears to originate from growth selection. Over lengths well exceeding hundred micrometers the fibres change crystallographic orientation continuously in the order of one degree. While the laminated organic fibre/inorganic nanoparticle strategy provides a degree of shell flexibility the inorganic fibre/polymer membrane composit provides a high stiffness and micro- and nanohardness.

Lu-Hf geochronology of eclogites from the Dabie-Sulu terrain: Constraints on the timing of eclogite-facies metamorphism

A. SCHMIDT1, S. WEYER1, Y. XIAO2, J. HOEFS2 AND G.P. BREY1

1 Institut für Geowissenschaften, JWG Universität Frankfurt, (alexander.schmidt@em.uni-frankfurt.de)
2 Geowissenschaftliches Zentrum Göttingen

The Qinling-Tongbai-Dabie-Sulu belt was formed by the collision of the Yangtze and the Sino-Korean cratons, and is one of the largest ultrahigh-pressure metamorphic belts worldwide. Micro-diamond and coesite was found in eclogites and country rocks of this area, indicating a deep subduction of continental material at mantle depth. The eastern UHP part of the belt is subdivided in the Dabie and the Sulu terrain. The latter was offset 500km to the North by the Tan-Lu fault. Various geochronometers (U-Pb, Sm-Nd, Rb-Sr, Ar-Ar) have been applied to date the metamorphic events in this collision zone. However, UHP and eclogite facies metamorphism are controversially constrained to a Triassic age between 210 Ma and 245 Ma.

Here we present a new approach using the Lu-Hf isotope system to date garnet-clinopyroxene mineral assemblages in three eclogites from the Dabie terrain (sample localities are Bixiling, Shima and Lidu) and three eclogites from the Chinese Continental Scientific Drilling Program (CCSD) in the Sulu terrain. Garnets of our samples are very homogeneous and virtually non-zoned.

The Lu-Hf isochrons yield tightly grouped ages between 219.6 Ma and 223.4 Ma for both terranes (Dabie Shan and Sulu), yielding a mean age of 222.0 Ma for all six samples. This age is in good agreement with earlier estimates on the timing of UHP metamorphism. However, in contrast to previous studies our results indicate a tight age range for eclogites of the entire Dabie complex. Based on U-Pb zircon ages, Liu et al. (2006) and Hacker et al. (2006) recently proposed three metamorphic events within age ranges of 244-236 Ma, 230-220 Ma and 220-205 Ma, respectively. Liu et al. (2006) interpreted their ages as distinct eclogite facies events. In contrast, our Lu-Hf results show no evidence of multiple or long lasting eclogite facies conditions. Alternatively, Hacker et al. (2006) proposed a "precursor" UHP, a "main" UHP and an amphibolites facies metamorphic event for the Dabie-Sulu area. Our Lu-Hf ages fall into their proposed UHP event (220-230 Ma), however, define a much smaller range. This implies a very rapid UHP event on a large regional scale. Alternatively, not UHP, but the transformation of pre-cursor rocks into ecлогite or closure of the Lu-Hf system in garnet in the Dabie and Sulu terrain occurred within a very limited timescale.

Using 222Rn as environmental tracer for assessing groundwater/surface water interaction

AXEL SCHMIDT AND MICHAEL SCHUBERT
Helmholtz Centre for Environmental Research – UFZ, Leipzig, Germany (axel.schmidt@ufz.de; michael.schubert@ufz.de)

The exchange of water between lakes or rivers and hydraulically connected aquifers provides a major pathway for chemical transfer between the respective water bodies. For instance, the migration of dissolved carbon, oxygen, and/or nutrients coupled to such exchange processes has to be considered a main driver for biogeochemical processes on both sides of the surface water/groundwater interface. Furthermore, dissolved contaminants, such as dissolved NAPL, pharmaceuticals, or heavy metals, are not only influential on the aquatic life or the biological properties of the affected water body, but also on its overall water quality. Generally speaking, if the status of a surface water or groundwater resource is to be assessed or its fate to be predicted it must not be looked at as a separate aquatic system but interactions at the surface water/groundwater interface have to be taken into account.

The groundwater flux into a meromictic lignite mining lake (Lusatia Mining District, Germany) was quantitatively assessed by means of a geochemical tracer technique using the naturally occurring radio isotope 222Rn. The noble gas radon makes an ideal environmental tracer because of its chemically inert behaviour and its ubiquitous presence in groundwater, where it appears in concentrations well above the commonly used ones in surface waters (Nazaroff and Nero, 1988). In a long-term project radon concentrations in the water of the studied mining lake and in the groundwater sampled from surrounding monitoring wells were determined monthly over a two-year period. Evaluation and interpretation of the data sets allowed for assessing the dynamics of the local groundwater/surface water exchange processes. It can be shown that there is a high variability in the groundwater/surface water interaction rate, depending on changes of the (seasonal) precipitation rate, even within very short time scales.

The radon technique used has a high potential to improve the quality of the investigation of limnic environments. As a additional advantage the possibility of on-site determination of radon concentration in water samples (Schubert et al., 2006) allows for straightforward decisions concerning the further strategy of ongoing sampling campaigns.

**In situ** studies of aqueous fluid properties at high pressures and temperatures using hydrothermal diamond-anvil cells

CHRISTIAN SCHMIDT

GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (hokie@gfz-potsdam.de)

Aqueous fluids and their interaction with mineral assemblages play a key role for the mobility of elements and, thus, material flux in the lithosphere. The invention of the hydrothermal diamond-anvil cell (HDAC) [1] has extended the **PT** range, in which aqueous fluid properties can be studied **in situ**, up to the conditions of the lower crust and dehydrating slabs.

Modifications of the HDAC design [2,3] permit application of synchrotron-radiation X-ray techniques to investigate the behavior of dissolved heavy elements with X-ray emission energies as low as ~4 keV and absorption edge energies as low as ~5 keV. Time-resolved SR-XRF analyses have been used to study the solubility of minerals containing elements with Z≥22 in aqueous fluids, the kinetics of fluid-mineral interaction, and trace element partitioning between aqueous fluids and silicate melts [e.g., 4, 5]. A minimum detection limit of about 2 ppm for Ti (Ko energy=4.5 keV) was achieved in recent in situ SR-XRF experiments on the solubility and dissolution kinetics of rutile in H₂O+NaAlSi₃O₈ and H₂O+Na₂Si₃O₇ fluids to 800 °C and 1.3 GPa. Complexation and speciation of heavy elements in aqueous melts and fluids have been investigated in situ by X-ray absorption techniques, e.g., SR-XAFS analyses of the La L₂,3-edge in a study of the hydration structure of aqueous La₃⁺ (0.007 m) to 300 °C and 160 MPa [6] or SR-XANES measurements on Fe²⁺ in water-saturated haplogranitic melt up to 700 °C and 500 MPa [7].

Raman spectroscopy and Bassett-type HDACs have been used in a number of studies to obtain information on the behavior of light elements at high **PT**, e.g., on the speciation of silica to 900 °C and 1.4 GPa [8] or the complexation of boron to 600 °C and 2 GPa [9]. However, utilization of Raman spectroscopy as a quantitative tool is still in an early stage. Much remains to be learned about fluids in deeper portions of the lithosphere, and further method developments (e.g., to determine electrical conductance and density of such fluids) are needed.

**Trace elements in foraminiferal calcite: New understanding based on** **in situ** **analysis**

D.N. SCHMIDT¹ AND S.A. KASEMANN²

1Department of Earth Science, University of Bristol, Bristol UK; (d.schmidt@bristol.ac.uk)

2Grant Institute of Earth Science, University of Edinburgh, Edinburgh UK; (simone.kasemann@ed.ac.uk)

Trace element concentrations in foraminiferal carbonates are a widely used as proxy to assess past climates and ocean circulation. Planktic foraminifers strongly discriminate against trace element incorporation, resulting in Me/Ca ratios which are significantly lower than ambient sea water concentrations. Physiological (e.g., photosynthesis, respiration, and calcification) and ecological processes (e.g., depth migration) can modify the trace element uptake into the foraminiferal calcite and thus exert an important influence on Me/Ca ratios.

**in situ** analysis of spatially resolved elemental ratios increase our understanding of biological processes influences in incorporation of these proxies in foraminifers. The applicability of the proxy and the precision of palaeoclimatic assessment will depend on our understanding of the incorporation of these trace elements into foraminiferal carbonate.

To this end, we have performed trace element analysis using Secondary Ionization Mass Spectrometry and Electron Microprobe on planktic foraminifers from sediment samples and sediment traps. The sediment trap samples from the Canary Islands and the western equatorial Atlantic allow for direct comparison between ambient conditions and Me/Ca ratios. We analysed symbiont bearing (*G. ruber, G. sacculifer*) and asymbiotic (*G. truncatulinoides, G. tumida*) species which are living in different depth habitats. Mg/Ca, Ba/Ca, Li/Ca and Sr/Ca ratios were analysed in profiles and spot measurements in and across several chambers and specimens. The profiles at a resolution 2.0 µm clearly display the chemical variability within the multi-layered foraminiferal test. Additionally, we document Me/Ca variability during the development of the organism and, using specimens from different seasons with optimal and suboptimal growth rates, assessed the influences of foraminiferal growth rates on element incorporation.

Foraminiferal test displays strong heterogeneity in Mg/Ca, B/Ca, Ba/Ca, and Li/Ca but not in Sr/Ca ratios. B/Ca within one specimen range from 20 to 120 mmol/mol, Ba/Ca from 1.2 to 4.5 mmol/mol, Mg/Ca ratios from 0.6 to 1.2 mmol/mol. The proloculus, the first chamber, displays significantly higher Mg/Ca and B/Ca ratios but not Sr/Ca and Ba/Ca which can not be explained by environmental conditions alone.
Influence of impactors on the chemical composition of the Earth

G. SCHMIDT

Institute of Nuclear Chemistry, University of Mainz, Germany (gerhard.schmidt@uni-mainz.de)

The relative abundances of highly siderophile elements (HSE: Os, Ir, Ru, Pt, Rh, Pd) in the Earth’s primitive upper mantle (PUM) and the continental upper crust (UCC) is a key issue for understanding their origin and the influence of impactors on the chemical composition. The past twelve years we have measured the HSE in many mantle suites of the Earth by neutron activation. Estimates of Rh/Ir, Ru/Ir, Pd/Ir, and Pt/Os derived from most mantle suites indicate modestly suprachondritic compositions for average PUM. The enigmatical mantle Ru/Ir ratio of 2.01 ± 0.12 (Schmidt 2004) in comparison of 1.51 ± 0.04 of the known different chondrite groups has been observed by other groups as well (Pattou et al. 1996; Becker et al. 2006). From highly melt depleted peridotites (Schmidt et al. 1998) and metasomatized mantle xenoliths (Schmidt et al. 2003) we conclude that the effects of melt depletion, refertilization and metasomatism can be discounted. However, the Os, Ir, Ru, Pt, and Pd pattern on melt depletion, refertilization and metasomatism can be unparalleled in terrestrial magmatic systems. In fact, the HSE (UCC) is strongly fractionated. Highly fractionated Ru/Ir is formation (Snow and Schmidt 1998)?

The HSE and Ni pattern of the upper continental crust (UCC) is strongly fractionated. Highly fractionated Ru/Ir is unparalleled in terrestrial magmatic systems. In fact, the HSE and Ni systematics closely resembles IIIAB iron meteorites (many impact craters on Earth are produced by this type of projectile with a radius of 54 ± 4 km as an upper limit that a projectile with a radius of 54 ± 4 km as an upper limit would yield the abundances of HSE and Ni in the UCC.

First direct sampling of superhot supercritical vapor phase fluids at the Mid-Atlantic Ridge

K. SCHMIDT1, A. KOSCHINSKY1, D. GARBE-SCHÖNBERG2 AND R. SEIFERT3

1Jacobs University Bremen, Earth and Space Sciences, 28759 Bremen, Germany; (k.schmidt@jacobs-university.de)
2Universität Kiel, Institute of Geosciences, 24098 Kiel, Germany; (dgs@gpi.uni-kiel.de)
3Universität Hamburg, Institute of Biogeochemistry, 20146 Hamburg; (seifert@geowiss.uni-hamburg.de)

Within the German Special Priority Program 1144 "From mantle to ocean: energy-, material-, and life-cycles at spreading axes", unique hydrothermal fluids were sampled at two newly discovered hydrothermal vent fields located at the spreading axis of the Mid-Atlantic Ridge at 4°49’S. Turtle Pits and Sisters Peak, both located at 3000 m water depth, emanate vapor phase fluids with stable sampling temperatures of about 390°C–407°C. In addition, temperature measurements recorded short-term spikes of up to 464°C, by far the highest temperature ever measured in submarine hydrothermal fluids. The fluids, representing a supercritical vapor phase sampled near the critical point of seawater, are characterized by a Cl depletion of 50% compared to seawater. The estimated temperature and depth of the initial phase separation with ~430°C, and 360 bar agree with the depth of the reaction zone about 500 m below the seafloor (constrained by Si concentrations). The overall fluid geochemistry is similar to those observed in other phase-separating systems at mid-ocean ridges, with an extremely high mobility of Fe and enhanced H2 concentrations. Most chloride-normalized element concentrations are greater than seawater, indicating advanced water-rock interaction. Despite a similar chlorinity and major element composition, different fluid samples emanating from the same vent orifice show a very heterogeneous endmember composition with respect to metals such as Cu, Zn, Pb and rare earth elements, indicating the mixing of the superhot vapor phase with another liquid or solid phase. Small differences in the fluid geochemistry between Turtle Pits and Sisters Peak can be related to a somewhat deeper zone of phase separation beneath the Sisters Peak field.

Total and Cl-normalized major and trace element concentrations will be evaluated with respect to possible mixing processes of different types of fluids in the subsurface. The respective influences of vapor-brine fractionation, (low-Cl) water-rock equilibria, and a different elemental speciation in supercritical vapors on the fluid geochemistry of the Turtle Pits and Sisters Peak fluids will be discussed.
Fluids, melts, and supercriticality in the MSH system and element transport in subduction zones

M.W. SCHMIDT AND E. MELEKHova
Dep. Earth Sciences, ETH Zürich, Switzerland
(max.schmidt@erdw.ethz.ch, elena.melekhova@erdw.ethz.ch)

The dichotomy of aqueous fluids and hydrous melts which includes fluid saturated melting is known to be limited in pressure, as the critical temperature of the miscibility gap between the two liquid phases strongly decreases with pressure. The critical P-T curve of the immiscibility gap intersects with the fluid saturated solidus at a critical pressure between 1 (SiO$_2$-H$_2$O) and 12 GPa (MgO-SiO$_2$-H$_2$O), nevertheless, the critical pressures for natural rock systems are largely unknown and under discussion. This discussion stems from the imperfection of all available experimental methods, which will be critically reviewed.

Our new experimental results on the MSH peridotite model system suggest that the entire system goes supercritical around 12 GPa, where phase A and chondrodite are stable at the solidus in the Mg-rich portion of MSH. Supercriticality moves stepwise from the SiO$_2$-rich side to the MgO-rich side, and hitherto insufficiently defined equilibria involving enstatite are needed to define the MSH phase diagram completely. While supercriticality eliminates fluid saturated melting, it is irrelevant to fluid-absent melting, and thus to devolatilization of deeply subducted oceanic mantle. Even above 12 GPa, phase E has a realistic chance to undergo fluid absent melting in thermally relaxing subducted lithosphere.

Secondly, while the question of supercriticality of the fluid-melt pair is petrologically challenging, it is, also in the presence of a fluid, of moderate practical relevance to the real world. In subduction scenarios, we do expect to have one liquid (either fluid, or melt or supercritical liquid), compositionally buffered by and coexisting with the residual minerals. The main questions relate then to solubilities of key elements in and to the viscosity and wetting behavior of this liquid.

Is “ballen quartz” diagnostic for shock metamorphism?

M. SCHMIEDER AND E. BUCHNER
Institut für Geologie und Paläontologie, Universität Stuttgart, Herdweg 51, D-70174 Stuttgart, Germany

Ballen quartz has been observed in impactites from a number of terrestrial impact structures, predominantly in impact melt rocks, suevites, and target rock clasts affected by strong post-shock heating. In thin section, ballen are generally roundish to oval-shaped and typically range in size from several microns to ~200 µm. Ballen rims may vary in brightness and colour, and appear as curved open fractures, fractures filled by submicroscopic phases, or very faint lines. Accordingly, ballen quartz, with its typical crackled “fish-scale” pattern, has turned out to be a distinctive textural feature suggestive for shock metamorphism [1-5].

In addition to the reports available in literature, we detected ballen quartz in impact melt rocks from Manicouagan, Rochechouart, Kara, Terny, and strongly heated crystalline basement clasts from the Ries crater and Ilyinets. As ballen quartz is known from very small but also the largest terrestrial impact structures (e.g., Tenoumer or Chicxulub), one must assume that ballen quartz should have been primarily present at all terrestrial impact sites.

Three types of ballen quartz (homogenous ballen, optically individual ballen, and microcrystalline ballen) are distinguished by their optical properties corresponding to different shock stages [2]. Various models of ballen quartz formation have been proposed to date, such as by prograde silica transformations in the solid state [3;4] or by the melting of silica, lechatelierite formation, and retrograde recrystallisation [1;5]. However, it is widely accepted that quartz ballen represent pseudomorphs after cristobalite [3-5]. The formation mechanism of ballen quartz, nevertheless, still appears to be somewhat enigmatic.

Domains of typical “granular cristobalite” in siliceous volcanic rocks [6], fulgurites [7], and heated industrial quartz ceramics [8] - i.e., non-impact materials of emphasised thermal history - display essentially the same textural pattern, which further suggests that ballen quartz originates from granular cristobalite and that ballen texture develops during cristobalitization of silica (and the high-low inversion of cristobalite [5]) at high temperatures. Therefore, ballen quartz might not be restricted to impactites, and we put into question that the sole presence of ballen quartz can be considered as reliable evidence for shock metamorphism.

Natural mass-dependent Cd isotopic variations determined by TIMS
A.-D. SCHMITT1,2, S. J. G. GALER1 AND W. ABOUCHAMI1
1Max-Planck-Institut für Chemie, Postfach 3060, 55020
Mainz, Germany (sig@mpch-mainz.mpg.de;
waфа@mpch-mainz.mpg.de)
2Université de Franche-Comté, Département des Géosciences,
16 route de Gray, 25030 Besançon Cédex, France
(anne-desiree.schmitt@univ-fcomte.fr)

We present a high-precision double spike (DS) technique for Cd isotopes in which the Cd is measured by thermal ionisation mass spectrometry (TIMS). Since we observe anomalous odd-even isotope mass bias during measurement, we utilize even isotopes of Cd only. The "natural" fractionation is expressed as deviations in \(^{112}\text{Cd}/^{110}\text{Cd}\) (in parts per 10\(^{-6}\)) from our JMC Cd shelf standard. The commonly-used "JMC Münster Cd" standard lies at -1.11 \(^{112}/^{110}\text{Cd}\) on this scale. The external reproducibility (2SD) for double-spiked JMC Cd shelf (100 ng) is ±0.14 \(^{112}/^{110}\text{Cd}\) (i.e. ±7 ppm/amu) which is a factor of 4 to 10 times better than that reported in previous MC-ICP-MS studies (e.g. Wombacher et al., 2003; Lacan et al., 2006; Ripperger and Rehkämper, 2007).

We have analyzed \(^{112}/^{110}\text{Cd}\) in over sixty samples from different terrestrial reservoirs and environments (MORB, OIB, loess, Fe-Mn nodules, continental and hydrothermal sulphides). Our study confirms the limited variations found by Wombacher et al. (2003) in terrestrial materials—the total range is ~5 \(^{112}/^{110}\text{Cd}\), but most samples lie between -1.0 and +1.0. Three mid-T hydrothermal sulphides differ by ~4 \(^{112}/^{110}\text{Cd}\), suggesting significant Cd isotopic fractionation occurs in this setting, though other sulphides are much more tightly clustered. Analyses of 31 hydrogenous Fe-Mn deposits (and phosphorites) worldwide range from -0.6 to +2.0, and display isotopically heavier Cd (by 1 to 2 \(^{112}/^{110}\text{Cd}\)) in the top 2000 m than in the deeper ocean. These differences might reflect shallow inorganic scavenging of Cd by Fe-Mn oxides and its remineralization at depth. However, allowing for interlab bias, three shallow seawater samples of Ripperger and Rehkämper (2007) have \(^{112}/^{110}\text{Cd}\) of +0.5 to +2.2. These data are quite consistent with our shallow Fe-Mn nodule data, implying that only minor Cd isotope fractionation occurs on Fe-Mn oxide precipitation from seawater. The principal cause of the heavy Cd in the surface ocean then appears to be partitioning of light Cd into phytoplankton, entirely consistent with the sense and magnitude of the fractionation factor (7 ± 3 \(^{112}/^{110}\text{Cd}\)) determined by Lacan et al. (2006). Overall, these considerations suggest that \(^{112}/^{110}\text{Cd}\) is potentially useful as a paleoproductivity proxy, in much the same way as Cd/Ca.

Zircon U-Th ages from Laacher See indicate coeval crystallization of coerupted carbonatite and silicate magmas
A. K. SCHMITT1 AND G. WÖRNER 2
1Department of Earth and Space Sciences, University of California Los Angeles, USA (axel@argon.ess.ucla.edu)
2Geowissenschaftliches Zentrum Göttingen, Abteilung Geochemie, Universität Göttingen, Germany (Gwoerner@gwdg.de)

In order to constrain the origins of spatially associated carbonatite and silicate magmas and to quantify the time scales during which they interacted in a shallow magma system, we are employing U-Th dating of individual zircon crystals by secondary ionization mass spectrometry (SIMS). Laacher See (Germany) erupted a suite of crystal-rich xenolithic clasts that range from carbonate-free intermediate (dominantly syenitic) compositions to carbonatites (sövites). Because of the youthful age of the Laacher See eruption (~12,900 a BP), SIMS U-series geochronology can be applied which provides unrivalled temporal resolution in the order of ~10\(^3\) – 10\(^4\) years for individual grains or grain domains that are analyzed in situ (thin-section) at ~30 μm lateral resolution and crater depths <5 μm. Our initial results from three syenitic sövite clasts yield overlapping U-Th zircon isochron ages that average 15.8±2.7 ka (1σ; MSWD = 0.45; 30 spot analyses). This age overlaps within uncertainty with the U-Th isochron age for zircons from early erupted Laacher See differentiated phonolite and late-crystallized zircons in vesicles of carbonate-free syenite ejecta clasts (17.1±1.3 ka; Schmitt, 2006).

These results indicate coeval crystallization of carbonatite and differentiated silicate magmas that were stored at the top of a shallow magma body. Thus far, the zircon record lacks unequivocal evidence for protracted (several 10\(^3\) to 100’s of ka) pre-eruptive crystallization within a long-lived shallow Laacher See magma chamber and rather suggests crystallization and differentiation at most within few ka prior to eruption. The geochronological results are also in line with trace element evidence that indicate a close chemical affinity between carbonatites and Laacher See phonolites (Liebsch, 1996). Coeval zircon crystals in both, Laacher See carbonatites and phonolites/syenites have indistinguishable initial (\(^{230}\text{Th})/(^{232}\text{Th})\) ratios (0.885±0.013 and 0.894±0.010, respectively). This further supports the hypothesis of consanguineous carbonatite and silicate melts in the Laacher See magma chamber that originated by liquid immiscibility.

High resolution S-XRF study of stardust impact tracks

S. SCHMITZ¹, F.E. BRENNER¹, L. VINCZE², B. VEKEMANS², M. BURGHAMMER³ AND C. RIEKEL³

¹JWG University, Dept. of Mineralogy, Frankfurt M., Germany (schmitz@em.uni-frankfurt.de)
²University of Ghent, Dept. of Analytical Chemistry, Ghent, Belgium
³ESRF, Grenoble, France

Introduction
Stardust was the first sample return mission which captured extraterrestrial solid particles on a flight-by through the coma of a comet (Wild 2) which enables the investigation of cometary dust in its direct contextual setting [1] with the best available analytical system available in any laboratory on Earth. The nature of cometary material is of great importance for the understanding of the history of the early solar nebula and the protoplanetary disk.

Data processing
Several keystones, each including an impact track with a terminal particle (TP) at its end, were studied [2]. Track No. C2044, 37 was investigated with high resolution synchrotron XRF and XRD (S-XRF/XRD) techniques at beamline ID13 at the ESRF (Grenoble, France) with 13 keV to determine the elemental abundances from Ca to Se. The focus spot size was 200 nm enabling an investigation with very high spatial resolution of grains having sub micron size.

Results
The evaluation of the diffraction pattern obtained from the TP yield a mixture of olivine and pentlandite and/or pyrrhotite [3].

S-XRF data reveal several chemical hot spots along the track with most of these fragments having sizes of only several 100 nm. Some have Fe concentrations of more than 20 wt. % indicating Fe–Sulphide as possible phases along the track. These fragments are also high in Mn and Cr in comparison to the other hotspots. Fe-Ni sulphide or - metal is also assumed for a fragment containing up to 2.5 wt. % Ni.

For the TP, S-XRF reveals a complex chemical structure showing band like Fe- and Cr-features inside the particle. Fe- and C1 normalized abundances for the TP show relative enrichments for Mn and Cr and CI abundance for Ca, Ti, Cu and Zn.

Multiple hydrothermal fluid flow in the NW Rhenohercynian

J. Schneider1, M. Chatziliadou2, S. Sindern3, Ch. Hilgers3 and U. Kramm3

1Department of Geology and Centre for Archaeological Sciences, K.U.Leuven, Celestijnenlaan 200E, B-3001 Leuven, Belgium (jens.schneider@geo.kuleuven.be)
2Institut für Mineralogie und Lagerstättenlehre, RWTH Aachen, Wüllnerstr. 2, D-52062 Aachen, Germany (sindern@rwth-aachen.de)
3Institut für Mineralogie, Leibniz University of Hannover, Callinstrasse 3, D-30167 Hannover, Germany

The NW Rhenohercynian belt of the Central European Variscan orogen, studied in the northern Eifel area, was affected by several pre-, syn- and postorogenic hydrothermal events.

Investigation of core material from the RWTH-1 drill hole in Aachen revealed mineralogical, geochemical and structural evidence of intense Variscan hydrothermal activity. Recently published temperatures of up to 370 °C (Lögering et al. 2006) but low illite ‘crystallinites’ can only be explained by a short duration (< 10000 a) of this hydrothermal event, which was initiated by dewatering of sedimentary rocks during Variscan compressional tectonics. This synorogenic fluid flow did not result in significant large-scale element transfer, except for nitrogen which was incorporated into clay minerals as ammonium.

Important postorogenic, sandstone-hosted Pb-Zn deposits in the northern Eifel have been dated at 170 ± 4 Ma (Schneider et al. 1999). This Jurassic event caused large-scale element mobilisation in the Palaeozoic sedimentary rocks, as indicated by the homogeneous Pb isotope signatures of the sphalerites. However, new geochronological data give evidence for at least one Cretaceous hydrothermal event in the NW Rhenohercynian. Direct Rb-Sr-dating of non-economic vein sphalerites from the Sandgewand fault (Hastenrath near Stolberg) yields an age of 134 ± 2 Ma, while the Pb isotope signatures of these ores are identical to the Jurassic ones.

Thermal spring waters in Aachen represent the youngest stage of hydrothermal events in the NW Rhenohercynian. They are characterized by high concentrations of particle-associated Zn. Isotope ratios of Pb and Sr determined directly on water and sinter samples indicate several metal sources, such as postorogenic base metal ores but also evolved Devonian-Carboniferous sediments and a yet unidentified source characterized by unradiogenic Pb isotope signatures.

The Cr isotope label of the solid Earth and hydrothermal pathways

R. Schoenberg, S. Zink, M. Staubwasser and F. Von Blanckenburg1

Institute for Mineralogy, Leibniz University of Hannover, Callinstrasse 3, D-30167 Hannover, Germany

The Cr isotope compositions of Earth’s major silicate rock reservoirs and Cr-bearing minerals of metamorphic and high-temperature hydrothermal origin were obtained by high-precision double-spike MC-ICP-MS Cr measurements.

The principle igneous reservoirs of the Earth share a common stable Cr isotope composition. Within the 95% confidence interval, Student’s t-tests do not allow to distinguish the Cr isotope compositions of several mantle lherzolites (δ53/52CrSRM979 = –0.104±0.110‰; 2 SD), ten ultramafic cumulate rocks (–0.119±0.113‰) and six continental and oceanic basalts that represent partial mantle melts (–0.151±0.050‰). Thus, unlike suggested for Fe isotopes [1], partial mantle melting does not appear to fractionate Cr isotopes. The average δ53/52CrSRM979 value of –0.082±0.058‰ for 12 different chromite seams from the Bushveld and Great Dyke layered igneous intrusions is identical to that of the silicate igneous Earth reservoirs. This again supports the notion that Cr isotopes do not fractionate during partial mantle melting, since chromites crystallize from Cr-rich partial mantle melts that enter an overlying magma chamber containing an evolved Cr-depleted liquid. The Cr isotopic compositions of Cr(III)-bearing uvarovite and fuchsite minerals from amphibolite-facies metamorphic terrains are also equal to those of igneous rock reservoirs. Since partial mantle melting and metamorphism do not involve redox-changes for Cr and differences in the Cr-ligands of solids and melts, high-temperature isotope fractionation appears to be too small to be detectable.

However, crocoite (PbCr(VI)O4), a mineral that forms in oxidizing zones of high-temperature hydrothermal systems, shows δ53/52CrSRM979 values from +0.640 to +1.037‰. Precipitation experiments of crocoite from Cr(VI) solutions reveal (equilibrium) isotope fractionation with Δ53/52Crcrocoite-Cr(VI)aq ≈ 0.1 to 0.2‰. This is too small to explain the heavy Cr isotope compositions of crocoite. One possible explanation is that oxidation of dissolved hydrothermal Cr(III) to Cr(VI) is accompanied by isotope fractionation. Alternatively, Cr behaves like its chemical twin Se that only fractionates during reduction [2]. Partial Cr(VI) reduction [3] may explain the heavy compositions of the crocoites, which in turn allowed quantification of redox-changes along the hydrothermal pathway.

Experimental study on crustal wehrlites of the Oman ophiolite

STEPHAN SCHOENBORN1, JUERGEN KOEPKE1, SANDRIN T. FEIG1, FRANCOISE BOUDIER2 AND ERIC HELLEBRANDT3

1Institut für Mineralogie, Leibniz Universität Hannover, Germany (sschoenborn@web.de)
2ISTEEM, University Montpellier, France (boudier@dstu.univ-montp2.fr)
3SOEST, University of Hawaii, USA (ericwgh@hawaii.edu)

In the Wadi Haymiliyah of the Oman ophiolite (Halyn block), discordant wehrlite bodies ranging in size from decameters to hundreds of meters intrude the layered gabbro series at different crustal levels. Common feature of all wehrlite bodies is the dominance of olivine and clinopyroxene with high Mg# (MgO/(MgO+FeO)*100, molar) varying between 85 and 95. SIMS analyses of clinopyroxenes from different wehrlite bodies reveal REE and trace element patterns suggesting that the clinopyroxenes were crystallized from tholeiitic, MORB-type melts which were highly depleted in incompatible trace elements. Some wehrlites from the upper section bear mm-sized poikilitic pargasite as magmatic phase, implying that the associated melts showed a high water activity, at least in a late stage. In order to evaluate the genesis of the Oman crustal wehrlites, we combined experimental work with investigations on natural rocks.

The experimental study under controlled $f_{O_2}$ and $aH_2O$ at pressure of 200 MPa is aimed to constrain the physical conditions of wehrlitic magmas within the lower oceanic crust. Especially, we want to clarify whether the crustal wehrlites from the Oman ophiolite are derived from wet primitive tholeiitic magmas, as suggested by a model of Feig et al. (2006). Starting material are mixtures of natural olivines and clinopyroxene separated from wehrlites from the lower Wadi Haymiliyah section, and a synthesized glass representing the "lost" equilibrium melt. Experiments were performed in AuPd capsules (pre-saturated with iron) at temperatures between 1020 and 1160°C with $f_{O_2}$ varying between QFM and QFM+2 (QFM=quartz fayalite magnetite buffer). First experiments at nominal dry conditions above 1140°C ($f_{O_2}$ ~ QFM) reveal the stability of plagioclase (newly formed crystals), while the doped clinopyroxene became unstable (decomposition by reaction with the melt). Thus, we were not able to reproduce the characteristic wehrlite paragenesis (olivine plus clinopyroxene without plagioclase) under dry conditions, implying that wehrlitic crystal mushes cannot be generated in dry, primitive tholeiitic systems at crustal pressure by simple accumulation of fractionating crystals. The corresponding experiments at wet conditions are in progress.

Recent developments in U-Pb thermochronology

B. SCHOENE1,2 AND S.A. BOWRING,1

1Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, MA, USA (sbowring@mit.edu)
2Université de Genève, Section des Sciences de la Terre, Geneva, Switzerland (blair.schoene@terre.unige.ch)

Investigations can now be designed to exploit and explore volume diffusion in accessory minerals with the goal of generating accurate temperature-time paths for rocks. Despite the abundance of high-U minerals with high to moderate nominal closure temperatures for the diffusion of Pb (e.g. titanite, apatite, and rutile; $T_c$ ~ 400-650 °C), U-Pb thermochronology has received little attention compared to lower temperature systems such as $^{40}$Ar/$^{39}$Ar and U/Th-Hc. However, understanding thermal histories of rocks in the 400-650 °C temperature range is crucial for deconvolving the thermal histories of middle and lower crustal rocks.

We have investigated the potential and limitations of U-Pb thermochronology through single- to sub-grain ID-TIMS analysis of apatite and titanite in conjunction with BSE and CL imaging and numerical modeling. The precision of U-Pb thermochronology is usually limited by relatively low ratios of radiogenic lead to initial (a.k.a. common) lead. In systems that have undergone complex rock-fluid interactions, the common Pb composition due to fluid interaction may be inaccurate. This is especially important in slowly-cooled rocks where the common Pb composition due to fluid interaction may change in time and/or space.

In minerals where volume diffusion controls the distribution of daughter product in a mineral, one expects intra-grain diffusion gradients such that the smallest grains and the rims of large grains record the youngest dates. We have explored relationships between grain size and date (here called a-t curves) in apatite and titanite in combination with CL imaging and numerical modeling. The precision of U-Pb thermochronology through single- to sub-grain ID-TIMS thermochronology has received little attention compared to lower temperature systems such as $^{40}$Ar/$^{39}$Ar and U/Th-Hc. Given some geologic constraints, utilizing a-t curves in two minerals from the same rock will allow, in some cases, the generation of unique and non-linear temperature-time paths regardless of the effects of post-cooling reheating from magmatic intrusions.

Numerical modeling can also be used to evaluate the effect of differences in U zonation, cooling rate, and grain shape on closure temperature and a-t curves. In many cases these minerals do not form a-t curves. This is likely because U-Pb thermochronometers are often involved in metamorphic reactions at a range of temperatures, and therefore characterizing the internal zonation, trace element patterns, and petrographic setting of these minerals may be crucial for generating accurate thermal histories of rocks. This work in conjunction with studies exploiting the U/Th-Hc method will become more useful in characterizing the behavior of U and its daughter products in high-U thermochronometers and determining thermal histories of rocks from lower-crustal to near surface conditions.
REE systematics of fluorites in (per-)alkaline systems

JOHANNES SCHÖNENBERGER, JASMIN KOEHLER AND GREGOR MARKL

Universität Tübingen, Inst. f. Geowissenschaften, D-72074 Tübingen, Germany, johannes.schoenenberger@uni-tuebingen.de, jasmin.koehler@uni-tuebingen.de, markl@uni-tuebingen.de

The mid-Proterozoic Gardar Province (South Greenland) is a failed rift province hosting 12 major (per-)alkaline intrusions [1]. High fluorine contents occur in a great variety of magmatic rocks all over the Gardar Province. Rare earth element (REE) patterns of fluorite and associated minerals like cryolite (Na₃AlF₆), calcite and siderite provide information about the magma source, crystallisation history, fluid-melt interaction and late-magmatic processes.

We focused on fluorites from three intrusions representing the whole compositional range of the Gardar Province: the Ilímaussaq intrusion which is mainly composed of silica-undersaturated agpaitic nepheline syenites; the Motzfeldt intrusion with its mostly miaskitic nepheline syenites; and the Ivigtut intrusion famous for its now mined-out cryolite deposit hosted by an A-type granite [1].

All chondrite-normalized REE patterns of fluorite show a negative Eu anomaly which is attributed to feldspar fractionation. The REE patterns of the Motzfeldt and Ilímaussaq intrusions in the eastern part of the Gardar province show a positive Y anomaly if Y is plotted between Dy and Ho according to [2]. In contrast, the patterns of the Ivigtut intrusion famous for its now mined-out cryolite deposit hosted by an A-type granite [1].

All chondrite-normalized REE patterns of fluorite show a negative Eu anomaly which is attributed to feldspar fractionation. The primary magmatic fluorite of the Motzfeldt and Ilímaussaq intrusions show almost identical patterns with an enrichment in light REE suggesting an early crystallisation [3]. Later crystallised fluorites of veins are less concentrated in REE and exhibit flatter patterns or enrichment of the middle/heavy REE typical of the late-magmatic to hydrothermal crystallisation stage. The REE patterns of minerals from Ivigtut are slightly enriched in heavy REE and indicate a strong interaction with a fluid phase as evidenced by the very pronounced tetrad effect.

Our preliminary results show that REE in fluorite reflect the source but can also act as tracers for the transition from early magmatic to hydrothermal conditions during the crystallisation of (per-)alkaline intrusions. The tetrad effect reflects strong water-rock interaction and the fluid’s influence on the fluorite genesis.

The chemical stability of bacteriogenic uraninite, “UO₂”, is one of the seminal issues governing its success as an in situ immobilization strategy in remediated subsurface locations. Little detail is known about the structure and reactivity of this material, but based on comparison to its closest abiotic analog, UO₂-x (0 < x < 0.25), we expect that it is complex and disordered, likely to exhibit non-stoichiometry, and capable of structurally incorporating common ground water cations and U(VI). These subtle changes in mineralogy are expected to substantially impact its stability in ground water.

In this study, the product of microbial U(VI) reduction under varying conditions of pH, carbonate and divalent cation concentration (Mg²⁺, Mn²⁺, and Ca²⁺) was investigated. To facilitate x-ray scattering measurements, a gentle aqueous cleaning method was developed to separate the bioxide and organic components without altering the biooxides. The material exhibits a range of particle sizes with a mean around 4 nm. The first oxygen shell is distorted, consistent with a nonstoichiometric composition. Mn²⁺ and Mg²⁺ were found to attenuate the particle size of bacteriogenic UO₂-x and to be structurally incorporated. These findings suggest that ground water composition can have a pronounced impact on the structure and properties of bacteriogenic uraninite.
Do particulate $^{231}$Pa/$^{230}$Th ratios depend on water depth?

JAN C. SCHOLTEN$^1$ AND J. FIETZKE$^2$

$^1$Marine Environment Laboratories, International Atomic Energy Agency, 4 Quai Antoine 1er, 98000 Monaco (j.scholten@iaea.org)
$^2$IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (jfietzke@ifm-geomar.de)

The natural radionuclides $^{230}$Th ($T_{1/2} = 75.6$ ky) and $^{231}$Pa ($T_{1/2} = 32.1$ ky) are widely used as tracers for paleoceanographic process studies. Both isotopes are produced in seawater by radioactive decay of uranium isotopes ($^{234}$U, $^{235}$U) and due to their particle reactivity they adsorb on sinking particles and are removed to the sediments. Since $^{231}$Pa is less particle reactive than $^{230}$Th i.e. $^{231}$Pa has a longer residence time ($\tau$) in the water column compared to $^{230}$Th ($\tau = 230$Th: 20-40y; $\tau = 231$Pa: 80-200y), $^{231}$Pa is preferentially removed in areas of higher particle flux like e.g. ocean margins (boundary scavenging); and the variable $^{231}$Pa/$^{230}$Th ratios stored in the sediment record are believed to reflect changes in the paleofluxes (or paleoproductivity) during the geological past. Further processes which may influence $^{231}$Pa/$^{230}$Th ratios are the composition of sinking particles, i.e. the higher affinity of $^{231}$Pa to adsorb on biogene opal compared to $^{230}$Th, and the dissolved $^{231}$Pa/$^{230}$Th in water masses.

In a study of $^{231}$Pa/$^{230}$Th ratios in surface sediments from the southeast Atlantic off Namibia we find $^{231}$Pa/$^{230}$Th ratios higher than the production ratio ($P$) of both isotopes ($P_{Pa/Th} = 0.093$) at the ocean margin and lower ones in the open ocean, a distribution typical of boundary scavenging. For this data set we observe a strong negative correlation ($r^2 = 0.82$) between $^{231}$Pa/$^{230}$Th in surface sediments and water depths. Also for previously published data from the Pacific and Arabian Sea we find negative correlations between $^{231}$Pa/$^{230}$Th ratios in surface sediments and water depths, however, these correlations are less strong. We will discuss to what extent changes in the fractionation between $^{231}$Pa and $^{230}$Th with depth, high opal content, and/or boundary scavenging may cause $^{231}$Pa/$^{230}$Th ratios to depend on water depth off Namibia.

Trace element behavior in sulfidic porewaters of the Oder estuary, SW Baltic Sea

F. SCHOLZ$^1$ AND T. NEUMANN$^1$

$^1$Institut für Mineralogie und Geochemie, Universität Karlsruhe, 76131 Karlsruhe, Germany (thomas.neumann@img.uka.de)

The diagenesis of trace elements in anoxic sediments of the Achterwasser lagoon, which is part of the Oder estuary in the Baltic Sea, is examined and evaluated in the context of pyrite formation.

Certain trace elements show the same distribution pattern within the pore water regime suggesting a similar diagenetic behavior. The release of Zn, Cu and Cd into the pore water occurs prior to the reduction of Fe and Mn, indicating that they are released from organic matter in the thin oxic surface layer of the sediments. While a considerable part of these elements is recycled into the water column another part diffuses downcore and is removed as soon as H$_2$S appears in pore water. Since degrees of trace element pyritization (DTMP) for Zn and Cd range well below 1%, it is inferred that they become trapped as monosulfide. Copper appears as both monosulfide and impurity in pyrite (DTMP: 12%).

The accumulation of V, Cr, Co and As in the pore water starts concomitantly to that of Mn and Fe suggesting that these elements are liberated through reductive dissolution of Mn- and Fe-oxyhydroxides. Increasing concentrations of dissolved V, Cr, Co and As with depth demonstrate that the fixation of these elements is not quantitatively controlled by the process of pyrite formation. While pyritization of Co and As is intense with median DTMP values of 35% and 17%, respectively, Cr (DTMP: 4%) is less and V (DTMP: <1%) almost not incorporated into pyrite.

The conconstant increase of DOP and DTMP with depth suggests that, in analogy to Fe pyritization, addition of trace metal sulfide complexes on preexisting pyrite grains may be responsible for increasing DTMP values for Co, Cu and Zn. Arsenic does not form sulfide complexes but rather As(III) oxyanions under reducing conditions, suggesting that again adsorption of complexes is responsible for increasing pyritization with depth.
Different sources of hydrocarbon pollution in surface sediments of the Campeche Sound, Gulf of Mexico, revealed by biomarker analysis

BARBARA SCHOLZ-BÖTTCHER1, FELIPE VAZQUEZ-GUTIERREZ2 AND JÜRGEN RULLKÖTTER1

1Institute of Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, P.O. Box 2503, D-26111 Oldenburg, Germany (bsb@icbm.de)
2Laboratorio de Fisicoquímica Marina, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autonoma de Mexico, Apartado Postal 70-305, Mexico 04510. D. F., Mexico (felipe@icmyl.unam.mx)

The Campeche Sound in the Gulf of Mexico is the largest oil field in Mexico. Oil production, refinery activities, heavy ship traffic as well as natural petroleum seeps are potential sources of pollution of water and sediment in the area (García-Cuéllar et al., 2004). Embedded in a grid system of a long term environmental monitoring program (e.g., Vázquez and Virender, 2004) surface sediments from the shelf area of the Campeche Sound and also from the adjacent abyssal plain further west were studied. The nonaromatic hydrocarbon biomarkers in these surface sediments, several crude oils and drill cuttings samples were investigated by GC-MS.

The overlapping fossil hydrocarbon envelopes indicate multiple sources like discharged drilling fluids, the heavy ship traffic or land run-off. Samples taken close to known asphalt seeps exhibit biomarker patterns virtually identical to those of the reference crude oils, and thus have apparently escaped from petroleum reservoirs with fractured cap rocks. These sediments and the asphalts both lack of angiosperm biomarker oleanane (cf. Moldowan et al., 1994) as expected for crude oils from a Jurassic source rock. Other surface sediments, superimposed on the fossil hydrocarbons, contain biomarkers neither typical of mature fossil fuels nor of typical immature organic matter in marine surface sediments. Their origin from drill cuttings recovered from Tertiary to Cretaceous deposits and disposed of into the sea would be a reasonable explanation. The regional distribution of indicative biomarkers will be shown and discussed.

The timescale of the Earth’s accretion and volatile loss: New constraints from Pd-Ag systematics

M. SCHÖNBÄCHLER1,2, R. W. CARLSON2, M. F. HORAN2 AND E. H. HAURI2

1Impact and Astromaterials Research Centre (IARC), Imperial College, London SW7 2AZ, UK
2Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015, USA

The extinct radionuclide $^{107}$Pd decays to $^{107}$Ag with a half-life of 6.5 Myr and is a useful chronometer to study early solar system processes [1]. It provides constraints for the accretion and subsequent chemical differentiation of planetary bodies in a similar way as the $^{182}$Hf-$^{182}$W system. In contrast to the refractory elements Hf and W, there is a distinct difference in volatility between the more refractory element Pd and moderately volatile Ag. Thus the Pd-Ag system can be used to study accretion and core formation but also volatile depletion.

In particular, the Pd-Ag decay system has been successfully applied to study the formation and differentiation of iron meteorites [1]. Internal isochrons determined for these meteorites generally yield initial $^{107}$Pd/$^{108}$Pd ratios in the range of $1.5 - 2.5 \times 10^{-5}$ [1]. Combined with recent results for carbonaceous chondrites, this suggests that the initial $^{107}$Pd/$^{108}$Pd ratio of the solar system may be in the range of $6 \times 10^{-5}$ [2].

Here we report new high precision Ag isotope data for a variety of terrestrial basalts from different geological settings. The data indicate an $\varepsilon^{107}$Ag of 2.1 ± 0.6 for the Ag isotopic composition of bulk silicate Earth relative to the NIST SRM 978a Ag standard. In contrast, the CV3 chondrite Allende has a well-constrained $\varepsilon^{107}$Ag of -0.4 ± 0.5. Assuming that the Earth accreted from material with similar volatile depletion as the CV3 chondrites and that Ag isotopes are not significantly affected by stable isotope fractionation, it is possible to model the Earth accretion and core formation. A simple two-stage model suggests that the last complete metal-silicate equilibration took place no longer than 15 Myr after the start of the solar system. This is at odds with the results of the well-investigated Hf-W system, where the same model yields a time of ~30 Myr. Different scenarios can be considered to reconcile the apparent discrepancy: (1) the Earth accreted from material having greater volatile depletion than CV3 chondrites (Pd/Ag > 20). Some ordinary chondrites feature such high Pd/Ag ratios. (2) Metal-silicate equilibration was incomplete and affected the Pd-Ag and Hf-W system differently. (3) Significant volatile depletion took place prior to the giant impact, for example during the accretion of the Earth.

Geomorphology and chemical weathering on basaltic islands
HERDIS H. SCHOPKA AND LOUIS DERRY
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY 14853, (hhs22@cornell.edu)

We are investigating the relationship between geomorphology and chemical weathering on actively eroding basaltic oceanic islands in the tropics, using the Hawaiian islands as a natural experiment. Our field sites include the islands of Kaua‘i and Hawai‘i, which represent the extremes in ages and soil development on the islands. Hawai‘i is largely dominated by constructive volcanic shield topography. On Kaua‘i early shield topography has been heavily dissected by fluvial erosion, creating a landscape of high relief characterized by serrated ridges and deep fluvial valleys. Less than ~10% of Hawaii’s surface has undergone fluvial erosion while only ~20% of Kaua‘i’s original shield topography remains. This system, where relief increases substantially with age as the volcanic edifice is eroded by fluvial erosion, is very different from the conventional school of thought which postulates that after relief is created by an initial disturbance subsequent erosion will smooth the relief and lower it. We wish to investigate how the competing effects of increasing age and weathering are offset by increasing incision and development of relief.

Initial observations indicate a link between Si concentration in river water and hillslope, where watersheds with steeper slopes exhibit higher concentrations of Si than do streams draining more gently sloping topography under similar flow conditions. In the Waimea Canyon on Kaua‘i we have observed a nearly 4-fold increase in Si concentrations in the trunk of the river as it plunges over the edge of the Koke‘e Plateau (the only remnant of Kaua‘i’s original volcanic shield, ~1000 m a.s.l.) into the canyon (~300 m a.s.l.) and mixes with tributaries originating from the western wall of the canyon. The low Si concentrations in river water coming off the plateau reflect interaction with highly weathered and Si-depleted soils. The Si concentrations in the canyon tributaries tend to be 5-6 times higher than in the river water before it flows off the plateau, indicating that the tributaries tap sources of groundwater that has interacted with fresh rock at depth in the volcanic pile. Streams draining young bedrock on Hawai‘i, where the river profile still follows to a large degree the original shield topography, have nearly as low Si concentrations as rivers draining old, stable shield surfaces, indicating that rivers in an early stage of incision do not tap groundwater sources. Groundwater that discharges directly to the ocean is an important geochemical pathway on Hawai‘i and our data indicate its Si-concentrations are similar to the highest Si concentrations observed in the Waimea Canyon tributaries.

Development and application of novel organic proxies
STEFAN SCHOUTEN, JOHAN W.H. WEURS, FRANCIEL PETERSE, MARCEL T.J. VAN DER MEER AND JAAP S. SINNINGHE DAMSTÉ
Royal Netherlands Institute for Sea Research, Department of Marine Biogeochemistry & Toxicology, PO Box 59, 1790 AB Den Burg, The Netherlands

Sediments contain a myriad of organic compounds which potentially contain information on past microbial communities and the environments in which they lived. Research over the last few decades has improved our knowledge on the structure and origin of these compounds and their use as qualitative and quantitative proxies for past climatic conditions is rapidly increasing. Recently we developed several novel proxies based on the distribution and isotopic composition of terrestrial and aquatic biomarkers. Analysis of different soils from all over the globe showed a significant correlation between the distribution of branched tetraether lipids, derived from bacteria, and mean annual air temperature. We used this correlation to reconstruct continental temperature changes in several climatically important periods such as glacial-interglacial changes in the Quaternary and Cenozoic periods of global warming and cooling. Further validation of this proxy is currently underway by e.g. analysing soils surrounding hot springs. These soils are geothermally heated thereby providing a natural temperature gradient in soils of similar composition.

Another proxy which we are currently developing is the relative deuterium content of algal biomarkers as a proxy for sea water salinity. First results show a significant correlation between the δD of long chain alkenones with salinity and δD of growth water. This has been used to reconstruct past salinity changes in the Holocene Black Sea and the Aegean Sea during time of sapropel S5 deposition. Further culture studies are now underway to examine other factors influencing the δD of alkenones and to test other biomarkers as potential paleosalinity proxies.
Peering at the subsurface biosphere through a diamond window

MATTHEW O. SCHRENK
Carnegie Institution of Washington-Geophysical Laboratory, 5251 Broad Branch Rd. NW, Washington, DC 20015, USA (m.schrenk@gl.ciw.edu)

Investigations of the subsurface biosphere have pushed the depth limits of microbial ecosystems to greater than 800 meters below the seafloor in marine sediments and 3-4 km into the continental lithosphere. In subsurface environments, the mode-of-growth for microorganisms is attached to minerals in structures known as biofilms. In many rock-hosted, subsurface environments, organisms are confronted with multiple stressors including not only high pressures, but elevated temperatures and low energy fluxes. Subsurface microorganisms live at a precarious boundary between geologically-supported growth and cell death and remineralization. A significant limitation in the study of deep ecosystems has been an inability to distinguish and quantify microbial activities under conditions found in their native habitats. I will describe a research plan aimed at improving our ability to observe and characterize biogeochemical processes under conditions relevant to the deep subsurface environment. This plan relies upon the establishment of a one-of-a-kind research facility optimized for conducting high pressure experimental microbiology, borrowing from tools developed for materials science and hydrothermal geochemistry applications. Preliminary results show that the physiological status of microorganisms indigenous to the deep subsurface can be distinguished in vivo using molecular probes and geochemical measurements. A future goal is to make the system modular, allowing for its use in both laboratory and field-based studies. An analytical suite necessary to characterize biogeochemical transformations at microbe-mineral interfaces can be employed to follow the products of high pressure experiments, but will also be amenable to a range of studies in near-surface endolithic environments. The data obtained from these experiments will be important aid in deciphering both the extent and the biogeochemical consequences of a deep subsurface biosphere.

Using $^{222}$Rn for assessing nutrient transfer into the sea via SGD

M. SCHUBERT$^1$, A. SCHMIDT$^1$, J. SCHOLTEN$^2$, M.M. RUTGERS VAN DER LOEFF$^3$ AND M. SCHLUETER$^3$

$^1$Helmholtz Centre for Environmental Research – UFZ, Leipzig, Germany (michael.schubert@ufz.de, axel.schmidt@ufz.de)
$^2$Marine Environment Laboratories, International Atomic Energy Agency, Monaco (J.Scholten@iaea.org)
$^3$Alfred-Wegener Institut, Bremerhaven, Germany (mloeff@awi.de, mschlueter@awi.de)

Submarine Groundwater Discharge (SGD) has to be considered an important pathway of contaminant/nutrient transfer from aquifers into the coastal sea. One of the main reasons for temporal changes in the SGD rate is the altering hydrological gradient between groundwater and sea determined by the tidal cycle.

While SGD is known to sum up to about 6% of the global river discharge into the oceans, the actual SGD rate in a particular coastal area is usually hard to be quantified due to the generally complex spatial SGD distribution. However, naturally occurring stable and radioactive isotopes have shown to be useful environmental tracers in SGD studies (e.g. Burnett and Dulaiova, 2003).

At Cabbé, Bay of Roquebrune (Mediterranean Sea, France), the temporal SGD pattern was investigated over a 24 h period using naturally occurring $^{222}$Rn as an environmental tracer. At a location at the shore, known to represent a SGD spring, $^{222}$Rn measurements of the sea water were carried out as time series using a portable radon monitor (Dulaiova et al., 2005). Tidal range, water temperature, and salinity were monitored using a CTD. Discreet samples for nitrate analyses were taken for assessing the nutrient transfer into the sea via SGD. In addition, off-shore surface water samples were taken along two near-shore transects.

Temporal variations in $^{222}$Rn show a clear dependence on the tidal cycle. The results are backed up by the temperature and salinity data. High tide periods are characterized by lower $^{222}$Rn concentrations, higher water temperatures, and higher salinities consistent with a decreased SGD rate.

Variations of nitrate concentrations basically follow those of $^{222}$Rn, suggesting a strong dependence of the nutrient input into the sea on the SGD rate. In conjunction with the transect data and based on the nitrate and radon endmembers representative for groundwater (29.7 µM and 28.3 kBq/m³, respectively) and off-shore water (both below detection limit) a nitrate flux was estimated. The results suggest that SGD may be an important nitrate source for the coastal area investigated.

Biogeochemical investigation of asphalt seepage at the Chapapote Knoll in the southern Gulf of Mexico

FLORENCE SCHUBOTZ1, THORSTEN WILHELM2, HANS-JÜRGEN HOHNBERG1, SABINE KASTEN2, MATTHIAS ZABEL1, GERHARD BOHRMANN1 AND KAI-UWE HINRICH1

1DFG-Research Center Ocean Margins & Dept. of Geosciences, University of Bremen, 28359 Bremen, Germany (schubotz@uni-bremen.de, hohnberg@uni-bremen.de, mzabel@uni-bremen.de, gbohrmann@uni-bremen.de, khinrichs@uni-bremen.de)
2Alfred Wegener Institute for Polar and Marine Research, 27570 Bremerhaven, Germany (twilhelm@awi-bremerhaven.de, skasten@awi-bremerhaven.de)

Seepage of asphalt-laden heavy oils in 3000 meter water depth is fueling a unique cold seep habitat at the Campeche Knolls in the Southern Gulf of Mexico (MacDonald et al., 2004). We studied the Chapapote Knoll, one of the various salt domes in this area, which is covered with asphalt beds that extend over more than 1km².

During the expedition of RV Meteor M72/2 in 2006, we recovered a diverse set of asphalt samples and benthic organisms inhabiting this extreme environment to further explore mechanistic details of asphalt leakage and accumulation and its role for fueling benthic ecosystems.

The asphalt samples are highly diverse in terms of their content of gaseous hydrocarbons. Maximum concentrations of gaseous hydrocarbons were associated with methane hydrate. Samples with very low concentrations of methane and higher gaseous hydrocarbons were associated with methane hydrate. The relative distribution of individual hydrocarbons in the C1-C5 range is highly diverse in the asphalts. We interpret this diversity to be reflective of the postdepositional history, which could be due to outgassing, leaching or biodegradation.

Oily sediments recovered by gravity coring show evidence of a sulfate/methane transition zone at several meters subseafloor depth due to sulfate-dependent turnover of hydrocarbons. Stable carbon isotope analysis of methane in these cores indicate biological activity close to sulfate reduction. The resulting dactic magma evolves to rhyolitic composition through crystal fractionation. (ii) The basaltic magma itself differentiates by crystal fractionation forming a basaltic andesite magma. (iii) Andesites are produced by mixing of basaltic with dacitic melts. These processes were traced by iron isotopes: (i) During the differentiation from the dacites to the rhyolites the δ56/54Fe value increases successively. This increase (e.g., 0.15‰ for the 4000 B.P. eruption) can be described by a Rayleigh fractionation model using a constant bulk fractionation factor between the silicate liquid (L) and all mineral phases (M) of $\Delta^{56/54}Fe_{L} = -0.1‰$. (ii) No isotopic fractionation was found between the basalts and the basaltic andesites which have an average $\Delta^{56/54}Fe_{IRMM-014}$ value of 0.068 ± 0.057 (2SD), identical to mean basaltic values reported by other studies [2-5]. This observation is consistent with the limited change in iron concentration in the remaining silicate liquid during crystal fractionation and small mineral-melt Fe isotopic fractionation factors expected at high temperatures. (ii) The iron isotope composition of the andesites is matching the basaltic andesites and the less evolved dacites, compatible with a mixing process.

The observations suggest that the iron isotope composition of the crust can be slightly modified by magmatic processes and that magma differentiation processes are reflected in the iron isotope composition of some evolved silicic rocks.

Iron isotope fractionation during the volcanic evolution of Hekla, Iceland

JAN A. SCHUESSLER1, RONNY SCHOENBERG1 AND OLGEIR SIGMARSSON2

1Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, D-30167 Hannover, Germany (j.schuessler@mineralogie.uni-hannover.de)
2Laboratoire Magmas et Volcans, CNRS - Université Blaise Pascal - OPGC, 5 rue Kessler, Clermont-Ferrand, 63038 France

The aim of this study is to systematically investigate potential iron isotope fractionation in the Earth’s crust by magmatic processes. High precision iron isotope analysis by high resolution MC-ICP-MS were performed on a suite of rock samples representative for the volcanic evolution of the Hekla volcano (Iceland). The whole series of Hekla’s rocks results from several processes [1]. (i) Basaltic magmas rise and induce partial melting of meta-basalts in the lower part of the Icelandic crust. The resulting dacitic magma evolves to rhyolitic composition through crystal fractionation. (ii) The basaltic magma itself differentiates by crystal fractionation forming a basaltic andesite magma. (iii) Andesites are produced by mixing of basaltic with dacitic melts. These processes were traced by iron isotopes: (i) During the differentiation from the dacites to the rhyolites the δ56/54Fe value increases successively. This increase (e.g., 0.15‰ for the 4000 B.P. eruption) can be described by a Rayleigh fractionation model using a constant bulk fractionation factor between the silicate liquid (L) and all mineral phases (M) of $\Delta^{56/54}Fe_{L} = -0.1‰$. (ii) No isotopic fractionation was found between the basalts and the basaltic andesites which have an average $\Delta^{56/54}Fe_{IRMM-014}$ value of 0.068 ± 0.057 (2SD), identical to mean basaltic values reported by other studies [2-5]. This observation is consistent with the limited change in iron concentration in the remaining silicate liquid during crystal fractionation and small mineral-melt Fe isotopic fractionation factors expected at high temperatures. (iii) The iron isotope composition of the andesites is matching the basaltic andesites and the less evolved dacites, compatible with a mixing process.

The observations suggest that the iron isotope composition of the crust can be slightly modified by magmatic processes and that magma differentiation processes are reflected in the iron isotope composition of some evolved silicic rocks.

Neutron capture-induced $^{150}\text{Sm}$ anomalies in IAB Iron meteorites and Winonaites

T SCHULZ,1,2,3, D. UPADHYAY 2, K. MEZGER 2, C. MÜNKER 3,2 AND H. PALME 1

1Institut für Geologie und Mineralogie, Universität zu Köln, Zülpicher Str. 49b, 50674 Köln, Germany

3Mineralogisch-Petrologisches Institut, Universität Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany

Isotope anomalies produced by neutron capture in nuclides with large neutron capture cross sections can be used to constrain the irradiation history of extra-terrestrial matter [e.g. 1]. This study investigates the exposure history of IAB irons and Winonaites, which are presumed to come from the same body [2], using the increase in $^{150}\text{Sm}$ as a result of neutron capture by $^{149}\text{Sm}$. For this purpose, Samarium was separated from 200-500 mg samples using standard dissolution and ion exchange techniques. The isotope ratios were measured on a Triton TIMS in static mode. Analytical uncertainties on the reported ratios are $<12$ ppm (2 sd; n=8) for the standard and $<35$ ppm for the samples (2 se).

Figure 1 shows the neutron capture-induced isotopic shifts in $^{150}\text{Sm}/^{152}\text{Sm}$ measured on three IAB silicates (1.1-1.8 $\varepsilon$-units) and two Winonaites (1.0-5.5 $\varepsilon$-units). The corresponding neutron fluences for the IABs (1.5-2.5 x 10$^{15}$ n/cm$^2$) and the Winonaites (1.4-7.4 x 10$^{15}$ n/cm$^2$) are similar to those of chondrites [1]. The similar fluences calculated for the IABs are difficult to reconcile with their different cosmic ray exposure ages [e.g. 3], unless one invokes a common regolith history on the parent body followed by high shielding depths within their meteoroids (so that they were only insignificantly affected by exposure to cosmic rays after ejection from the parent body).

Fig. 1: HaH = Hammadah al Hamra; CC = Caddo County; CD = Canyon Diablo; NWA = North West Africa; STD = terrestrial standard; Cosmic ray exposure age [Myr].

High-precision Pb isotope measurements discriminate different subduction components along the Solomon island arc

S. SCHUTH1,2, C. MÜNKER2, E.E. SCHERER1 AND S. KÖNIG1,2

1(schuths@uni-muenster.de) 2(muenker@uni-bonn.de)

Along the Solomon island arc, SW Pacific, the Indian plate is subducting beneath the Pacific plate. Geophysical evidence indicates the presence of a fossil slab of Pacific oceanic crust that was subducting until ca. 6 Ma [e.g., 1]. To assess the influence of subducted oceanic crust and Ontong Java Plateau material along the arc, we determined Pb isotope compositions of representative arc magmas covering the complete southern island arc chain (ca. 1000 km). Most of their Hf-Nd isotope compositions overlap with those of the Australian-Indian mantle domain, indicating that the active trench does not mark the boundary between the Australian-Indian and Pacific mantle domains [2]. In contrast to Hf-Nd, Pb isotope compositions of the lavas are dominated by subduction components. To achieve sufficient analytical resolution, Pb isotope compositions were obtained using MC-ICP-MS and normalization to Tl that was added prior to measurement.

High-precision Pb isotope data for silicate reference materials obtained by Tl normalization using MC-ICP-MS are in good agreement with previously published data, supporting the reliability of the analytical method. An external reproducibility of better than ±130 ppm (2σ) can be achieved. The measured 206Pb/204Pb, 207Pb/204Pb, and 208Pb/204Pb in the Solomon arc magmas range from 18.351 to 18.853, 15.479 to 15.564, and 38.105 to 38.462, respectively, indicating the absence of significant amounts of subducted pelagic sediments. The high-precision Pb data clearly reveal a bimodal distribution, reflecting the presence of two distinct types of subduction component, originating from either the currently subducting Australian plate or the fossil Pacific plate. Notably, domains with Australian-Indian type Pb isotope signatures are confined to the central New Georgia group, where the active Woodlark spreading center is being subducted. Due to a lower geothermal gradient, all other segments of the subarc mantle have apparently not yet been fluxed by subduction components from the Australian-Indian plate that has been subducting since ca. 6 Ma.

Lead isotope compositions of some samples show evidence that material from the Ontong Java Plateau was subducted together with the Pacific plate, consistent with geophysical evidence [e.g., 1].

Ultrastructure of bone: Hollow apatite crystals, solution chemistry and organic inhibitors

HENRY P. SCHWARCZ
School of Geography and Earth Sciences, McMaster University, Hamilton, ON L8S 4K1, Canada

The ultrastructural nature of bone is a matter of long debate. While all studies confirm that an apatitic mineral component makes up at least 60 wt % of bone, the morphology and even the composition of this phase is uncertain, due to the small size of the crystals (10’s of nm in maximum dimension).

TEM analysis of ion-milled and focused ion-beam milled sections of bone reveals that most of the apatite in bone is in the form of apparently hollow fibers 5 to 10 nm in diameter and several hundred nm long, which are oriented parallel to collagen fibers. Lesser amounts of apatite occur in the gap zones spaced at 67 nm along collagen fibrils. The core of the apatite fibers is assumed to be filled with a protein, probably collagen, making up ca. 5% of the total collagen in bone. The fibers are constructed of single crystals of apatite, with their c-axes oriented parallel to the fibers. Boyde (1974) found similar structures in dentine.

Although bathed in an extracellular fluid (ECF) which is supersaturated with respect to apatite, the crystals have remarkably uniform dimensions, implying that, after initial formation, further deposition of apatite is strongly inhibited. Osteopontin (OPN) and other molecules in the ECF (e.g., Pampena et al. 2004) are known to inhibit apatite growth.

Both Ca and PO₄ ions are essential to the vital activity of all metazoans. The ECF of invertebrates is also supersaturated in hydroxyapatite (HA), with saturation index values up to 10¹⁵. The relative scarcity of apatite as a biomineral suggests that strong inhibition of HA formation must occur in the ECF of invertebrates as well.

Integrated air quality assessment – A synthesis of elemental and organic air pollution indicators

L. SCHWARK AND E. LEHNDOFF
Department for Geology and Mineralogy, University of Cologne, Germany; (lorenz.schwark@uni-koeln.de)

In a multidisciplinary approach atmospheric quality in the Greater Cologne Area (GCA) was studied using pine needles as bioreceptors. This contribution describes accumulation behaviour, transport fractionation, source allocation, and the spatial distribution of major and trace elements including platinum group elements. Special emphasis is placed on synthesizing the inorganic and organic pollutant load on pine needles for improved differentiation of traffic, industrial and power plant emissions. The interpretation is corroborated by δ13C and δ15N isotopes and environmental magnetic data.

The GCA comprises various element emission sources, mainly lignite fueled power plants, urban regions of high traffic density and reduced air mixing, domestic heating and large industrial complexes along the Rhine Valley. We will first demonstrate that element accumulation on pine needles occurs in a systematic and predictable manner by analyses of 3 to 50 month old needles taken separately in summer and winter at six key locations. This allows for interpretation of spatial distribution maps constructed from 71 locations covering 3000 km² in the GCA. Absolute concentrations of elements and element enrichment factors were used for spatial analyses. Normalization to average dust composition was achieved using the sum of REE, as Ti was regionally enriched in the volcanic province of the “Siebengebirge”.

Source characterization based on element concentrations revealed that Mo was best suited to identify petrochemical emissions. Cu enrichment results from petrochemical emission and traffic sources. PGE showed a predominantly traffic origin for Pt and Pd, the latter also affected by fertilizer application in agricultural areas. Ru and Re were less traffic dependent, for Pt and Pd, the latter also affected by fertilizer application and traffic sources. PGE showed a predominantly traffic origin emissions. Normalization to average dust composition was achieved using the sum of REE, as Ti was regionally enriched in the volcanic province of the “Siebengebirge”.

Normalization to average dust composition was achieved using the sum of REE, as Ti was regionally enriched in the volcanic province of the “Siebengebirge”.

Traffic pollution was clearly depicted by enhanced Sb and Ba concentrations, whereby Ba showed a higher degree of dispersal. Fe and V were shown also to be related to traffic emissions in urban areas but as well originate from power plant emissions. Verificaton of emission sources was achieved by polycyclic aromatic hydrocarbon (PAH) pollution indicators. Lignite-fueled power plants emit preferentially phenanthrene, cyclopentenophenanthrene, and dibenzothiophene; urban traffic is characterized by higher load of alkylated phenanthrenes and different isomer patterns of e.g. methylphenanthrenes. Correlation of element and PAH pollution indicators was excellent although certain pollutant sources were depicted by one group only. For example Pb/Zn mining activity in the Rhenish Massif was only detected by elevated Cd concentration.

Inorganic and organic multiproxy air quality analyses allows for very reliable and independent source allocation even in areas with multiple emission sources.

Constraints on the revision of the K decay constants

WINFRIED H. SCHWARZ AND MARIO TRIELOFF
Universität Heidelberg, Im Neuenheimer Feld 236, D-69120 Heidelberg (winfried.schwarz@min.uni-heidelberg.de)

As the accuracy of current K-Ar age calculations is seriously limited by the uncertainties of the 40K decay constants [1,2], a reevaluation is required. 40K has a dual decay to 40Ar and 40Ca with a branching ratio of 10.48/89.52 [1,3] and a total decay constant of 5.543·10⁻¹⁰ a⁻¹ (calculated with data from [3] and a 40K/K ratio of 0.01167% [4]). Thus for conventional K-Ar and Ar-Ar dating (where the age calculation depend on mineral standards dated by conv. K-Ar technique) all three values are needed in the age equation.

To revise the decay parameters for 40K, the systematic offset of Ar-Ar and U/Pb mineral ages of rapidly cooled rocks were determined [e.g. 5]. Using the H chondrite parent body cooling history [6,7] it is possible to calculate the age offset of U/Pb and Ar-Ar ages for c. 4.6 Ga old rocks – it is c. 30 Ma [8], significantly smaller than 1% which is noted in [5] or [9]. A biotite from the Great Dyke Intrusion in Zimbabwe/Africa with an age of c. 2.5 Ga, lead to an age discrepancy of c. 20 Ma. The age data for the c. 2.0 Ga old Vrededorp impact structure from [10] recalculated for a new NL25 standard age [11] lead to a difference of c. 17 Ma.

These new age data lead to a decay constant of c. 5.520·10⁻¹⁰ a⁻¹, only a little smaller than that defined by [1] - this result will not change including the available literature data [e.g. 5,9]. It is slightly different from the determination of the total decay constant of 5.545·10⁻¹⁰ a⁻¹ via LSC by [12] and [13], but different 40K/K and branching ratios were used for these calculations. Using the geochemical data and the age equation for K-Ar dating is not possible (though not important for calulating ages) to decide whether the branching or the 40K/K ratio is wrong by about 1%. Assuming a 40K/K ratio of 0.01167% would lead to the decay constant to 40Ar of c. 0.575·10⁻¹⁰ a⁻¹ and thus a branching ratio of c. 10.42/89.58. Nevertheless an independent redetermination of the 40K/K and the branching ratio is desirable.

The AsO$_6$ polyhedron in arsenates, statistics and the novel compound Ti$^{1+}$Ti$^{3+}$As$_4$O$_{12}$

K. SCHWENDTNER$^1$, U. KOLITSCH$^2$ and E. TILLMANNS$^1$

$^1$Institut für Mineralogie und Kristallographie, Althanstraße 14, 1090 Wien, Austria (karolina.schwendtner@univie.ac.at)

$^2$Naturhistorisches Museum Wien, Burgring 7, 1010 Wien, Austria

Inorganic arsenates comprise a large number of compounds, demonstrated by 1145 entries in the ICSD (version 2006/2), however, only 23 compounds ($R < 8\%$) contain the rare AsO$_6$ octahedral unit.

Hydrothermal synthesis (Teflon-lined stainless steel autoclave, 7 d, 493 K) using the starting materials Tl$_2$CO$_3$ and arsenic acid led to the growth of hexagonal platelets of the novel compound Ti$^{1+}$Ti$^{3+}$As$_4$O$_{12}$ (single-crystal X-ray diffraction, $P$=31m, $Z$ = 1; $a$ = 4.848(1), $c$ = 11.091(2) Å, $V$ = 225.75(8) Å$^3$). The new compound is closely related to the following three structure types: $M^6$As$_6$O$_{18}$ ($M^6$ = Ca, Mn, Co, Ni, Cd, Hg, Pb), $H_2$As$_2$O$_6$, and LiAsO$_4$. All of these, as well as the novel compound, are built of layers of edge-sharing AsO$_6$ octahedra, which are connected by the usually octahedrally coordinated metal cations. In the case of Ti$^{1+}$Ti$^{3+}$As$_4$O$_{12}$, Ti$^{1+}$ is octahedrally coordinated whereas the coordination polyhedron of the larger Ti$^{3+}$ can be described as a trigonal antiprism.

![Image of Ti$^{1+}$Ti$^{3+}$As$_4$O$_{12}$ structure]

Considering the scarce data available for AsO$_6$ polyhedra a statistical analysis of bond lengths in AsO$_6$ groups was conducted. A total of 40 AsO$_6$ polyhedra in 38 different compounds were analysed. The bond lengths in the AsO$_6$ octahedra range between 1.736 and 1.918 Å, with a mean value of 1.827(29) Å. The individual bond lengths are very strongly influenced by the next nearest neighbours. As-OH bond lengths are considerably shortened to a mean value of 1.767(14) Å, which gives the perfect bond valence contribution of 1.00 for this As-O bond. Exactly the opposite effect is found in protonated AsO$_4$ tetrahedra, where the As-OH bond lengths are elongated to a mean value of 1.719(27) Å. As-O bond lengths to other AsO$_4$ and AsO$_6$ polyhedra are very close to the mean value with 1.834(33) and 1.824(20) Å, respectively. The longest mean distances are to edges of other metal octahedra with 1.846(23) Å. No clear correlation between the bond-length distortion and mean bond lengths of individual polyhedra could be established. Financial support by a DOC-FFORTE Fellowship of the Austrian Academy of Sciences (ÖAW) is gratefully acknowledged.

Detector strategies to measure Osmium isotope ratios in small samples by NTIMS

JOHANNES SCHWIETERS$^1$, DIETMAR TUTTAS$^1$, CLAUDIA BOUMAN$^1$, JOHN C. LASSITER$^2$ AND TODD B. HOUSH$^3$

$^1$Thermo Fisher Scientific, Hannah-Kunath-Str. 11, 28199 Bremen, Germany; (johannes.schwieters@thermofisher.com)

$^2$Department of Geological Sciences, The University of Texas at Austin, USA

Negative Thermal Ionization Mass Spectrometry (NTIMS) is the method of choice for high precision Osmium isotope ratio measurements of small sample sizes. Because of its high selectivity and high ionization efficiency optimum sample utilization as well as low backgrounds are achieved.

One of the limiting factors when analyzing small samples with Faraday detectors, is the noise level of the current amplifiers. The noise level is reduced as the resistor value and the gain of the current amplifier is increased. Today’s instruments use 10$^{12}$Ohm amplifiers as a standard. Larger resistor values maybe used to reduce the noise level, however there is a practical limit due to the limited insulation resistance of the PCB as well as the insulation resistance of the Faraday cup and the feedthroughs itself.

Single collector ion counting or even multicollector ion counting detectors overcome the noise problem and promises higher precision touching the limit of counting statistics. Today’s multicollector instruments are equipped with a single ion counting channel as a standard and very small samples can be measured in single collector by peak jumping procedures. The laminated magnet of the TRITON instrument from Thermo Fisher Scientific allows fast peak jumping sequences with short settling times between peak jumps. Nevertheless, this still is a sequential method, whereas the Multi-Ion-Counting (MIC) aproach allows a simultaneaous measurement of all isotopes of interest and thus maximises sample utilization and also eliminates the effect of signal fluctuations on the isotope ratio measurement.

In this experimental study, the performance of all three different detector strategies are compared on the basis of measured data of Osmium samples with different ion beam intensities ranging from >1 Mcps to a few Kcps. The different detector strategies are: (i) Faraday detectors combined with 10$^{12}$ Ohm amplifiers, (ii) fast peak jumping single collector ion counting using an SEM, and finally (iii) multi-ion-counting using multiple channeltron detectors. The best operation range and the pros and cons of each detector strategy for different signal intensities are discussed.
Experimental study of the Na-in-cordierite thermometer at different fluid compositions (NaOH-H$_2$O; NaCl-H$_2$O)

M. SCOLA, P.W. MIRWALD AND P. TROPPER
Institute of Mineralogy and Petrography, Univ. Innsbruck, Austria (peter.mirwald@uibk.ac.at)

Orthorhombic cordierite, (Mg,Fe)$_2$Al$_4$Si$_5$O$_{10}$*(Na, H$_2$O, CO$_2$ etc.), a characteristic mineral phase of medium to high grade metapelites, has thermometric properties. A previous study in the model system Mg-cordierite – 1n Na(OH) (Mirwald, 1986) showed that the Na-content is inversely related to temperature, is largely pressure independent, and stabilises cordierite by about 75MPa relatively to the upper stability boundary according to the reaction (1) Crd + H$_2$O = Tc + Q + Ky (Mirwald, 1984).

In this study we investigated the Na-incorporation in Mg-cordierite using different NaCl solutions (X$_{H_2O}$= H$_2$O/(H$_2$O+NaCl; X$_{H_2O}$: 1, 0.8, 0.6, 0.4 and 0.2) which implies, in addition, different H$_2$O activities covering the P-T range 0.2 – 1.1GPa and 650 to 750°C. Thus, the present experiments were conducted in a slightly acidic fluid milieu. The experiments were carried out in a piston cylinder and a hydrothermal apparatus. Microprobe and X-ray diffraction were used for sample characterisation.

The preliminary data confirm the inverse temperature relation without a significant pressure dependence. Previous Na-T relation: Na(apfu) = 0.406+/-0.003 –0.000471*T(°C); this study: Na(apfu) = 0.398+/-0.015 – 0.000466*T(°C). Again, the Na incorporation stabilises cordierite by about 75MPa, varying H$_2$O activities have no significant influence on the position of reaction (1).

Further experiments performed on quartzphyllite samples and application of the Na-in-cordierite thermometer to high-grade rocks are presented by Wyhlidal et al. (2007) at the same meeting.

Water-rock interactions at the new Gotthard rail base tunnel, Switzerland

ULRIKE SEELIG$^1$ INGRID STOBER$^2$ AND KURT BUCHER$^1$
$^1$University of Freiburg, Germany; (ulrike.seelig@minpet.uni-freiburg.de)
$^2$Geological Survey of BW; (ingrid.stober@rpf.bwl.de)

In Switzerland the new 57 km long rail base tunnel traversing the Central Alps is currently under construction. From the 11.35 km long Amsteg-Sedrun section in the northern part of the tunnel 110 water samples from fractures and open fissures have been collected and analyzed. Geologically this section lies completely in the steeply dipping crystalline basement of the Aar massif.

Depending on the lithology the tunnel water samples show different compositions and the total of dissolved solids is varying from 171 to 4014 mg/l. The most prominent cation is sodium. Magnesium is in most samples close to or below the detection limit of 0.02 mg/l. The majority of the waters has also a very low calcium content. Only a few samples have elevated Ca-concentration, which can be related to the dissolution of fracture anhydrite. The major anions represent a mixture of bicarbonate, chloride and sulphate with varying concentrations. Chloride together with an equivalent amount of sodium is contributed to the waters from leaching of crushed fluid inclusions and grain boundaries. Sulphate originates mainly from the oxidation of sulphide minerals and to a minor extend from the dissolution of anhydrite locally present in fissures.

One striking feature of the tunnel waters is their surprisingly high fluoride content of up to 29 mg/l. In low-TDS waters the fluoride concentration can even exceed the chloride concentration. Fluoride is contributed by fluorite dissolution, which can be found both as secondary fracture mineral and in the granite matrix. The low calcium content of the fluoride-buffered waters leads to the observed extremely high fluoride concentration.

The other remarkable feature of the tunnel waters is their very high pH throughout all lithologies with values up to 10.4. It results from dissolution of calcite under closed system conditions, which leads to a strong decrease of the partial pressure of CO$_2$. Calcite was found frequently in the granitoid host rocks. Calcite dissolution is also the source of bicarbonate in the waters. The dissolved calcium is then removed via a combination of plagioclase alteration and formation of zeolites. The hydrolysis of albite (anorthite content of the plagioclase is below 5 mole%) releases sodium as major cation into the water. Zeolites, especially laumontite, are present as thick mats on fracture surfaces in the tunnel. Zeolite formation is then responsible for the removal of calcium from the water.
Rare earth elements as natural tracers in the Thau basin karst system (Southern France)

J.L. SEIDEL¹, T. IZRAHIM² AND F. ZWAHLEN³

¹UMR HydroSciences, CNRS-IRD-UM1-UM2, Université Montpellier 2, France; (seidel@msem.univ-montp2.fr)
²Catchment Science Center, University of Sheffield, Sheffield, United Kingdom; (T.G.Ibrahim@sheffield.ac.uk)
³CHYN, Université de Neuchâtel, Neuchâtel, Suisse; (francois.zwahlen@unine.ch)

Rare Earth Elements (REE) have been more frequently used as natural tracers in hydrogeology (Smedley, 1991; Johannesson et al., 1996), with the analytical progresses for their determination at very low concentrations (ng/L). These elements cannot be considered as perfect conservative tracers, but REE patterns of groundwaters are mostly inherited from aquifer rocks through which they flow. As a consequence, REEs can be useful to study flow pathways and water mixing processes at different scales.

Because of the few REE studies realized in karst environment, the method was applied to the karst system of the Thau basin (southern France), which is characterized by a high complexity of water mixing processes (Aquilina et al., 2002). Three endmember water bodies (hydrothermal, karstic and sea or brackish waters) are present. The Vise submarine spring constitutes one of the main permanent outlet of the aquifers.

Rain, surface and ground waters were sampled from 2005 to 2007 over the Thau basin karst system. Major elements were determined by ionic chromatography. Trace elements and REE, after preconcentration, were analyzed by ICP-MS. Characteristic REE profiles enable to differentiate several types of water and to follow the hydrodynamics of the submarine spring. The study allowed to individuate the different concerned aquifers and to illustrate their possible temporal connections in function of the hydrologic cycle. Further studies are under progress to investigate REE complexation with organic matter.

³School of Earth, Ocean and Planetary Sciences, Cardiff University, Cardiff CF10 3 YE, Wales, UK

Up to six meter long sediment cores were recovered from a backbarrier tidal flat area of the island of Spiekeroog in the Northwest German Wadden Sea and analyzed by a combination of complementary geochemical, molecular biological and microbiological methods to investigate the activity and composition of microbial communities.

One of our analytical approaches is the analysis of intact polar lipids (IPLs) using HPLC-ESI-MS. These diagnostic membrane lipids are rapidly degraded after cell lysis and thus are considered suitable biomarkers to trace viable microorganisms.

The quantities of the detected IPLs decreased only slightly with depth and correlate well with the total cell counts obtained by DAPI staining.

Furthermore, phospholipids with alkyl diether and mixed alkyl-acyl side-chains become dominant with increasing depth. In accordance with the molecular biological results this may indicate a substantial proportion of sulphate-reducing bacteria (SRB) in the microbial community even in deeper sediment layers because these lipids were detected in mesophilic SRBs (Rütters et al., 2001).

Whereas in the uppermost layers phospholipid-type diethers of archaeal origin were absent, archaeol-containing phospholipids were detected throughout the deeper part of the sediment column. In layers with low contents of methane high numbers of ANME-2 and ANME-1 archaea were found using molecular biological methods.

The major IPLs detected in a deep sulphate-methane transition zone were phospholipids with archaeal and hydroxyarchaeol cores which support the identification of ANME-2 consortia. The isotopic composition of these diethers is currently examined to show whether they are constituents of cell membranes from archaea mediating AOM.

\(^1\)Institut für Biogeochemie und Meereschemie, Universität Hamburg, Germany (seifert@geowiss.uni-hamburg.de)
\(^2\)School of Engineering and Science, Jacobs University Bremen, Germany

Introduction

We have measured concentrations of dissolved methane and hydrogen in a set of fluid samples recovered by ROV from hydrothermal systems located on the Mid-Atlantic Ridge (MAR) at 15°N and between 4° and 10°S under the auspices of the German SPP 1144 project. Fluids investigated originate from different settings comprising peridotitic to basaltic host rocks, hot and diffuse vents, and water depths between 1500m and 3000m.

Results and discussion

Fluid endmember concentrations calculated based on the Mg content were up to 3.5 and 19 mmol/L for CH\(_4\) and H\(_2\), respectively, for fluids from the Logatchev hydrothermal field. Similar exceptional high concentrations with 1.4 mmol/L of CH\(_4\) and 11.6 mmol/L of H\(_2\) were also found in fluids of the recently discovered smoking crater Drachenschlund located at 08°18’S and characterised by ultramafic host rocks alike the Logatchev hydrothermal field.

Much lower gas concentrations were found in the fluids of basalt hosted systems. Among these, a black smoker of the Turtle Pits field (4°49’S) emanating vigorously boiling fluids with temperatures of up to 407°C at 3000m depth showed the highest fluid endmember concentrations of 0.3 mmol/L H\(_2\) and 0.018 mmol/L CH\(_4\). Black smoker fluids with no indication of phase separation revealed significantly lower gas concentrations.

Signatures of stable C isotopes for CH\(_4\) covered a range from \(\delta^{13}C\) -9.2 to -13.7‰ for all fluids sampled from vents at about 3000m water depth with no systematic difference between the various settings. Only CH\(_4\) in fluids of the Lilliput hydrothermal field (9°33’S) emanating at 1500m water depth with temperatures < 20°C revealed \(\delta^{13}C\) values of about -32‰. This might be attributed to distinct p/T conditions during abiotic CH\(_4\) generation or to a significant microbial contribution. \(\delta^2H\) values of H\(_2\) were used to estimate temperatures of emanating fluids.

Conclusion

Hydrogen dominates over methane among reactive gases within black smoker fluids. Host rock composition and phase separation processes strongly affect the gas concentrations in hydrothermal fluids but not the stable isotope distributions within the gases.

Evaluation of geothermometers for a zircon-rutile-corundum intergrowth

W. SEIFERT AND D. RHDE

GeoForschungsZentrum Potsdam (GFZ), Potsdam, Germany (ws@gfz-potsdam.de and rhede@gfz-potsdam.de)

A corundum megacryst (7x5 mm) from residues of an alkali basalt from SE Saxony (Germany) includes zircon and rutile. It provides a suitable specimen to test recently published geothermometers (“Ti-in-zircon” and “Zr-in-rutile” (Watson et al., 2006), and may be revealing about the origin of this mineral paragenesis, which is uncommon for basalts.

Rim-core-rim traverses of the trace elements Ti and Zr in zircon and rutile, respectively, were performed using an electron microprobe JXA-8500F under different analytical conditions (see figures below, detection limits in brackets).

Calculated temperatures are about 1100 °C for zircon (distance of analysis points to rutile >60 µm), but about 1015 °C for the core of rutile and 940 °C for the rim of rutile.

The shape of the traverses are discussed in consideration of secondary fluorescence, temperature, and chemistry of the crystallizing medium.

Lithium isotopes of the early solar system and terrestrial planets

HANS-MICHAEL SEITZ, GERHARD P. BREY, JUTTA ZIPFEL, ULRICH OTT AND STEFAN WEYER

1Institut für Geowissenschaften, J.W. Goethe Universität Frankfurt, Germany, (h.m.seitz@em.uni-frankfurt.de)
2Sektion Meteoritenforschung Forschungsinstitut und Naturmuseum Senckenberg, Frankfurt, Germany
3Max-Planck-Institut für Chemie, Mainz, Germany

Despite large mineralogical, textural and chemical differences between carbonaceous chondrites, ordinary chondrites and achondrites, the range of δ⁷Li is restricted from +0.5 to +5.4‰. Hydroxide alteration and metamorphism are extremely variable in chondrites but Li isotopes show no obvious correlation with petrological types. Neither carbonaceous or ordinary chondrites, nor achondrites exhibit a correlation between their Li abundances and δ⁷Li, suggesting that Li isotopes did not fractionate during early stages of our solar system nor during magmatic differentiation on smaller asteroidal bodies.

Based mainly on the composition of basaltic and ultramafic rock types from Earth, Elliott et al. [1] and Magna et al. [2] suggested a δ⁷Li-value for BSE (bulk silicate Earth) of ~ +4‰. Elliott et al. [3] derived a weighted average of +3.4‰ for unmetasomatised mantle peridotites. Seitz et al. [4] and [3] concluded that a δ⁷Li of ~ +4‰ should also be the value for the inner planets, because rocks from the Moon and Mars give average values. McDonough et al. [5], on the other hand, suggested a δ⁷Li-value of 0‰ for the solar system, an average of a restricted number of measurements on chondrites. More recent work by McDonough et al. [6] revealed a slightly heavier average composition (δ⁷Li = +1.3‰). However, such low values are not supported by our measurements which comprise a much wider range of chondrite types. We find an average of +3.3‰ for carbonaceous chondrites. Ordinary and enstatite chondrites give a lighter average of +2.3‰.

The previously suggested ‘BSE’ value of ~ +4‰ by [1,3,4] was based mainly on basaltic rock types. The average δ⁷Li-value of unmetasomatised peridotites [3,7] and of olivines from relatively pristine spinel peridotites [1] is +3.3‰, indistinguishable from carbonaceous chondrites.

We therefore suggest, in agreement with Elliott et al. [3], that the δ⁷Li-value for BSE and also for the inner planets is +3.3‰. In turn, the different isotope signatures of carbonaceous chondrites on one side and of ordinary chondrites on the other are interpreted to reflect distinct reservoirs in the early solar nebula.

Re-Os isotope systematics of kimberlites from SW Greenland: Implications for an isolated lithospheric mantle during 500m.y.

R. SENDA, K. SUZUKI, H. KAWABATA, AND I. KANEOKA

1Institute for Research on Earth Evolution (IFREE), Japan
2Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan (r.senda@jamstec.go.jp)
3ERI, Univ. Tokyo, Bunkyo-ku, Tokyo, Japan

Kimberlite magma is well known to entrain many xenoliths and diamonds, which suggest that the magma originated from a source at the depth deeper than 200km. However, the nature of this source material is still highly debated. Here, we report the Re-Os data for kimberlite dykes from the Sarfartoq area, SW Greenland. In this area, the alkaline ultramafic dykes intrude into the boundary between the Archean craton and the Palaeo-proterozoic orogen. The kimberlites were erupted around 600Ma with a large carbonatite complex, which is located at the center of a widely distributed kimberlite swarm (Larsen et al., 1983; Larsen and Rex, 1992).

The Re-Os whole rock reference age of 1100 Ma is significantly older than the eruption ages of the Sarfartoq kimberlites, determined by K-Ar and U-Pb methods (Larsen et al., 1983; Bizzaro et al., 2002). It implies that the kimberlite source mantle was separated from convecting mantle at the time of the Re-Os reference isochron age and remained isolated until eruption. The Re-Os TMA ages of the kimberlites, however, are similar to the eruption ages. Thus, in this case it appears that Re-Os TMA ages record the eruption. The initial 187Os/188Os ratio of the kimberlites, 0.113, is in the range of the continental lithospheric mantle. The 187Os/188Os values of the kimberlites at 1100 Ma are also similar to those of the lithospheric mantle xenoliths from Somerset Island (Irvine et al., 2003), rather than the primitive upper mantle estimated by Meisel et al. (1996), supporting the isolated source hypothesis.

Numerical simulation on the thermal evolution and differentiation of iron meteorites’ parent body

HIROKI SENSHU1 AND TAKAFUMI MATSUI2

1Research Center for the Evolving Earth and Planets, Tokyo Institute of Technology, Tokyo, Japan (senshu@geo.titech.ac.jp)
2Department of Complexity Science and Engineering, Graduate School Frontier Science, University of Tokyo, Tokyo, Japan (matsui@k.u-tokyo.ac.jp)

According to Hf-W chronometry, the parent bodies of iron meteorites had experienced silicate-metal separation within the first a few myr since CAI formation (e.g., Markowski et al., 2006). In this case short-lived radioisotopes such as $^{26}$Al and $^{56}$Fe may have been survived and played a key role in thermal history of parent body (Urey, 1955). However the thermal history and the mechanism of silicate-metal separation have been unclear so far. Thus, in this study, we developed a numerical model on the thermal evolution and differentiation of planetesimal-sized (from a few km to about 100km-sized) celestial body to clarify the timing and mechanism of the formation of metallic core, which is one of the most plausible candidate of the origin of iron meteorites.

Our model takes into account the internal heating due to short-lived radioisotopes, radiative cooling from the surface, the porosity effect on the thermal conductivity, sintering of silicate media (pores shrink due to the effect of pressure and temperature), and silicate-metal separation due to permeable flow of molten metal through silicate media. Since the melting temperature highly depends on the sulfur content, we also consider the change in sulfur content along the phase diagram in Fe-FeS system (Kullerud, 1967).

According to our numerical results, there are two conditions for the planetesimal-sized body to form a metallic core. At first, the parent body should form within the first 2 myr from CAI formation, otherwise it would have insufficient heat source. Next, the radius of the body should be larger than about 7 km, otherwise the body would be cooled rapidly. Once these conditions are satisfied, molten metal, into which sulfur preferentially dissolves, migrates toward the center of the body to form metallic core. Afterward, as the core cools down precipitation of pure iron takes place in accordance with the phase diagram in Fe-FeS system. Finally a pure iron ‘inner core’ forms at the center of the metallic core, which would be the origin of iron meteorites. Resulting cooling rate of metallic core at 800 K is slower than several 100 K/myr depending on the planetary size, which is consistent with the cooling rate of iron meteorites obtained from the analytical study, from 1 to 500 K/myr (e.g., Wood, 1964).

Syn-plutonic dykes and magma mingling: An example from the Alvand plutonic complex, Sanandaj-Sirjan metamorphic belt, Iran

ALI A. SEPAHI

Department of geology, Bu Ali Sina University, Hamadan, Iran, (sepahei@basu.ac.ir)

The Alvand plutonic complex is composed of various mafic to felsic plutonic rocks (gabbro-diorite-tonalite-granite) formed by repeated injections of magmas of crustal (anatectic) and mantle origin. Two extreme end-members of magmas in the complex include: 1) M-type magmas generating gabbro-diorite-tonalite suite and mafic-intermediate dykes and 2) crustal anatectic magmas generating S-type granites and related rocks. There are many NE-SW trending microdioritic-microtonalitic syn-plutonic dykes in the complex which in the some places they are disaggregated to mafic microgranular enclaves (MME). Their appearance, mineralogical and geochemical affinities are similar to other dioritic rocks of the complex but they are finer grained, richer in quartz-ocelli and mafic clots and they are more silicic than their coarse grained equivalents. Regarding to field, petrographic, mineralogical and geochemical features a suite of pure anatectic to hybrid and to mantle type plutonic rocks can be distinguished in the Alvand plutonic complex. The dioritic-tonalitic rocks are hornblende-rich (30-50 %) but anatectic monzogranites-granodiorites are hornblende-free. The evidence of hybridization due to magma mingling in the region is better understood by characteristics of mafic end member than felsic one. This is due to volumetric abundance of two original magmas so that felsic magma has been more abundant than mafic one at the time of hybridization, and therefore, the mafic magma has been surrounded by the felsic magma, so that, solidified parts of the felsic magma have been disintegrated into mafic magma. Since that the felsic magma has been near the end of its crystallization (solidification) history its mixing with mafic magma has been limited. The geochemical properties of both of the felsic and mafic rocks of the region have been slightly affected by hybridization process.
Geochemistry and petrogenesis of the Tamuteh leucogranites in SW Saqqez, northwestern Iran

A. A. SEPAHI1, S. F. ATHARI2 AND M. MOAZZEN3

1Department of Geology, Bu Ali Sina University, Hamadan, Iran (sepahi@basu.ac.ir)
2Department of Mining, University of Kurdistan, Sanandaj & Young Researchers Club of Kurdistan, Iran (sfathari@gmail.com)
3Department of Geology, University of Tabriz, Iran (moazzen@tabrizu.ac.ir)

The Tamuteh area is located in the southwest of Saqqez in the north of the Kurdistan Province, western Iran. The Tamuteh leucogranites are situated in the Sanandaj-Sirjan Metamorphic Belt, Zagros Orogen and are composed of various granitic rocks including syenogranite, monzogranite, granodiorite, tonalite and microtonalite. They are cut by lamprophyric dykes and silicic veins. Geochemically, these leucogranites are subalkaline (calc-alkaline), metaluminous and weakly peraluminous and their characteristics resemble the I-type granites. According to the geochemical classification scheme of Frost’s et al. (2001), Tamuteh leucogranites are magnesian to weakly ferroan and calc-alkalic to calcic. They contain low concentrations of Rb, Y, Zr, Th, U, Ce, FeOt+MgO and high concentrations of SiO2, Ba and high Sr/Y and Ba/Rb ratios. They show general trends of decreasing contents of Al2O3, Fe2O3, MgO, P2O5 and TiO2 with increasing SiO2 but CaO, Na2O and K2O amounts show no regular patterns. According to tectonic discrimination diagrams of Pearce et al. (1984), Tamuteh leucogranites were generated in a volcanic arc setting. Behaviour of trace elements in the Tamuteh leucogranites is similar to those of well-known volcanic arc granites from Chile and Jamaica. Normalized trace element patterns show enrichment in LILEs (Rb, Ba, K, Th and Ce) relative to HFSEs (Nb, Zr and Y) and similar to calc-alkaline subduction related rocks from orogenic belts, including that they have had much interaction with crustal materials. The Tamuteh leucogranites also have high Sr and low Y and Rb contents, therefore can be related to mantle-derived magmas. The calc-alkaline, I-type leucogranite or syenogranitic to tonalitic composition and the presence of lamprophyric dykes indicate the formation of two magmas experiencing subsequent mixing/mingling processes. Therefore, these leucogranites may have resulted from contamination of mantle-derived magmas by continental crust during an ancient subduction event.

Large 14C age offsets between fine aragonite fraction and coexisting planktonic foraminifera in shallow Caribbean sediments

S. SEPULCRE, K. TACHIKAWA, L. VIDAL AND E. BARD
CEREGE, UPCAM3, CNRS, Collège de France, Europôle de l’Arbois, 13545 Aix-en-Provence, France (sepubcre@cerge.fr)

14C is a widespread dating tool in paleoceanography. Age models are usually derived from coarse fraction planktonic foraminifera (>150 µm), but many proxies used in paleoclimatic research such as fine aragonite or organic components belong to the fine fraction (<63µm). Several studies have shown time-lags between records from various granulometric fractions (Paull et al., 1991; Thomson et al., 1995; Mollenhauer et al., 2005) due to different processes such as changes in sediment sources or abundances, sedimentation rates, bioturbation, reworking...

We studied the temporal phasing between the coarse and the fine fractions from sediments retrieved in the Northern Caribbean Sea. Detailed stratigraphies over the past 40 kyr of δ18O and 14C of aragonite fine fraction and planktonic foraminifer Globigerinoides ruber, and their respective abundances were performed on core MD032628 (Walton Basin, 17°21N, 77°42W, 846m water depth).

δ18O records are nearly in phase for both fractions, with a slight lead of the fine fraction during the last deglaciation. 14C ages are identical within errors over the past last 5 kyr. The age difference increases through time with a fine fraction being younger than G. ruber. The discrepancies range between 1.33 kyr at the end of the last deglaciation up to 5 kyr during the LGM.

Bioturbation and variations in accumulation rates are likely causes for the observed discrepancies (Bard et al., 1987; Wheatcroft, 1992; Bard, 2001). Indeed, G. ruber abundance is highest during the LGM and decreases over the last deglaciation. Inversely, the fine fraction is minimum during the LGM and reaches its maximum during the Holocene. Bioturbation has probably mixed a “lighter δ18O-younger 14C” fine fraction of the last deglaciation downward with “heavier δ18O-older 14C” G. ruber. The relative influence of various mechanisms (size-dependant bioturbation, sedimentation rates, abundances) has been tested by using a numerical model (Bard et al., 1987).

The geochemistry of Ni isotopes in mafic-ultramafic layered complexes

D.S. SERGEEV1, A.S. SERGEEV2, E.M. PRASOLOV2,3, I.N. KAPITONOVA1 AND S.A. SERGEEV2,3

1University of Neuchatel, Institute of Geology, Switzerland; (dmitry.sergeev@unine.ch)
2Saint-Petersburg State University, 7/9 Universitetskaya em., 199034 St.-Petersburg, Russia
3Centre of Isotopic Research, VSEGEI, 74 Sredny pr., St.-Petersburg, Russia; (sergey_sergeev@vsegei.ru)

Introduction

For better understanding the natural processes involved in the formation of Ni ore deposits in igneous layered complexes, we analyzed Ni isotopes in a section through the 2.45 Ga Burakovsky layered mafic-ultramafic massif (NW Baltic Shield, Russia). In order to constrain the mechanisms of Ni isotopic fractionation, we also analysed Ni isotopes in samples that have undergone Ni-enriching by the Mond process, where synthesis gas (95-97% CO and H) is used for highly effective Ni extraction involving metal-carbonyl formation.

Analyses were made on whole-rock (WR) samples and on separated pyroxenes and Ni-rich sulphide minerals with a Neptune MC-HR-ICP-MS. The measuring precision achieved for δ62Ni/60Ni was at ±0.1‰ with a maximum observed fractionation value for Δ62Ni/60Ni of 5‰.

Results

1) WR samples from the section through the Burakovsky Massif (BM) (from -700 to -50m) show a clear fractionation trend of enrichment of light Ni isotopes from the base towards the roof of the massif (change of δ62Ni/60Ni of +0.3‰ at the base, towards -1.5‰ at the top).

2) Ni-rich sulphide secondary minerals, which are forming the upper layer of the intrusion, have the lightest measured Ni isotope composition in the natural samples, in particular those which are associated with carbon minerals (δ62Ni/60Ni = -2‰).

3) The Ni isotope ratios in pyroxenes changes independently of their position in the section. This may indicate the importance of a secondary, low temperature process.

4) Materials from the technological process of metallic nickel production show the most intensive 64Ni/60Ni and 64Ni/60Ni fractionation (δ62Ni/60Ni from +0.5 to -4.5‰). Lighter isotopes accumulate in the chamber’s top, where the gas phases condense.

5) Gas analyses from the BM WR samples show up to 41.5 vol% of (N2+CO) component.

Interpretation

The observed trends of Ni isotopic fractionation in the BM rock, similar to those observed in the technological Mond process, as well as the presence of trapped (N2+CO) gasses, suggest a model of natural kinetic Ni fractionation involving reducing gasses and natural metal-carbonyl formation. Such gasses may either have a juvenile origin or may be formed from heating (intrusion contact, metamorphism) and water vaporization of carbon-bearing geological units.

Development of a mosaic-like micro-pattern during Mg-calcite crystal growth

INGO SETHMANN

Institut für Mineralogie, Universität Münster, Corrensstr. 24, D-48149 Münster, Germany. (isethma@uni-muenster.de)

In natural calcium carbonate precipitation systems, Mg2+ ions play a major role due to their inhibiting effect on calcite growth and the formation of CaCO3-MgCO3 solid solutions, resulting in the modification of precipitation kinetics and rates, thermodynamic stability of the precipitate, as well as in changes of crystal morphology. Marine sedimentary and biomineralized Mg-calcite crystals have been reported to contain up to about 20 mole% MgCO3, although such high-Mg-calcite crystals are considered to be metastable under seawater-like conditions. These natural Mg-calcite crystals usually show micro-morphologies different from pure calcite crystals.

To explore deeper into the conditions of high-Mg-calcite formation, Mg-calcite growth under different solution conditions has been directly observed using atomic force microscopy. Within a certain range of solution conditions, dependent on the Mg/Ca ratio in solution, on the saturation state, as well as on the presence of other ions in solution, an intriguing observation of crystal restructuring has been made: After fast crystal growth by step advancement as well as by two-dimensional nucleation and spreading of monolayer-islands on calcite cleavage faces, straight ridges of sub-nanometre height appeared at the crystal surface. These ridges do not grow on the crystal surface, but they pop up by bulging of the newly precipitated crystal layers. Ridge formation starts at one point and usually proceeds in one direction until they connect to another ridge or stop at a major crystal defect. Ridges occur in three crystallographically defined directions, which probably correspond to the equivalent planes of the prismatic {110} form. Through progressive development of new ridges, the growing crystal becomes subdivided into mosaic blocks that can be reduced down to a few hundreds of nanometres in diameter. When advancing steps stop at ridges, they pile up to form multilayer steps that separate the mosaic blocks from each other, which may finally lead to crystal growth as aligned fibres.

EDX analyses yielded a bulk content of about 8-10 mole% MgCO3 in the mosaic calcite, which should increase its solubility in water. However, dissolution of a mosaic takes place preferentially along the ridges, which may suggest a shift of the bulk strain and possibly exsolution-like dislocation of magnesium ions towards preferential crystallographic planes, where the accumulated strain gives rise to the ridges.

The described mechanism of crystal restructuring may have implications for the formation kinetics of CaCO3-MgCO3 solid solutions, and it may play a role in the formation of crystal ultrastructures, such as in biominerals.
Metal sulfide complexing – What we know and what we should know

T.M. SEWARD
Institut für Mineralogie und Petrographie, ETH Zurich, CH-8092 Zurich, Switzerland

Reduced sulfur occurs ubiquitously in aqueous fluids within and on the Earth’s crust over a wide range of conditions extending from ambient to high temperatures and pressures. In all these environments, metal ions may be complexed to varying degrees by simple inorganic ligands such as HS-, S2-, and SxS2- (polysulfide) as well as by thio-organic electron donors. Metal sulfide complexes and clusters play an important role in element sequestration and transport and biogeochemistry in aquatic (e.g. wetland) systems as well as in the ocean water column and in particular, in anoxic marine environments (e.g. the Black Sea dead zone). In seafloor and subaerial hydrothermal systems, metal-sulfide complexing (i.e. transport) and precipitation are in important not only in ore formation but also in defining many aspects of biodiversity in seafloor and surface discharge environments. At more extreme conditions within the Earth’s crust, metal sulfide complexes are considered to partition into volatile rich fractions during phase separation of saline, magmatic (hydrothermal) fluids. In volcanic gas environments, volatile metal sulfide complexes account significantly for the transition metal transport budget to the atmosphere.

Despite the overall importance of metal sulfide complexing in understanding many geo(bio)chemical phenomena, the stability and stoichiometry of many aqueous metal sulfide complexes are not well known, particularly at ambient temperature where the experimental determination of reliable equilibrium constants is fraught with problems. A few metal-sulfide complex are quite well defined over a range to supercritical conditions such as with the formation of silver and gold hydrosulfide/sulfide complexes. Both Ag and Au are soft Lewis acids and thus form very stable molecular moieties with reduced sulfur. Reliable equilibrium thermodynamic data also exist for sulfide complexes of Cu, Zn, Cd and Hg and some other elements (e.g. As, Mo) but there is a dearth of information available for many other metals with respect to the stability of the complexes as well as their related clusters and their structures. Our current state of knowledge will be discussed together with an assessment of the crucial gaps in our knowledge in metal-sulfide interactions under a variety of conditions.

A geochemical scenario for evolution of the Nain-Baft back arc basin

H. SHAFAII MOGHADAM1, M. RAHGOSHAY2, H. WHITECHURCH1 AND R. MONTIGNY1

1Ecole et Observatoire des Sciences de la Terre, Institute de Physique du Globe, Strasbourg, France, (hadi.shafaii@eost.u-strasbg.fr, hubert.whitechurch@eost.u-strasbg.fr, raymond.montigny@eost.u-strasbg.fr)
2University of Shahid Beheshti, Faculty of Earth Sciences, Tehran, Iran, E-mail: m-rahgoshay@sbu.ac.ir

The Nain-Baft ophiolitic complex is categorized as an oceanic back arc basin, opened during the middle Cretaceous in the active continental margin of the Central Iranian continental block (the Sanandaj-Sirjan zone), due to the oblique subduction of the Tethys Ocean beneath the Iranian block. This extensional basin is behind the Mesozoic magmatic arc of the Sanandaj-Sirjan zone but crosscutting by the Eocene magmatic rocks of the Urumieh-Dokhtar magmatic belt. The Upper Cretaceous is believed to be the time of crystallization or metamorphism of the rock units in this oceanic basin based upon the K-Ar age determination. Clinopyroxene grains in the basaltic rocks of the Nain-Baft ophiolitic complex are characterized by low content of TiO2 content, similar to those of basalts, erupted in arc related environments. The basaltic-gabbroic rocks and the more acidic terms of this belt are of both tholeiitic (IAT) and calc-alkaline affinity. Depletion in HFSE and enrichment in LILE are the more distinctive features. Fractional crystallization and various degrees of depletion/enrichment in the mantle source associated with different degrees of partial melting are the main mechanisms, responsible for the geochemical evolution of the rock series in these ophiolitic complexes.
An experimental approach to high-temperature iron isotope fractionation

A. SHAHAR1, C. E. MANNING1 AND E. D. YOUNG1,2

1Department of Earth and Space Sciences, University of California Los Angeles (ashahar@ess.ucla.edu, manning@ess.ucla.edu)  
2Institute of Geophysics and Planetary Physics, University of California Los Angeles (eyoung@ess.ucla.edu)

There is considerable variation in $^{57}$Fe/$^{54}$Fe among igneous minerals but the cause is uncertain. A central problem in interpreting natural iron isotope data is that equilibrium fractionation factors among coexisting minerals are poorly known. We performed experiments to establish the iron isotope equilibrium partitioning between fayalite and magnetite at a range of temperatures. These minerals are surrogates for mantle spinel and olivine. Experiments were performed in a piston cyldiner apparatus at 1 GPa and at 600, 700, and 800°C. Starting synthetic magnetite was spiked with $^{54}$Fe to track the approach to equilibrium (e.g., Matsuhisa et al., 1978). The experiments were conducted with added quartz to ensure that oxygen fugacity was fixed at the quartz-fayalite-magnetite equilibrium.

The results show that there is a resolvable fractionation between the fayalite and magnetite and that it decreases with increasing temperature: at 600°C $\Delta_{\text{mgt-fa}} = 0.45$‰, at 700°C $\Delta_{\text{mgt-fa}} = 0.31$‰, and at 800°C $\Delta_{\text{mgt-fa}} = 0.28$‰ +/- 0.017‰. The figure below shows our data compared with the predicted fractionation factors (Polyakov and Mineev, 2000). At higher temperatures the theory and experiments are in fair agreement, but as temperature decreases there is a more substantial difference. This study has experimentally determined for the first time inter-mineral $^{57}$Fe/$^{54}$Fe equilibrium fractionation at high temperature. The results show that the magnitudes of these fractionations are large and require consideration when interpreting iron isotope ratios observed in natural igneous samples.

Coeval Pan-African granitization and migmatization of the north Sudan Basement

C.K. SHANG1, M. SATIR1, H. TAUBALD1 AND G MORTEARANI 2

1University of Tuebingen, Institute of Geosciences, Wilhelmstrasse 56, 72074 Tuebingen, Germany (cosmas@uni-tuebingen.de ; shang004@yahoo.com)  
2Technical University of Munich Gmain Nr.1, 84424 Isen/Germany (gmortearani@gmx.de)

We have carried out geochronological and isotopic investigations (zircon U-Pb and Pb evaporation and Nd isotope analyses of North Sudan Basement granitoids and migmatites to characterize sources and to find comprehensive answers to the apparently misleading field chronology, where granitoids (quartz-monzonite, granodiorite, tonalite and granites) intrude (quartz-monzonite, granodiorite, tonalite and granites) migmatite-gneisses; thus suggesting post migmatization emplacement. Whole rock and biotite separates were also analysed for Rb and Sr isotope composition, to determine migmatization-reheating and/or cooling ages.

Zircon U-Pb isotope dilution analyses for representative granitoid that intrude or form lenses and pods interbeded with migmatites, yield ages of 602 ± 3.1 Ma and 602 ± 28 Ma, while zircon $^{207}$Pb/$^{206}$Pb evaporation data give similar mean ages of 602 ± 3.5 Ma and 599 ± 3.8 Ma. U-Pb analyses for migmatic zircon fractions from representative samples yield ages of 599 ± 12 Ma to 606 ± 7 Ma and zircon $^{207}$Pb/$^{206}$Pb evaporation analyses give similar mean ages of 603.8 ± 2.1 Ma and 603.5 ± 3.7 Ma. We interpret these identical zircon age data as crystallization ages for the North Sudan basement granitoids and migmatites Both rock types have crustal signatures ($\varepsilon$Nd = -3.5 to -4.8 for migmatites and $\varepsilon$Nd = -2.4 to -8.9 for granitoids). These basement rock types are different from the older (717.6 ± 0.61 Ma and 707.3 ± 0.97 Ma) mantle sourced ($\varepsilon$Nd = +5.6 to +6.9) granitoid Ring complexes. Rb/Sr whole rock isochron for migmatites give an age of 583 ± 21 Ma, being identical within error limits to basement rock zircon ages. Biotite Rb/Sr cooling ages for both migmatites and granitoids are younger and very similar, (566 ± 11 Ma to 570 ± 17 Ma) with a mean age of 567.5 ± 2.8 Ma and are interpreted as the metamorphic-cooling ages.

While isotope data indicate crustal sources for North Sudan basement migmatite and associated granitoid melt, their similar Pan-African zircon age data and identical biotite cooling ages suggest concomitant crystallization, with inference for coeval indicate coeval crystallization, which together with identical biotite cooling ages, suggest concomitant granitization and migmatization of the North Sudan basement.
Amino acids in shungite matter of Precambrian sedimentary rocks of Karelia

S.N. SHANINA AND Y.E.A. GOLUBEV
Institute of Geology, Syktyvkar, Russia
(shanina@geo.komisc.ru)

Amino acid composition of Karelian shungites (Shunga, Zazhogino and Nigozero deposits) of the Onega area from Palaeoproterozoic with various carbon contents (from 3 up to 98 %) was investigated.

It was established, that the general contents of amino-acids in calculation on percentage of organic matter increase with concentration decrease of organic carbon. The lowest concentrations of amino-acids were established in rocks with the migratory organic matter (0.0005 mg·g<sub>org</sub>). In shungite rocks containing sedimentary organic matter, amino acid contents were increased by 1–2 order (0.002–0.02 mg·g<sub>org</sub>).

In the area of Shunga deposit the group composition of amino acids for sedimentary and mixed organic matter look as follows: aliphatic ≈ hydroxil. In migration organic substance the relation varies: aliphatic > hydroxil. In sedimentary shungite of Zazhogino deposit the group composition of amino-acids is submitted substantially by aliphatic differences (60 %), and in migratory-elastic shungite substance of Nigozero deposit the concentration of amino acids containing acid groups is increased: aliphatic > acid > hydroxil. Among individual amino acids increased contents of serine, glicine and alanine are characteristic. In a sample with the least content of organic carbon (lidite, Shunga deposit) was established high tyrosine quantity and presence of lisine (basic amino acid) which is absent in high-carbon shungite.

Additional researches of sedimentary shungite remains (Zazhogino deposit) after bitumoid extraction have shown that more than 60% of amino-acids were removed from a sample as a result of extraction by chloroform and methanol-benzene. Content of amino acids up to extraction is 0.075 mg·g<sup>-1</sup>, after extraction – 0.029 mg·g<sup>-1</sup>. This fact allows us to believe that the significant part of amino acids in shungite structure includes in bitumoid organic matter.

Our results well coordinate with previous data about distribution of bitumoids in shungite rocks (Solov’eva et al., 2000). The more content of carbon in shungite, the less amount of bitumoids it contains, and accordingly amino acids. Amino acids in shungite matter of sedimentary origin are the best kept; with increase of carbon contents the quantity of amino acids sharply decrease, but does not disappear totally. That is connected with originality shungite structure formed nanoporous fullerene-like carbon particles.

Fluid composition in veins of the Outokumpu drilling site, Finland

L. SHARIF, J. KOLB AND F.M. MEYER
Institute for Mineralogy and Economic Geology, RWTH Aachen University, Wuellnnerstr. 2, 52062 Aachen, Germany. (sharif@iml.rwth-aachen.de)

The Outokumpu drilling site is located in the vicinity of the Outokumpu ore deposit in SW Finland. The Proterozoic Outokumpu formation, consisting of mica schist with black schist interlayers, serpentine, skarn rocks, and pegmatitic gneisses, is thrust over an Archaean basement. The borehole (2.5 km deep) transects the Outokumpu formation and was intended to encounter the Archaean basement.

Core samples with quartz and carbonate veins were taken in order to study fluid inclusions. The wallrocks were metamorphosed in the amphibolite facies. Three different vein types can be discerned: (i) quartz-filled with a biotite-rich alteration halo, (ii) quartz-filled without alteration zone, and (iii) carbonate-filled with an Mg-Hbl alteration zone. The quartz veins show variable sizes in length and thickness ranging from a few mm to several cm, which range from lenses and thin to relatively large veins. The type (iii) veins have a smaller thickness of a few mm.

The investigated fluid inclusions in the quartz veins are primary and pseudosecondary showing one to three phases containing vapor and/or liquid. These inclusions occur together on intragranular trails, in clusters, or as single inclusions in quartz. Locally, pure gas inclusions form intragranular trails. Transgranular trails which indicate secondary inclusions are rare. They also consist of mixed aqueous and carbonic inclusions.

The lowest measured homogenization temperature (Th) is at about 250°C but most of the measured Th are in the range of 300-400°C. The eutectic temperatures (Te) have values of about –22°C and final melting temperatures (Tm) of about –12°C which indicate a salinity of 15–19 wt.% NaCl eq. in the aqueous solution. The Te for gas inclusions have values of about -56°C and a Th of 26°C which points to a CO<sub>2</sub>-rich composition.

The minimum formation temperatures around 300-400°C and the alteration mineralogy (Hbl, Bt) suggest a formation of the hydrothermal quartz veins at conditions of the lower amphibolite facies. This saline and carbonic fluid composition is typical for metamorphic rocks.

The investigation of the fluid inclusions provides a documentary of the fluid development and the possible hydrothermal mobilisation/remobilisation of the Outokumpu ores during later metamorphism.
How well do we know the initial Nd isotopic state of the Earth?

M. SHARMA AND R. ANDREASEN

Department of Earth Sciences, Dartmouth College, Hanover, NH 03755 USA. (Mukul.Sharma@dartmouth.edu, Rasmus.Andreasen@dartmouth.edu)

As is evident from the extensive studies of CAIs and presolar grains in meteorites, the material in the Solar System is a mixture of debris from widely different nucleosynthetic sources. The differences in isotopic composition of bulk meteorite samples may therefore reflect variations in the mixing ratio of various components in different “planetary” materials. It would then follow that models of planetary evolution that are based on small shifts in isotopic ratios due to radioactive decay (Boyet and Carlson, 2005) are strongly dependent on the initial isotopic state and a “bulk solar” value that cannot be properly assumed. A key issue to understand the evolution of early Earth has been whether the available samples of meteorites accurately reflect the Nd isotopic composition of bulk Earth (Andreasen and Sharma, 2006; Ranen and Jacobsen, 2006). We have addressed this question using high precision Sr, Ba, Nd, and Sm isotopes in large samples of chondrites and a eucrite (Andreasen and Sharma, 2006; 2007).

High-precision barium isotopic compositions of large samples of St. Severin (LL6) and Juvisn (eucrite) are identical to the terrestrial values. In contrast, Murchison and Allende (carbonaceous chondrites) reveal excesses in $^{135}$Ba and $^{137}$Ba of around +39 and +22 parts per million, respectively; no anomalies are resolvable in $^{130,132,136}$Ba. High precision Sr isotopic compositions of all meteorites are identical within error. The data are consistent with carbonaceous chondrites having an excess in r-process $^{135,137}$Ba with respect to Earth, Eucrite Parent Body, and ordinary chondrites. The carbonaceous chondrites, however, display no variation in the r- and s-process Sm and Nd isotopes suggesting that the r-process sources of Ba and the lanthanides were decoupled. The homogeneity of Ba and Sm isotopes in the Earth, Eucrite Parent Body and ordinary chondrites indicates that the Solar Nebula that fed planetesimals between ~1 to ~2.4 AU was well mixed with respect to these elements. It was heterogeneous beyond ~2.7 AU where carbonaceous chondrite parent bodies formed. These observations also indicate that the best estimate of the Nd isotopic composition of the Earth is obtained from ordinary chondrites and not from carbonaceous chondrites, as is normally assumed. Since the terrestrial upper mantle shows a $^{142}$Nd anomaly of +18±6 parts per million with respect to the ordinary chondrites, this is further evidence that the upper mantle retains a memory of early Earth differentiation and sequestration of a reservoir with an average Sm/Nd ratio lower than that of chondrites.

Remediation of heavy metals with species and green vegetables

S. SHARMA1, K. S. PATEL1, V. K. JENA1 AND S. C. PATEL2

1School of Studies in Chemistry, Pt. Ravishankar Shukla University, Raipur-492010, CG, India, (analrsu@sify.com)
2Department of Earth Science, Indian Institute of Technology, Powai, Mumbai-400 076, India

The common spices and green vegetables (i.e. Amaranth, Anise, Coriander, Methi and spinach) grown in the contaminated soil of the pyrite belt area, Mandala, central India has been studied for remediation of heavy metals (HMs) i.e. As, Cr, Mn, Fe, Ni, Cu, Zn, Hg, Pb. These plant have remarkable accumulation capacity for these elements. The total mean soil contents of metals i.e. As, Cr, Mn, Fe, Ni, Cu, Zn, Hg and Pb were found to be 53.0, 1380, 1832, 8900, 667, 743, 153, 4.8 and 387 mg kg$^{-1}$, respectively. The total mean contents of HMs i.e. As, Cr, Mn, Fe, Ni, Cu, Zn, Hg and Pb in these plants were 0.48-2.81, 107–5869, 76–1700, 716-53381, 56–8837, 19.9-165, 59–196, 0.9–11.2, 4.6-54 mg kg-1 of DW respectively. The species: Anise, Coriander and Spinach were found to be hyperaccumulator for Cr (> 0.1); Cr (>0.5), Fe (> 5%), Ni (> 0.8%) and Cr (>0.4%), Ni (>0.2%). A sequential extraction procedure was used to fractionate heavy metals in highly contaminated soils into the conceptual metal pools: exchangeable; carbonate bound; bound organically; bound in Fe-Mn oxides; and residual. The leachable and total contents of metals in soil, total metal contents in six plant species and their correlations are discussed. Among five plant leaf tested, Anise, Coriander and Spinach showed the extremely high accumulation tendency towards the heavy metals (i.e. Cr, Fe, Ni), may be due to micellization with essential oils, and sequestration with dibasic acids i.e. oxalic, succinic, etc. The species: Anise, Coriander and Spinach accumulated Cr, Cr, Fe and Ni; Cr and Ni at extremely high levels and considered as hyperaccumulator. These spices provide new plant resource for exploring the mechanism of metal hyper accumulation to use in the phyto remediation of the heavy metal contaminated soils.
Subduction of hydrated lithosphere: 300 ppm H₂O in subducting olivine would eliminate the metastable olivine wedge

T. G. SHARP¹, T. DIEDRICH¹, F. C. MARTON² AND W. DUFRANE¹

¹School of Earth and Space Exploration, Arizona State University, Tempe, AZ 85287-1404; (tom.sharp@asu.edu)
²Department of Science and Technology, Bergen Community College, Paramus, NJ, 07652-1595.

In subducting slabs, where temperatures may be low enough to inhibit equilibrium transformation of olivine, the persistence of metastable olivine into the earth’s transition zone would reduce subduction rates and possibly result in deep focus earthquakes through transformational faulting. Several studies have used experimental transformation kinetic data to model the depth range of metastable olivine persistence under subduction zone conditions (Kirby et al. 1996; Mosenfelder et al. 2001, Marton et al. 1999, 2005). H₂O in olivine has been shown to enhance growth rates in the olivine-wadsleyite and olivine-ringwoodite phase transformations (Kubo et al. 1998, 2004) Recent modeling of the depth range of metastable olivine persistence has included a power law dependence of water concentration (Hosoya, 2005). Here we present new experimental results on the transformation of hydrous San Carlos olivine (300 wt-ppm H₂O) to ringwoodite at 18 GPa. Our experiments show that 300 ppm H₂O greatly enhances ringwoodite growth rates, resulting in an activation enthalpy of 186 kJ/mole. Even at temperatures as low as 700 °C, we obtain measurable growth rates, implying that rapid ringwoodite growth at temperatures corresponding to the interiors of cold subducting slabs. Combining our kinetic data with thermal modeling of subduction zone shows that even for very old and fast subduction zones, 300 ppm H₂O would eliminate the metastable olivine wedge. Alternatively, if deep-focus earthquakes are triggered by olivine-transformational faulting in cold subducting slabs, then the olivine in such slabs cannot be significantly hydrated.

Chlorine isotope distribution on Earth

Z.D. SHARP AND J.D. BARNES

Department of Earth & Planetary Sciences, University of New Mexico, Albuquerque, New Mexico 87131 (zsharp@unm.edu)

With our ability to analyze ³⁷Cl/³⁵Cl ratios (δ³⁷Cl values) of small amounts of solid materials, it is now possible to use chlorine isotope geochemistry of low Cl-concentration solids as a tracer of fluid movement in the subduction process. Cl is a hydrophilic ion that should faithfully track aqueous fluids throughout the crust and mantle. The δ³⁷Cl values of primitive carbonaceous chondrites, pristine MORB glasses and samples of sub-continental mantle origin are all close to 0‰, equal to average crustal values (Sharp et al., Nature ’07). Notable variations do exist, however. Primitive sodalite inclusions from Allende (CV chondrite) average -1.3(±0.6)%o, and MORB glass from 12°N, EPR have δ³⁷Cl values of -1.0‰. The sodalite may represent a separate nebular Cl reservoir or have low δ³⁷Cl due to an equilibrium isotopic fractionation. The 12°N, EPR data may represent mantle heterogeneity, as is seen in other geochemical systems. The overall homogeneous δ³⁷Cl value of 0% for Earth means that even small deviations from this value require a distinct source or fractionation process to explain the non-zero values.

Chlorine isotope fractionation between phases is generally very small, and cannot change the δ³⁷Cl of a system by more than ~0.5‰. Two mechanisms which cause appreciable fractionation have been identified. The first is vaporization of NaCl, where liquid-vapor fractionation at 800°C is ~0.7‰. While not large, fractionation in a Rayleigh distillation process in the solar nebula could easily exceed 2‰, even at high T, if 90% of a sample is vaporized. Far more remarkable is the fractionation between hydrochloric acid and vapor, where fractionations in excess of 8‰ are observed in simple boiling experiments. This fractionation process explains extremely variable δ³⁷Cl values (covering a range of 16‰) found in high temperature, acidic volcanic fumaroles in Central America (Barnes et al., this meeting). Excepting these unusual fractionation processes, chlorine isotope ratios should maintain fidelity throughout subduction and return in arcs. Non-fractionated samples from Central America and the Izu Bonin arcs have values clustering around -2‰, presumably recording the value of their source.

How well do trace element proxies predict slab fluid behavior?
A.M. SHAW1, E.H. HAU Ri2, R.J. STERN3 AND J. HAWKINS4

1Woods Hole Oceanographic Institution, Woods Hole MA 02543 (ashaw@whoi.edu)
2DTM, Carnegie Institution of Washington, Washington DC 20015 (hauri@dtm.ciw.edu)
3University of Texas at Dallas, Richardson TX, 75083 USA
4Scripps Inst. of Oceanography, La Jolla CA, 92093, USA

We present volatile, major and trace element data for olivine-hosted melt inclusions from a suite of cross chain seamount samples extending across the Mariana arc from Guguan volcano to the Mariana Trough. H2O, CO2, S, F and Cl abundances, as well as trace elements, have been determined by SIMS [1]. Our results show that there is a strong decoupling of water and slab fluid tracers such as Ba/La and B contents, beyond the main arc system. As might be anticipated, trace element enrichments generally associated with the subducting slab show a systematic decrease across the arc into the back-arc. However, water contents in cross-chain samples, 230 km above the subducting slab, show similar values to the arc-front samples, implying that water release is a continuous process across the arc. This finding is consistent with experimental results [2] and melt inclusion studies across the Central American arc [3]. In contrast to H2O contents, we observe significantly higher CO2 contents in the cross chain samples (up to 820 ppm) as compared to the arc samples (max CO2= 550ppm), suggesting either enhanced decarbonation at depth, or that the cross chain samples have experienced less degassing. Our observations show that fluid release can be substantial behind the main volcanic front and that a re-evaluation of the common use of slab-fluid tracers is clearly needed.

An experimental study of the origin of reaction textures in mantle xenoliths
C.S.J. SHAW 1 AND D.B. DINGWELL 2

1Department of Geology, University of New Brunswick, Canada. (cshaw@unb.ca)
2Earth and Environmental Sciences, University of Munich, Germany

Sieve-textured clinopyroxene and spinel are common in mantle lherzolite and harzburgite xenoliths. Various interpretations have been put forward to explain the origin of this texture, including partial melting, mantle metasomatism and host magma – xenolith reaction during transport. Shaw et al. (2006) suggested that sieve texture was a result of a two stage process involving breakdown of orthopyroxene with generation of a secondary Si-Al-alkali-rich melt, followed by migration of this melt along grain boundaries where it dissolved clinopyroxene and spinel in an incongruent reaction. In this study, we have performed a set of time series experiments to test the above hypothesis. The experiments were performed under both reducing and oxidized conditions at 1200 and 1156 °C at one atmosphere, using a synthetic leucitite melt and discs of natural herzolite. Experiment durations ranged from 1 to 15 days.

Sieve texture was developed on clinopyroxene and spinel in all experiments, but only on grains in direct contact with melt derived from symplectic reaction zones around orthopyroxene. Reaction zone thickness does not show a simple relation to experiment duration, however reaction zones developed at 1156°C are narrower than those formed at higher temperature.

Our results show that sieve texture development on clinopyroxene and spinel in orthopyroxene-bearing mantle xenoliths is the result of a multistage reaction process. In the first step, orthopyroxene undergoes incongruent dissolution to produce a silica and alkali-rich melt together with olivine and clinopyroxene. As this melt migrates along grain boundaries it causes incongruent dissolution of clinopyroxene and spinel. The incongruent dissolution reactions involve complete dissolution of the reacting mineral followed by nucleation and growth of the secondary phases once the reacting melt is saturated with them. These secondary phases have a smaller volume than the primary grains leaving behind a reaction zone with interstitial melt, i.e. a sieve textured zone. The reaction of orthopyroxene, clinopyroxene and spinel with infiltrated host magma results in a range of melt compositions that are indistinguishable from those interpreted to be due to very small degrees of partial melting.

Geochemical and microbiological controls on the corrosion and transport of depleted uranium in soil

S. SHAW1, A.C. BAXTER2, S.A. JACKMAN2 and I.P. THOMPSON3

1School of Earth and Environment, University of Leeds, Leeds, UK.
2NERC Centre of Ecology and Hydrology, Oxford, UK.

Assessment of the environmental impact of depleted uranium (DU) from munitions in oxic soil is hampered by limitations on information regarding uranium mobilisation and transport. Soil geochemistry, mineralogy and microbiology have been shown to have a significant effect on the behaviour of uranium within many natural environments.

The aim of this study is to determine the relative influence of geochemical and microbiological factors within the context of the overall biogeochemical processes, including the speciation and mineralogy of the uranium present during the DU metal breakdown.

In this study 2 soil columns were collected from field sites (Kirkcudbright and Eskmeals) in the UK where DU metal samples had been buried for ≈8 years. The Kirkcudbright soil is organic and clay rich, whereas the Eskmeals soils is a quartz-rich dune sand. Samples of soil up to 50cm from the DU metal were analysed by Sequential Extractions (SE), Sampling Electron Microscopy (SEM), mini-focus X-ray Adsorption Spectroscopy/ X-ray Fluorescence (XAS/XRF), X-ray Diffraction and pore water analysis (ICP-MS). The microbial population in the soil was also characterised using culturing and Biolog techniques.

The SE and XAS data indicate that within the soils the uranium is only present as U(VI). In the Eskmeals site the contaminated soil is dominated by schoepite \((\text{UO}_2)_3\text{O}(\text{OH})_6\cdot6\text{H}_2\text{O}\) coating the quartz grains (fig. 1). In the Kirkcudbright soils mini-focus XAS and XRF analysis indicate the U is more dispersed and associated with ferric oxyhydroxide minerals. The contaminated zone around the corroding metal is relatively small in the Eskmeals soil, with total [U] <10ppm within 10cm of the DU metal. The bacterial community counts from the soil are not affected by the U concentration, but there is a significant decrease in the metabolic diversity within the contaminated zone. The pore water in the contaminated zone also contains high concentrations of oxalic acid indicating a significant biological response.

The distribution pattern study of rare earth elements in Choghart iron ore mine, Bafq area, Iran

M.R. SHAYESTEHFAR1 A. ZARRABI1 AND A. YAZDI2

1Mining Engineering Department, Shahid Bahonar University of Kerman, 76175-133 Kerman, Iran.
2Iranian Central Iron Ore Company, Mining Manager of Sechahun mine, Iran.

From the metallogenic points of view, Iran is divide into several provinces and belts out of which, metallogenic province of Saghand-Golpayegan-Bafq has a special importance. The presence of rare earth elements along with the elements such as Fe, P, U and Ti is known only in this province. Metallogenic province of Saghand-Golpayegan-Bafq is made of the different mines, out of which, the Choghart iron ore mine is one of them. This mine is one of the most important iron ore mines of Iran which could be important due to presence of the REE. The Choghart iron ore mine is situated in central Iran plateau and its geographical coordinate is as: 55°28'02" longitude and 31°42'00" latitude. In order to study the behaviour of REE in Choghart mine, samples from magnetite and apatite have been analysed by NAA. Aquired results show that, as a whole, magnetites from this mine are not much enriched from the REE. All magnetites show less LREE enrichment and only the aquired sample from the borehole with degree of high purity of iron shows more enrichment in LREE. \((\text{La/Lu})_{in}\) ratio shows that the fractionation between LREE and HREE occur nearly in all magnetites but magnetite with degree of high purity of iron shows more extent of fractionation between LREE and HREE in Choghart mine. Also these conclusions show that Choghart mine apatites are enriched from REE in such away that the percent of REE in these apatites is about 1.54%. The great slope of spidergrams and amount of \((\text{La/Lu})_{in}\) ratio show intense fractionation between LREE and HREE, depletion of HREE and enrichment of LREE in these apatites. Therefore apatites from this mine have very high values in order to obtain LREE or Ce group. We come to know that in mineral processing stage of iron ore of Choghart mine, if the apatite concentration with degree of high purity produces, then the extraction of these elements will be considerable.

Keywords: Rare earth elements, magnetite, apatite, Choghart mine, metallogenic province.

Cretaceous-Cenozoic exhumation of Dabashan from apatite fission track thermochronology and its implication for growth of the northeastern Tibetan plateau margin

C.B. SHEN1 AND L.F. MEI2

1Faculty of Earth Resources, China University of Geosciences, Wuhan, China (cugshen@126.com)
2Key Laboratory of Theory and Technology of Petroleum Exploration and Development in Hubei Province, China (lfmei@cug.edu.cn)

As a part of Qinling collisional orogenic belt, Dabashan located at the northeast margin of Sichuan craton basin and closely adjacent to the eastern Tibetan plateau margin, is an ideal region for better understanding the tectonic evolution of Qinling orogeny roundly and stepwise migration of the northeastern Tibetan plateau margin. Apatite fission track dating and time-temperature thermal history modeling were carried to analyze on 10 samples in the Dabashan. The new data yield ages ranging from 73±8 to 33±4 and mean track lengths between 11.4±1.6 to 12.7±1.6. Thermal history models based on the AFT data taken together with published K-Ar data (Zheng et al., 2006) indicate that the cooling and exhumation process of Dabashan can be divided into three stages since Cretaceous. The three stages are identified as (1) a phase of rapid uplifting cooling at 120-110 Ma, (2) following by a period of relative thermal stability during which rocks remained at temperatures with in AFT partial annealing zone (∼60-110°C), (3) ending with a new stage of accelerated uplifting during ∼10Ma to resent. The first rapid uplifting cooling phase has been suggested to reflect the large-scale transtensional deformation of Qinling orogeny belt, which is attributed to the Cretaceous eastward tectonic escape and Pacific backarc extension (Hu et al., 2006). Following the transition phase the subsequent slow cooling phase pattern implies a net reduction in horizontal compressional stress corresponding to increased extension rates along the continental margin due to the decrease in plate convergencce. The last accelerated uplifting event is response to eastward growth of Tibetan plateau uplift and lateral growth, which continues today. Numerous studies of Tibetan Plateau suggest that the onset of deformation in eastern and northern margin of Tibetan Plateau occurred in the latest Miocene (Tapponnier et al., 2001; Kirby et al., 2002; Zheng et al., 2006; Enkelmann et al., 2006).

Pedogenic origin dolomite developed within calcium concretion of Tertiary red clay at Loess Plateau, China

XF SHENG, J CHEN AND JF JI
Department of Earth Sciences, Nanjing University, Nanjing 210093, China (shenxuer@yahoo.com.cn)

Previous research has shown that the land-origin dolomite was almost deposited at the high salinity environments. Only a few researches reported the un-salina origin dolomite was existed in the paleosol of Hawaii for a particular geologic reason and not any data regarding the authigenic dolomite in Chinese Loess has been recorded.

The carbonate concretions are widely existed in Tertiary red clay layers developed at the Xifeng area of Loess Plateau, central China. With application of the XRD and the high-resolution SEM and TEM, lots of dolomite in rhombohedron in company with palygorskite has been detected, distributing along the dissolved interspaces within the calcium concretion. The morphological characters of those minerals indicate they are authigenic origin and come into being during the pedogenic period of the red clay. The former appearance needs enough Mg2+ in environment. In this case, Mg2+ is thought from the condensation of the outcome of the thorough weathering of the carbonate and silicate after the action of the heavy precipitation during the pedogenic period. The latter is widely considered only formed under the extremely dry climate. Electron Microprobe analysis farther testifies that the dolomite is with low Mg concentration and the lower ratio of Mg/Ca. Moreover, the cations such as Mg2+, Sr2+, Na+ etc. in dolomites at the different carbonate concretions are in a wide range, indicating the dolomites don’t come into being in the unitary soil solution, but at the dividable micro-environments with different salinity.

It can be concluded that, when the red clay come into being, the climatic condition was characterized as the alternation of heavy precipitation-high temperature and dry-high temperature. The result has also provided an example to explain the cause of formation of dolomite in terrigenous fresh-water environment.

This work was funded by the NSF of China through Grant 40503010.

Surface complexation of Uranium(VI) on Fe/Mn (hydr)oxides

DAVID M. SHERMAN1, CAROLINE L. PEACOCK1,2 AND CHRIS G. HUBBARD1

1Department of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (dave.sherman@bris.ac.uk)
2Present Address: School of Ocean and Earth Science, University of Southampton, Southampton SO14 3ZH, UK

The fate and mobility of U in oxic soils, groundwater and the marine environment is controlled by sorption of UO$_2^{++}$ onto nanocrystalline iron and manganese (hydr)oxides. Thermodynamic models for such reactions are needed before we can understand the aqueous geochmistry of U. However, we cannot develop useful thermodynamic models until we have a molecular-level understanding of U sorption and complexation. Previous EXAFS studies of UO$_2^{++}$ sorption on FeOOH have been interpreted as indicating an inner-sphere >Fe(OH)$_2$UO$_2$ surface complex formed by edge sharing with FeO$_6$ polyhedra (2E complex). However, this complex is at odds with the known surface site densities of FeOOH phases. On goethite, for example, 2E complexes can only occur on the {210} and {010} planes (space group setting Pnma) which comprise only a small fraction of the surface area. Here, we show that previous EXAFS spectra have been misinterpreted owing to the neglect or incomplete inclusion of multiple scattering. The dominant UO$_2^{++}$ surface complex on FeOOH is >Fe(OH)$_2$UO$_2$(H$_2$O,OH)$_3$ and >Fe(OH)$_2$UO$_2$CO$_3$ (2C complex) resulting from bidentate corner-sharing with two adjacent FeO$_6$ surface polyhedra. Ab initio calculations of U-O and U-Fe distances in the 2C complexes are consistent with the EXAFS results. On goethite, 2C complexes can form on the {101} planes which comprise nearly all of the reactive surface area; the 2C complex explains the high sorption capacity (>2 wt%) for U(VI) on goethite and, apparently, ferricydrite.

We developed a surface complexation model to fit a series of sorption experiments of U on goethite and ferricydrite. Using a 1pK formalism and Basic Stern model for electrostatics, we found we could fit our data using >Fe(OH)$_2$UO$_2$(OH) and >Fe(OH)$_2$UO$_2$CO$_3$ (2C complexes) consistent with EXAFS results. An analogous model for U sorption onto hexagonal birnessite was developed using the >MnO$_2$UO$_2$OH and >MnO$_2$UO$_2$CO$_3$ complexes assuming that UO$_2^{++}$ complexes over vacancies in the phyllosilicate layer. Implications of our models for the fate of U(VI) in soils and aquatic environments will be discussed.

The Os isotope heterogeneities in the mantle sequence of the Bangong Lake ophiolite, northwestern Tibet

R.D. SHI, X.C. ZHI, B.H. DING AND L. CHEN

CAS Key Lab. of C-M Materials and Environments, School of Earth and Space Sciences, USTC, Hefei 230206, China

Two type harzburgites occur in mantle sequence of the Bangong Lake ophiolite, NW Tibet. Type I is Cpx-bearing harzburgite with Cr$^2$ = 20–25 of spinel reflecting 10–15% degrees of partial melting; Type II is Cpx-free harzburgite with Cr$^2$ = 69–73 of spinel representing 35–40% degrees of partial melting formed in the suprasubduction zone (SSZ) [1]. In Type I, the $^{187}$Os/$^{188}$Os ratios (0.12446 to 0.12853) are chondritic and the $^{187}$Re/$^{188}$Os ratios (0.44 to 1.77) are suprachondritic reflecting that Re gain recently by basaltic melt percolating during the formation of the Bangong Lake crust 167 Ma ago [2], while in Type II, part of $^{187}$Os/$^{188}$Os ratios (0.12166 to 0.12896) are subchondritic, this can be explained by Re depletion during ancient partial melting. The old Os isotope model age (>950 Ma) of one Cpx-free harzburgite in a young ophiolitic mantle show that ancient Os isotopic heterogeneities can survive in the Earth upper mantle.

Osmium concentrations tend to decrease from Type I (Cpx-bearing harzburgites, 5.25-5.45ppb) to Type II (Cpx-free harzburgites, 4.4-4.45ppb, one sample is 1.32ppb) indicating that Os does not behave compatibly during melt percolation as it is observed during partial melting, but becomes dissolved and mobilized by the percolating melt [3]. But the heavy serpentinization likely caused the Os loss by the sulphide decomposition in a SSZ environment with high fO$_2$.

This study shows that Type I and II harzburgites of the Bangong Lake ophiolitic mantle have complex and different evolution. However, the Os isotopic features are consistent with a model where the two type harzburgites belong to the same melting regime producing the Bangong Lake oceanic crust. This scenario is also observed early in Troodos ophiolite [3].

Genesis of tholeiitic and calcalkaline series of Zao volcano, NE Japan arc, Japan

T. SHIBATA1, Y. TATSUMI2 AND A. SAKAYORI3

1Beppu Geothermal Research Laboratory, IGS, GRL, Kyoto University, Japan (tomo@bep.vgs.kyoto-u.ac.jp)
2Institute for Frontier Research on Earth Evolution, JAMSTEC, Japan (tatsumi@jamstec.go.jp)
3The Graduate School of Education, Kanazawa University, Japan (sakayori@ed.kanazawa-u.ac.jp)

Genesis of co-existing tholeiitic series (TH) and calcalkaline series (CA) in island arc and their relationship has been a focus of attention because it is critical to understanding magma genesis in island arc. The Zao is Quaternary volcano situated on the Tohoku Backbone Ranges, Northeastern Japan arc, and both of TH and CA co-exist in continuous volcanic activity (Sakayori, 1991). We investigated the Sr, Nd, Pb isotope and trace element compositions to discuss the genesis of TH and CA from Zao volcano.

The trace element compositions of the studied samples show the typical characteristics of island arc magma in the diagram of MORB normalized pattern, such as enrichment of LILEs and negative Nb spike. Positive Pb and Sr spikes are also apparent. The LILEs enrichment and negative spikes of Nb are relatively larger in CA than TH. Although abundance ratios of Cs/Nb of TH are restricted to 0.09 - 0.20, those of CA can be divided into two ranges, such as 0.20 – 0.25 and 0.42 – 0.57.

The isotopic compositions of TH are more enriched compared to CA. In all the diagrams presenting the relationship of the isotope compositions, TH and CA make different linear trends, which indicate the mixing relation. Furthermore, Pb isotopic compositions suggest that two depleted endmember is necessary to explain the trend of TH and CA. The depleted endmember of TH is relatively enriched than that of CA. On the other hand, tow enriched endmembers are required from the relationships between parent/daughter and the isotope ratios, because TH and CA show different linear trends in these relation and the linear trends are diverse in the direction of isotopically enriched side. The both of the enriched direction of TH and CA is differ from the mixing trend of mantle wedge and recycled materials form subducting slab observed from Northeastern Japan (Shibata and Nakamura, 1997). From the observations in the above, it can be concluded that four components are necessary to explain the chemical characteristics of TH and CA from Zao volcano and the different two enriched components are derived from different crustal materials, although the sources of those are not obvious yet.

Anthropogenic contamination of bivalves revealed by Cd isotopes

ALYSSA E. SHIEL1, KRISTIN J. ORIANS1, DANIEL COSSA AND DOMINIQUE WEIS1

1PCIGR, Earth and Ocean Sciences, Univ. of British Columbia, 6339 Stores Rd, Vancouver, BC V6T 1Z4, Canada; (ashiel@eos.ubc.ca)
2IFREMER, Centre de Nantes, BP 21105, F 44311 Nantes Cedex 03, France

We are studying Cd isotopic compositions in bivalves to assess their natural and anthropogenic variability and sources. Oysters (Crassostrea gigas) from BC were collected from Desolation Sound (BC coast) and Barkley Sound (west coast of Vancouver Island). For comparison, we analyzed bivalves collected off the coasts of France, oysters (C. gigas) from the Gironde estuary and northern Brittany and mussels (Mytilus galloprovincialis) from the Gulf of Lion.

Cd isotopes were measured by dynamic multi-collection using a Nu Plasma MC-ICPMS and sample-standard bracketing technique together with external normalization to correct for instrumental mass bias. Results are reported in del notation (δ), normalized to a mass difference of one atomic mass unit. Our reference Cd standard (High Purity Standards, Inc., lot 291012) has the same Cd isotopic signature as JMC Cd [1,2]. Reproducibility is estimated from repeat analysis of a secondary Cd standard (High Purity Standards, Inc., lot 502624), 0.37 ± 0.03 permil/amu (2SD; n=31).

BC oysters have Cd isotopic signatures consistent with those reported for seawater from the N Pacific [3,4] suggesting that the high Cd concentrations (4.8-15.8 ppm tissue dw) found in bivalves along this coast result from natural coastal upwelling. Oysters from the BC coast have a slightly lighter signature than those from the west coast of Vancouver Island, potentially resulting from a larger anthropogenic contribution consistent with this geographical location. Mediterranean mussels have Cd isotopic signatures within the range of NW Mediterranean seawater values [3]. Oysters from northern Brittany and the Gironde estuary have signatures significantly lighter than the literature value for the Atlantic [4]. The Gironde oysters have the lightest signatures consistent with pollution resulting from industrial evaporation-condensation processes, as documented by the shift to δ = –0.16 permil/amu for two dust samples from a Pb-Zn refinery plant in northern France [2]. These results demonstrate the ability of Cd isotopes to trace anthropogenic pollution.

**Geochemical variation and residence time of groundwater in Mt. Fuji area, central Japan**

NAOTATSU SHIKAZONO
3-14-1, Hiyoshi, Kohoku-ku, Yokohama 223-8522 Japan
(sikazono@applc.keio.ac.jp)

Many groundwater samples were collected from Mt. Fuji area, central Japan which is totally composed of basaltic materials. The samples were analyzed for Na\(^+\), K\(^+\), Ca\(^{2+}\), Mg\(^{2+}\), Si, Al\(^{3+}\), Fe\(^{2+}\), Fe\(^{3+}\), TC (total dissolved carbon), Cl\(^-\), NO\(_3^-\), SO\(_4^{2-}\) and TP (total phosphorus). Analytical data plotted against altitude indicate that alkali and alkali earth element (Na\(^+\), K\(^+\), Ca\(^{2+}\), Mg\(^{2+}\), Ca\(^{2+}\)) and Si concentrations increase with decreasing altitude, indicating that the dissolution of silicates in basaltic materials control the trends. Ca and Mg concentrations positively correlate with each other and the correlation coefficient is 1.64. This is consistent with CaO/MgO molal ratio of basalt which is 1.47. Therefore, it is inferred that Ca and Mg in groundwater were derived mainly from the congruent dissolution of basalt. Ca/Si concentration ratio determined by the dissolution reactions of basalt accompanied by the precipitation of allophane is 0.29 which is lower than 0.48 estimated from the analytical data on groundwater. This lower value could be due to the precipitation of silica mineral (SiO\(_2\)). The agreement between theoretical and analytical results indicate that Ca, Mg and Si concentrations of groundwater are governed by dissolution and precipitation reactions. In order to interpret groundwater chemistry and estimate residence time of groundwater in southeastern part of Mt. Fuji area (Kakitagawa site) was estimated to be several years to 30 years. This estimated residence time is consistent with isotope data (herium isotope and tritium concentration).

**CO\(_2\)-water-basalt interactions: Experimental and mineralogical study**

S.N. SHILOBREEVA\(^1\) AND I. MARTINEZ\(^2\)

\(^1\)Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia (shilobre@mail.ru)
\(^2\)IPGP, Laboratoire de Géochimie des Isotopes Stables, 4 place Jussieu, Paris, France (martinez@ipgp.jussieu.fr)

**Introduction**

Development of a better understanding of fluid-rock interaction is important in many areas of applied science and basic research. Investigation of reaction of basalt with H\(_2\)O and CO\(_2\) at different P-T-fO\(_2\) conditions is important both for planetary processes including processes in subduction zones of the Earth and mineral storage of CO\(_2\) including the problem of reducing the anthropogenic CO\(_2\) emission into the atmosphere. We have carried out experimental, mineralogical and carbon stable isotope study of this reaction.

**Experimental Method**

Carbonation experiments were run by exposing natural basalt powders (100-200\(\mu\)m grain size) to CO\(_2\) and H\(_2\)O under various conditions in a hydraulic press (total pressure 1 kbar and 400-500\(^\circ\)C). Oxalic acid (H\(_2\)C\(_2\)O\(_4\)) was used as a source of CO\(_2\) and H\(_2\)O. Additional amounts of H\(_2\)O were added in the platinum capsules. The thus produced CO\(_2\) and H\(_2\)O were then reacted with the basalt powder at high pressure and temperature. Gas phase and solid products of experiments were analyzed by manometry, step heating and mass-spectrometry techniques. Mineralogical study of the products of experiments by Scanning Electron Microscopy allowed the identification and observation of carbonates and water-bearing minerals.

**Discussion and Conclusions**

Our experimental results document the effect of the H\(_2\)O-CO\(_2\) medium on basalts under these P-T conditions and that calcite forms during the carbonation of plagioclase. We observed that carbonation reaction in basic rocks is different from that in ultrabasic rocks. Pressure, temperature and molar fractions of H\(_2\)O and CO\(_2\) are important parameters whose influences were quantified. Measured \(\delta\)\(^{13}\) C of gas and solid phase allowed to discuss kinetic and thermodynamic factors of carbon isotope fractionation in such reactions and are discussed in terms of mass balance.
A study on the formation mechanism of Temagami Iron-Formations, Canada

Y. SHIMADA¹, A. YASUMATSU¹, Y. MOTOMURA¹, R. OKAZAKI¹, T. NAKAMURA¹, H. OHMOTO², Y. OKAUE¹ and T. YOKOYAMA¹

²Penn State University

In order to elucidate systematically the formation mechanism of BIF (Banded Iron-Formations), a BIF sample collected at Temagami, Canada was characterized by optical microscope, EPMA, Xray microscope, SIMS, and chemical analysis. This BIF can be divided into three layers visually; black layer, white layer, red layer. Main minerals in the three layers were magnetite, dolomite and quartz with fine hematite particles respectively.

To estimate the formation temperature of each three mineral and the formation environment (especially oxidation-reduction conditions), the oxygen isotope ratios (¹⁸O/¹⁶O) and contents of rare earth elements were measured by SIMS and chemical analysis. The isotope equilibrium temperature of dolomite and magnetite located in the white layer were 250-350°C. In the rare earth elements patterns for all the layers, a positive Eu anomaly appeared suggesting contribution of the anoxic submarine hydrothermal fluid for the formation of the BIF. On the other hand, a negative Ce anomaly, which indicates a character of oxic sea water, was observed for a part of samples of the red layer. These dolomite and magnetite may be formed under reduction conditions at high temperature, that is, from mixed water of the large amount of anoxic hydrothermal water of 250-350°C and the small amount of oxic sea water. While magnetite and dolomite located in the black layer shows lower formation temperature of 100 °C than that of magnetite and dolomite in the white layer. The latter magnetite and dolomite may be formed from hydrothermal water with high mixing percentage of seawater.

As mentioned above, each mineral in the layers might be precipitate from the fluids formed by mixing of large amount of anoxic submarine hydrothermal fluid with high temperature and small amount of oxic seawater with low temperature. The mixing degree may be different among minerals in the BIF.

High-grade Ag-Cu-Sn-In mineralization in the Nishizawa-Ashio area, Tochigi Prefecture, central Japan

MASAAKI SHIMIZU¹, SATOSHI MATSUBARA², MARINA SHIMIZU¹, YOSHINORI KYOUNO³, AKIRA HARADA⁴ AND NIGEL J. COOK⁵

¹Department of Earth Sciences, University of Toyama, Japan (mshimizu@sci.u-toyama.ac.jp)
²Department of Geology and Paleontology, National Museum of Nature and Science
³Omochanomachi Branch, Ashikaga Bank, Japan
⁴D. O. C. Consultant, Japan
⁵Natural History Museum, University of Oslo, Norway

Mineral Identification and Observation

Polymetallic (Au-Ag-Cu-Pb-Zn-Fe-As-Sb-Bi-Sn-In-W) vein-type mineralization in the Nishizawa-Ashio area occurs in strongly altered late Neogene felsic volcanic rocks. Recently Ishihara (2006) and Ishihara et al. (2006) reported that indium had been exploited in ore concentrates (e.g., 1200 tons In at Ashio). At Nishizawa, roquesite and “sakuraiite” (CuZnInS₄) were identified as discrete In minerals, associated with Pb,Se-bearing matildite, electrum (Au:Au ≒ 5:5–7:3), chalcopyrite, sphalerite (1-2% FeS), cassiterite and quartz. Canfieldite-argyrodite, Se-bearing acanthite, proustite-pyrrargyrite, Ag-bearing tetrahedrite-freibergite (Cu:Au=5.4:6-4.2:5.7), smithite and ferbeite (Fe:Mn=9:1) are also observed. Roquesite frequently occurs as radiating prismatic crystals (up to 0.5 mm), and sometimes as intergrowths with “sakuraiite”.

Conclusions

In-bearing sphalerite as solid solution between sphalerite and roquesite has been previously reported (e.g., Burke and Kieft, 1980). The roquesite-“sakuraiite” intergrowths at Nishizawa reveal no solid solution between roquesite and sakuraiite, and instead imply that In-bearing sphalerite represents solid solution between sphalerite and incompletely defined “sakuraiite” (with petruke as an intermediate phase?).

Geochemical study on Bousei, Hotta and Smetanin Seamounts near the Japan Trench in Northwestern Pacific Ocean

G. SHIMODA1, O. ISHIZUKA1, K. YAMASHITA2,3, M. YOSHTAKE3, M. OGASAWARA3 and M. YUASA1

1Geological Survey of Japan, AIST, Tsukuba, Japan (h-shimoda@aist.go.jp, o-ishizuka@aist.go.jp, masa.ogasawara@aist.go.jp, yuasa-m@aist.go.jp)

3Department of Earth and Planetary Sciences Kobe University, Kobe, Japan (miwa@kobe-u.ac.jp)

The Northwestern Pacific plate is characterized by existence of a large number of seamounts (Koppers et al., 1998). It is widely accepted that these seamounts were produced by extensive magmatic activity during the Cretaceous in the South Pacific that is considered to be one of the largest volcanic events in Earth’s history. As this magmatism would represent large-scale mantle upwelling, the magmatism could provide a key constraint to understand chemical evolution of the Earth. Due to this importance, many researches have been conducted on the south Pacific islands, and thus present-day magmatism in the South Pacific is well constrained. In contrast, little constraint has been given to the past volcanic activity in this region.

It has been reported that there are two peaks in the volcanic activity in the South Pacific during the Cretaceous (after Winterer, 1976). As the volcanic peaks should be essential to understand the large mantle up-welling, an investigation on the volcanism during the Cretaceous should be important. The Cretaceous age seamounts near the Japan Trench (e.g., Takagi et al., 1989) are thus suitable examples to study the magmatism in the South Pacific. For the evaluation of the origin of these seamounts, we collected samples from these seamounts during Geological Survey of Japan Daini-Hakureimaru cruise. Drilling and dredging were conducted at 12 sites and fresh samples, alkali basalts and andesites, were recovered from three Seamounts; Bousei, Hotta and Smetanin Seamounts. The phenocrysts are mainly plagioclase and pyroxene with/without hornblende. The geochemical character of the rocks from the Bosei and Hotta are HIMU-type. In contrast, those from the Smetanin show less HIMU signature. In this presentation, we will discuss the origin of Seamounts along Japan Trench and constrain the volcanic activity in the South Pacific.

The influence of Philippine Sea Plate on the composition of mantle beneath Kyusyu, SW Japan arc: Along-arc variation of B data

M. SHIMONO1 M. MIYOSHI1 T. FUKUOKA2 T. SANO3 AND T. HASENAKA1

1Graduate School of Science and Technology, Kumamoto University, Japan (shimono@es.sci.kumamoto-u.ac.jp, miyoshim@es.sci.kumamoto-u.ac.jp, hasenaka@sci.kumamoto-u.ac.jp)
2Department of Environmental Systems, Rissho University, Japan (tfukuoka@ris.ac.jp)
3National Science Museum, Tokyo, Japan (sano@kahaku.go.jp)

Volcanism in Kyusyu island is associated with subduction of Philippine Sea Plate (PSP) under Eurasian plate. Kyusyu-Palau Ridge, which subducts nearly at right angles to central part of Kyusyu, marks the boundary between young (15-26 Ma) PSP in the north and old (37-115 Ma) PSP in the south. Thus volcanic rocks from Kyusyu are good samples to test the compositional difference resulting from the subduction of oceanic plates with different ages.

We studied the difference in subduction component using boron element, As boron is enriched in altered oceanic crust and ocean sediment, it is one of the best indicators to show the contribution of fluid phase coming from the subducting plate to the mantle beneath volcanic arc. The release of the fluid phase from the oceanic plate is believed to occur in two manners. One is by aqueous fluid at high temperature, and the other is by the dehydration process, i.e. the breakdown of hydrous phases at high pressures. In this case, fluid is continuously released from the plate with increasing pressure, because various phases were involved in producing boron-rich fluid at different pressures.

The ratio of B/Nb was used to see the contribution of the subducting plate. It eliminates the influence of different degrees of partial melting in the mantle and fractional crystallization and crustal contamination in the crust.

The across-arc variation as observed by B/Nb ratios in volcanic rock is almost absent in the northern Kyusyu (NK), whereas it shows a gradual decrease in B/Nb from the volcanic front to the back-arc side in southern Kyusyu (SK). In addition, the B/Nb ratio of rocks from the volcanoes at the volcanic front is relatively high in the SK (~7.5), whereas it is relatively low in the NK (~3.5).

The lack of lateral variation in subduction component in volcanic rocks from the NK indicates a possibility that the release of fluid phase is completed before the oceanic plate reaches the volcanic front. The relatively low number in B/Nb ratio also supports this hypothesis. The young age of oceanic plate suggests a high temperature gradient in the depth profile of the subducting plate. In contrast, the volcanic rocks from the SK show a normal across-arc variation of subduction component typically related with the subduction of relatively old and cold oceanic plate.
Oxygen and sulfur isotope characteristics of the Salmagora Complex, Kola Peninsula

D.B. SHIN¹ AND M.J. LEE²

¹Kongju Nat’l Univ, 314-701, Korea, (shin@kongju.ac.kr)
²KIGAM, Daejeon, 305-350, Korea, (mjlee@kigam.re.kr)

Introduction
Oxygen and sulfur isotope study on the rock of dunite-wehrlite-mellitolite (type 0) from the early stage of magma differentiation and on the rock of pyroxeneite-ijolite (type 1 and type 2) from the later stage, which are classified based on the mineralogical and geochemical characteristics, is performed for the contribution to the petrogenetic model of the Salmagora ultramafic-alkaline-carbonatite complex in the Kola Peninsula.

Experimental Method
25 bulk rock samples were analyzed for oxygen isotope using silicate oxygen preparation line and Finnigan MAT 252 mass spectrometer in Indiana University and splits of the samples used for oxygen isotope were also analyzed for sulfur isotope composition by CF-mass spectrometer.

![Graph showing variations of oxygen isotope compositions of the Salmagora Complex.]

Results and Discussions
In Figure 1, we can observe that oxygen isotope composition systematically increases from type 0, type 1 and to type 2. Especially each rock type of pyroxenite, melteigite, ijolite and urtite in type 2 has higher value than that in type 1 by +0.6 to +2.4‰. Sulfur content was below analytical limit in type 0. The isotope composition varies from -9.3 to -4.8‰ for only melteigite in type 1 and from -4.2 to +1.0‰ in type 2. The increases in oxygen isotope composition from type 0 to type 1 can be explained by common magmatic differentiation process [1] with the influence of crustal contamination, while type 2 seems to indicate another highly evolved magma. Similarly, the low sulfur isotope values in type 1 may also be the effect of crustal contamination and the higher values of type 2 indicates the effect of more evolved magma.

Inorganic arsenic speciation in contaminated soils, in Korea

MIYOUNG SHIN, HYEON YOON, MISUN PARK AND CHEOLHO YOON

Korea Basic Science Institute, Seoul center,
(dunee@kbsi.re.kr)

Materials and method
The selected site for this study is an area of arsenic contaminated region (abondoned mine) and near land. Total arsenic concentration in soil samples and reference materials were as follows. 0.1g of sample was accurately weighed into acid washed digestion vessels containing 9ml of HCl and 3ml of HNO₃, and the resultant solution was heated at 140°C for 1hr in a digestion block. The solutions were allowed to cool and then diluted to 100ml with deionized water. The extraction of the arsenic species for speciation analysis were as follows. 0.1g of soil sample and 15ml of extractant (1M of phosphoric acid + 0.1 M of ascorbic acid) were reacted in a microwave system (Milestone 1200 Mega, power 60W, 15min). This solution is then cooled at room temperature and centrifuged at 2500 rpm for 30min. Total arsenic and arsenic speciation of the supernatant solution was analyzed by ICP-AES and SPE-HG-ICP-AES respectively.

Result and discussion
Total arsenic concentration in samples were measured between 109.97 and 11758.31ppm. In all samples, the majority of arsenic was present as AsV, while AsIII only account for < 3% of the total arsenic. The extraction efficiency, relative to the total arsenic concentration, varied from 25 – 108%. Most of the samples - except to one samples – showed recovery efficiency of above 86%. Only one samples exist both AsIII and AsV and recovery efficiency is not good (respectively 3.18% (AsIII) and 22.18% (AsV)). This sample is tailing which is mostly composed of calcite mineral. Concentration of the Ca is about 24%. AsIII of the tailing sample is presumed to be adsorbed on the calcite surfaces.

Minor and trace element geochemistry of a branching coral *Acropora sp.* skeleton

K. SHIRAI1, N. TAKAHATA2, H. AMAKAWA2, T. WATANABE3, T. KAWASHIMA3, K. SOWA3, Y. SANO2

1HADEEP, Ocean Research Institute, the University of Tokyo (kshirai@ori.u-tokyo.ac.jp)
2Center for Advanced Marine Research, Ocean Research Institute, the University of Tokyo
3Dept. Natural History Sciences, Graduate School of Science, Hokkaido University

Incorporations of chemical elements and isotopes, into coral skeletons are influenced by ambient water conditions which may provide important information on past climate in the tropics. The geochemistry of *Acropora* is significantly important for the past-temperature reconstruction because *Acropora* is one of the main genera constituting the coral reefs. *Acropora* may also provide unique opportunity to evaluate the effects of physiological processes on the elemental incorporation. Branching coral *Acropora* consists of fast-growing axial corallite and slowly growing radial corallite at the visible scale. On the other hand, at the micro-scale, there are several types of skeletal elements precipitated under different biological mechanisms. However, geochemistry of branching corals has not been well understood. To investigate the mechanisms of elemental incorporation into *Acropora* skeletons, chemical and isotopic compositions in the skeleton were analyzed at various spatial resolutions.

The chemical profiles of both axial and radial corallite along with growth axes were measured by conventional ICP-MS and Stable Isotope Mass Spectrometry. The tip and basal parts of *Acropora* skeletons were also analyzed at micro-scale. The Mg/Ca, Sr/Ca, Ba/Ca, and U/Ca ratios were measured in ~5μm diameter spots by using NanoSIMS, and Mg, Sr, Ca, and S distributions were analyzed by Electron Probe Micro Analyzer (EPMA), with a spatial resolution of ~2μm.

Based on the elemental distribution obtained by EPMA, we found that the *Acropora*’s skeleton is composed of more than three types of the skeletal elements, “Framework”, “Infilling” and “High-Mg Low-S” skeletons. Observation of skeletal structure revealed that the skeletal porosity decreased with distance from the tip, because “Infilling” skeletons possibly filled the space between “Framework” skeletons. Micro-scale elemental analyses (EPMA and NanoSIMS) revealed that “Infilling” skeletons have lower Mg/Ca and higher Sr/Ca and U/Ca than “Framework” skeletons. Since the “Infilling” skeletons were probably formed under the slower calcification rate than “Framework” skeletons, the elemental fractionation pattern between two skeletal elements is consistent with the model of elemental incorporations dependent on calcification rate. The chemical profiles of axial corallite along with the growth were significantly affected by the proportions of “Infilling” skeletons.

Mantle and crustal processes in the Hadean and Archean: Evidence for the onset of subduction at 3.8 Ga

STEVEN B. SHIREY1, BALZ S. KAMBER2, MARTIN J. WHITEHOUSE2, PAUL A. MUELLER4 AND ASISH R. BASU7

5Earth and Environmental Sciences, University of Rochester, Rochester NY 14627; abasu@earth.rochester.edu

Considerable geochemical evidence supports initiation of plate tectonics on Earth shortly after the end of the Hadean. The present upper mantle retains old heterogeneities, some of which likely derive from subduction in the early Eoarchean. Nb/Th and Th/U ratios of mafic-ultramafic rocks from the depleted upper mantle begin to change from 7 to 18.2 and 4.7 to 2.9 (respectively) at 3.6 Ga. This signals the appearance of subduction-altered slabs in general mantle circulation from subduction initiated at 3.8 Ga. Juvenile crustal rocks begin to show derivation from progressively depleted mantle with typical igneous ε Nd: ε Hf = 1.2 after 3.6 Ga. Cratons with stable mantle keels that have subduction imprints begin to appear at 3.5 Ga. These changes all suggest that extraction of continental crust by plate tectonic processes was progressively depleting the mantle from 3.6 Ga onwards. Neoarchean subduction appears largely analogous to present subduction except for the production of large cratons with thick mantle keels. The earliest Eoarchean juvenile rocks and Hadean zircons have compositions that reflect the integrated effects of separation of an early enriched reservoir and fractionation of perovskite from the Mars-sized, impact-derived magma ocean, rather than separation of voluminous continental crust or oceanic plate tectonics. Hadean zircons most likely were derived from a continent-absent, initially mafic to ultramafic protocrust that was multiply remelted between 4.4 and 4.0 Ga under wet conditions to produce more evolved (felsic) rocks. If the protocrust was produced by global mantle overturn at ca 4.4 Ga, then the transition to plate tectonics resulted from radioactive decay-driven mantle heating. Otherwise, such protocrust would have been the typical product of mantle convection and the transition to plate tectonics resulted from cooling and stabilization of lithospheric plates.
The influence of neutron irradiation and thermal annealing on helium diffusivity in apatite

DAVID L. SHUSTER1 AND KENNETH A. FARLEY2
1Berkeley Geochronology Center, 2455 Ridge Rd. Berkeley, CA 94707 USA, (dshuster@bgc.org)
2Division of Geological and Planetary Sciences, Caltech, Pasadena, CA 91125 USA, (farley@gps.caltech.edu)

Accurate extrapolation of helium diffusivity over temperature and time is essential for quantifying long term erosion rates and the topographic evolution of Cenozoic orogens using (U-Th)/He thermochronometry. Naturally occurring radiation damage was recently shown to influence helium diffusion in apatite, such that the kinetics is controlled by the parent nuclide concentrations as an evolving function of time [1]. This implies that apatite helium ages are sensitive to lower temperatures and shallower depths than indicated by the diffusion kinetics presently observed in a given mineral. Here, we present results of controlled experiments to quantify the effects of (a) synthetic irradiation and (b) thermal annealing on helium diffusion kinetics in both synthetic and natural apatites. Exposure to a 1 MeV equivalent neutron fluence ($\Phi_{eq}$ [MeV, Si]) of $2\times10^{18}$ n/cm$^2$ (90 hours in the cadmium lined in-core irradiation tube, CLICIT, facility of the Oregon State University TRIGA reactor) caused the helium closure temperatures ($T_c$; 10 °C/My) to increase by up to $+27$ °C. The $\Delta T_c$ negatively correlates with the initial $T_c$, where apatites with higher initial $T_c$ were less perturbed by the neutron irradiation than samples with lower initial $T_c$. Conversely, simply heating natural apatites to 550°C for 1 hour caused $T_c$ in all cases to decrease to $47\pm7$ °C regardless of the initial $T_c$ (the maximum observed $\Delta T_c$ = -44 °C). The resulting $T_c$ agrees well with diffusion parameters constrained [1] for radiation damage-free apatite, $T_c$ = 52 °C.

These results clearly demonstrate that exposure to radiation causes the retentivity of helium in apatite to increase, whereas exposure to temperatures at which thermal annealing occurs causes the retentivity to decrease. The experiments suggest that after 1 hr at 550°C, effectively all natural radiation damage was annealed in each sample to yield a common $T_c$. This closure temperature ($\sim47$ °C) would correspond to the diffusion kinetics in the damage-free apatite structure. From radiation damage theory we estimate the damage caused by the 90 hr neutron irradiation to be roughly equal to the alpha recoil damage corresponding to [4He] $\sim10^{-8}$ mol/g, or roughly the present 4He concentration of Durango apatite. This implies that Durango apatite should presently have $T_c$ $\sim27$°C above the completely annealed state, or $\sim74$°C, which is in excellent agreement with observations. This study highlights a need to quantify the kinetic effects of damage accumulation and annealing on helium diffusion in minerals used for (U-Th)/He thermochronometry.

Geochemistry of Late Cretaceous tholeiitic volcanism and oceanic island arc affinities of the Chagai arc

REHANUL HAQ SIDDQUI1, MUHAMMAD ASIF KHAN2 AND MUHAMMAD QASIM JAN3
1Geoscience Laboratory, Geological Survey of Pakistan, Shahzad Town, Islamabad Pakistan, (rehanhs1@hotmail.com)
2National Centre of Excellence in Geology University of Peshawar, Pakistan,
3Quaid-e-Azam University Islamabad, Pakistan

The major part of the Chagai arc occur in the western-north part of Pakistan and a small part of it also extends towards north in Afghanistan and west in Iran. The Late Cretaceous volcanic rocks which are designated as Sinjrani Volcanic Group, is the most wide spread and the oldest unite of the Chagai arc. This volcanic Group is mainly composed of basaltic to andesitic lava flow and volcaniclastics including agglomerate.

The petrological studies of various lava flow revealed that these are mainly basaltic-andesites (53.27-55.93 wt.% SiO$_2$) with minor basalts (49.57-52.14 wt.% SiO$_2$) and andesites (59.12-59.88 wt.% SiO$_2$). Petrochemical studies based on major and trace elements suggest that these are medium to low K tholeiites. The trace element show variable enrichment in LILE and depletion in HFSE relative to N-MORB. Their primordial mantle-normalized trace element patterns show marked negative Nb anomalies with positive spikes generally on K, Ba and Sr which strongly confirm their island arc signatures. The chondrite normalized REE patterns shows minor but variable enrichment of LREE and positive Eu anomalies. The Zr/Y versus Zr, and Cr versus Y studies, lowers Mg # and lower abundances of Ni and Co suggest that the parent magma of these rock suites was generated by about 15-30 % melting of depleted sub-arc mantle source, and fractionated in an upper level magma chamber en-route to eruption. These volcanics exhibit lower $^{87}$Sr/$^{86}$Sr ratios (0.7038-0.7049), which are consistent with a depleted mantle source and closely correlate with oceanic island arcs rather than continental margin type arcs. On the basis of these studies it is concluded that the Chagai arc was initially developed as an oceanic island arc which was formed due to the intra-oceanic convergence in the Ceno-Tethys during the Late Cretaceous rather than constructed on the southern continental margin of Afghan block, as previously claimed by several workers.
The age of the Danube fault, 40 years after W. Schreyer

W. Siebel1, H.P. Hann1, Ch. Bertold1, C.K. Shang1, J. Rohrmüller2 and K. Wemmer3

1Universität Tübingen (wolfgang.siebel@uni-tuebingen.de)
2LfU, Martredwitz (johann.rohrmueller@glia.bayern.de)
3Universität Göttingen (kwemmer@gwdg.de)

As a result of his PhD study, Werner Schreyer published several papers about petrographic work in the Bavarian Forest where he investigated Variscan basement rocks close to the Danube valley. He also addressed the age of the Danube fault based on his observation from Natternberg, geological map sheet Deggendorf, and finally (in 1967) concluded that the Danube fault was formed during late-Variscan times and not, as suggested earlier (1961), during the Tertiary period.

The Danube fault stretches for about 200 km and is one of the most impressive fault lines in central Europe. As revealed by our recent field mapping, ancient motion along this fault has produced intensive cataclastic deformation along the Donaustauf segment of the fracture zone. The strain localised in this zone resulted in pervasive brittle deformation of the primary rock type, K-feldspar dominated granite. The cataclastic material was ultimately subjected to argillic alteration and K-feldspar was almost completely transferred into illite and other phyllosilicates. The crystallization age of the granite (known as “Kristallgranit”) derived from an unaltered sample is 325 Ma (Pb-evaporation method) whereas the age of argillic alteration is constrained by K-Ar dating of illite fine-fractions (<2 µm) at 266 and 255 Ma. The new ages bracket the time of deformation and imply near surface exhumation of the fault rocks already during the Permian period, confirming Werner Schreyer’s conclusion from 1967. Post-Cretaceous movement along the Danube fault, as indicated by offset of Mesozoic and Tertiary strata, did not re-open the K-Ar illite system. The illite ages also suggest that hydrothermal fluorite mineralization, genetically connected with the Danube fault, was an early Permian process.

Peat deposits from Central Europe to the East European Plains investigated by uranium-series dating

M. Sierralta and M. Frechen
Leibniz Institute for Applied Geosciences, GGA-Institut, Stilleweg 2, 30655 Hannover, Germany, (m.sierralta@gga-hannover.de)

Interstadial and interglacial peat deposits are widespread in a transection between Central Europe, Lithuania, Russia, and Siberia, and enable us to reconstruct the vegetation history of the Northern Hemisphere. Multidisciplinary studies including lithostratigraphy, palaeontology, and palynology were performed by partners all over the transect. The reliable chronological frame for the reconstruction of climate and vegetation history was investigated by uranium series dating. The suitability of the peat layers for dating strongly depends on two essential prerequisites: (1) during the initial formation process any thorium was absent and (2) a geochemically closed system behaviour excluding uranium and thorium migration after deposition. However, peat may contain varying amount of admixed thorium by dust and clay minerals, while water passing through the peat layer can cause migration of uranium. Therefore, dating has to be carefully checked for the fulfilments of the prerequisites. Uranium series dating was performed on peat and organogenic deposits applying the thermal ionisation mass spectrometry (TIMS). Coeval peat samples were burned to ash and prepared by the leachate/leachate technique, spiked, and chemically separated for measurements of the isotopic composition. Once isotope activities are determined, age calculation depends on the evaluation techniques used to obtain reliable ages. The evaluation procedure includes (1) estimation of the thorium index by the isochron method to (2) correct the activity ratios for admixed detrital thorium, (3) calculation of corrected single 230Th/U ages, (4) checking corrected ages with the Chi-square test, and (5) calculation of weighted mean of isochron derived detritally corrected age for the deposit. The study of a variety of sections of burial peat on the transect gave a widespread overview on the suitability of peat deposits. Several case studies were investigated by uranium series dating. At the Netiesos section located in Lithuania, the age determination for the peat failed owing to the impossibility of determining an isochron to correct the single ages for the admixed detrital thorium. Furthermore, the investigation of the peat section of Gröbern, Germany, failed due to wide spreading activity ratios clearly demonstrating open system behaviour. Comparisons with radiometrically investigated uranium series ages retrieve the possible reasons. An isochron derived detritally corrected age of 219 ±8 ka was successfully determined for the peat layer from Krivosheino in Siberia, which is in excellent agreement with independent age control.

210Pb-226Ra disequilibrium in basalts from Surtsey Island (Iceland) and implications for magma transport time

O. SIGMARSSON

Laboratoire Magmas et Volcans, OPGC-Université Blaise Pascal-CNRS, 5 rue Kessler, 63038 Clermont-Ferrand (France) and Institute of Earth Sciences, University of Iceland, Reykjavik (Iceland). (olgeir@opgc.univ-bp-clermont.fr)

Primitive basalts with radioactive disequilibrium between isotopes of the 238U decay chain may provide constraints on the timescales of mantle melt migration. Few results still exist on the 210Pb-226Ra disequilibria. Due to the short half-live of 210Pb (22.3 years), only basalts significantly younger than 100 years old can be studied for 210Pb-226Ra disequilibria generated in the magma pluming system or the mantle. Most lavas measured so far show either 210Pb-226Ra equilibria or 210Pb-deficit which have been attributed to the degassing of 222Rn in shallow magma chambers. Excess 210Pb has also been observed in a few cases and explained by accumulation of 222Rn that decays to 210Pb. Icelandic tholeiites from the last century are in radioactive equilibrium with (210Pb/226Ra) equal to unity. These basalts are fed from shallow magma chambers having residence time exceeding 100 years. In contrast, primitive alkaline basalts (MgO =7-12 %) from Surtsey island had (210Pb/226Ra) ranging from 0.45 ±0.04 to 0.82 ±0.06 at the time of eruption. These large 210Pb deficits are unlikely to result from shallow magma degassing since no magma chamber existed beneath this volcanic island which was born during the 1963-67 eruption. The 210Pb-226Ra disequilibria increase from the beginning towards the end of the eruption when the most primitive basalts were produced, and decrease systematically with increasing Th content. These same basalts show a negative correlation between Pb and Cu abundances which are inconsistent with exsolution of sulfur rich liquid or crystallisation of sulphides as a fractionation mechanism of 210Pb and 226Ra.

The large deficit of 210Pb in Surtsey lavas were thus most likely generated during mantle partial melting. In such a case, the time of melt transport from the source region to surface is constrained to be significantly shorter than 100 years.

Climate changes and volcanic signals during the Bronze Age: A stalagmite record

Z. SIKLOSY1, A. DEMENY1, T.W. VENNEMANN2, E. HEGNER3, J. KRAMERS4 and SZ. LEEL-OSSY5

1Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Budaorsi út 45, H-1112, Hungary, (demeny@geochem.hu)
2Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland, (Torsten.Vennemann@unil.ch)
3Institute for Mineralogy, Petrology and Geochemistry, University of München, (hegner@min.uni-muenchen.de)
4Institute of Geological Sciences, University of Bern, Switzerland, (kramers@geo.unibe.ch)
5Eotvos University, Budapest, Hungary, (losz@iris.geobio.elte.hu)

In this study we present high-resolution and multi-proxy records of a Holocene stalagmite showing volcanic signals detected the first time in a stalagmite by REE analyses. Stable oxygen and carbon isotope data profile along the speleothem deposited during the last 5000 years in the Mecsek Mts. (S-Hungary) suggest relatively stable conditions in most of the studied period. However, a significant d18O decrease (>2 %o) between approx. 3800 and 3500 years BP occurs in the record. Fluid inclusion water shows also significant D-depletion, supporting cooling. Combined isotope and trace element measurements indicated coupled temperature and precipitation quantity changes occurring in the above period. Rare earth elements (REEs) were also measured by LA-ICP-MS technique, and unlike the longer trends shown by C and O isotopes, the REE and Y distributions indicate sudden changes at the beginning of the cooling period. The La/Y ratio of this segment shows similarities with the volcanic rocks of of the Thera (Santorini) eruption that occurred at about 3650 years BP. As an independent indicator, 87Sr/86Sr ratios show slight decrease at the REE peak, supporting the inferred volcanic signal.

The climatic conditions ameliorated rapidly (within ~100 years) to close to present day conditions as reflected by the C, O and H isotope compositions. However, some of the trace elements show marked changes following the recovery. Elements indicating detrital material within the carbonate matrix (e.g. Si, Al, Th) show marked elevations, along with 87Sr/86Sr increase, suggesting increased amount of silicious material transported by dripwaters. However, the Mg content is also higher at this section part, thus, the increase of detrital material amount may be related to lower carbonate precipitation rate, rather than to stronger weathering of silicate rocks.

This study was financially supported by the Hungarian Scientific Research Fund (OTKA T 049713) and the Hungarian Scholarship Board (travel grants to Z.S.).
A geochemical gradient along the North Mid-Atlantic Ridge revisited: New Hf and Pb isotope data

SERGEÏ SILANTYEV¹, LAURE DOSSO² AND BARRY HANAN³

¹Vernadsky Institute, Russian Academy of Sciences - 117975 Moscow, Russia (silantyev@geokhi.ru)
²CNRS UMR 6538, IFREMER, BP70, 29280 Plouzané, France (laure.dosso@univ-brest.fr)
³Department of Geological Sciences, San Diego State University, 5500 Campanile Drive, San Diego, CA 92182, U.S.A. (bhanan@mail.sdsu.edu)

Basalts dredged along the Mid-Atlantic Ridge north of the 15°20’N fracture zone and the so-called 14°N anomaly (Bougault et al., 1988), from 15° 44’ to 17° 28’ show a well-documented gradient from enriched to depleted chemical characteristics (Dosso et al. 1991) where Sr isotopic compositions vary from 0.70288 to 0.70217, respectively.

We will present new Hf and Pb isotope data for this region of the MAR. Preliminary results show that the Hf and the Pb isotope ratios range between the ambient local MORB mantle source that defines the 14°N bathymetric and C-like (Hanan and Graham, 1996) geochemical anomaly and an extremely depleted mantle source unlike any other so far recognized along the North Atlantic ridge. The results will be discussed in terms of the regional tectonic framework.

Detection of biomarkers in oils using ToF-SIMS

SANDRA SILJESTRÖM¹, 2, TOMAS HODE³, JUKKA LAUSMAA², JAN TOPORSKI⁴, VOLKER THIEL⁵ AND PETER SJÖVALL²

¹Department of Geology and Geochemistry, Stockholm University, Sweden (sandra.siljestrom@geo.su.se)

³Department of Geology, Portland State University, USA
⁴WITec, Germany
⁵Department of Geobiology, University of Goettingen, Germany

To identify biological traces in geological samples molecular biomarkers are widely used. Traditionally GC-MS (Gas chromatography-mass spectrometry) has been used for the analysis. In recent years when concentrations of target compounds were low surface sensitive ToF-SIMS (Time of Flight – Secondary Ion Mass Spectrometry) analysis has been applied. We present the results of a study using GC-MS and ToF-SIMS for the characterization of biomarkers in oils and oil extracts, aiming to prepare for the analysis of smallest quantities in oil samples recovered from fluid inclusions.

The biomarkers steranes and hopanes were characterized using polyatomic primary ion source (Bi⁺) ToF-SIMS. These compounds were present in hexane extracts from natural oil samples by GC-MS analysis. The same extracts were analyzed by ToF-SIMS, allowing identification of individual biomarkers in this complex sample extract. This information was then used to interpret ToF-SIMS spectra derived from the crude oil by direct analysis. Although these spectra show the presence of a vast variety of components and compound fragments, the target biomarker components could be identified.

This initial study was done in preparation for the investigation of oil-bearing fluid inclusions in rocks from different environments and of different ages. Fluid inclusions may provide a wealth of yet undiscovered information due to their isolation from the environment. The capability to characterize smallest biomarker quantities from oil-bearing fluid inclusions contributes to the understanding of the environment in which the oil was formed and could provide insight into the biodiversity of early Earth.

Arsenic contamination of drinking water in some localities of Vila Real – Northern Portugal

C. SILVA, H. SOUSA, O. LOPES AND P. FAVAS
University of Trás-os-Montes e Alto Douro, 5001-801 Vila Real, Portugal, (pjcf@utad.pt)

The occurrence of problems resulting from arsenic contamination of drinking water in Vila Real (Northern Portugal) was recognized by the Supplier Company of domestic water itself. One of the most significant water quality problems that will be present for a long time to come is the Rebordolongo site, which has arsenic contamination far in excess of any other area.

This preliminary study discusses the geological occurrence, the origin, the environmental impact and the health risks of arsenic in drinking water of the public water supply of Rebordolongo. The approach taken by this study was to compare the water quality were from boreholes and wells with the water quality in the homes of the consumers. Hydrochemical analyses have confirmed the presence of dissolved arsenic in drinking waters, with concentrations exceeding the current WHO potable water guideline. The total arsenic content of all these waters varies between <10 µg/L, and 28 µg/L.

The field work have confirmed placed near the one of the wells an abandoned wolfram mine, the waste from which is typically rich in arsenopirite. The mineralogical composition of quartz-veins and waste samples from the mining site were undertaken to assess their potential as a subregional source of arsenic contamination. Tailings from the site are predominantly composed of quartz detritus with abundant arsenopyrite. The sulphides are mainly arsenopyrite and pyrite, with some galena and chalcopyrite.

The relatively high arsenic concentrations in the waters from the mine site may reflect the oxidation/weathering of arsenopyrite and other sulphide-bearing mine tailings. This allows for the solubilization of metals. Arsenic concentrations in domestic water were higher than those in the water from boreholes, probably suggesting direct mixing of effluent from mining area. Meanwhile, the domestic waters do not contain more than 14 µg As/L. However, arsenic is highly concentrated in the iron oxyhydroxides sampled in the bottom of the water reservoir. Upon contact with air, these waters locally form oxyhydroxides deposits, sorbing effectively arsenic. These deposits contain 0.83% As. Therefore, one can conclude that the environmental and health impact of these waters in Rebordolongo is not negligible.

A complementary phase that is in progress intends to characterise arsenic and heavy metals speciation more clearly and determine the link with iron oxyhydroxydes.

Global Ca-isotope signatures in post-Snowball Earth cap-carbonates

J.C. SILVA1, T.F. NÄGLER1, I.M. VILLA1, K. KYSER2, A.N. SIAL3, G.M NARBONE2, N.P JAMES2, DA SILVA4 AND M.A. FILHO

1Universität Bern (juancst@geo.unibe.ch, naegler@geo.unibe.ch, villa@geo.unibe.ch)
2 Queens University (kyser@geol.queensu.ca, narbonne@geol.queensu.ca, james@geol.queensu.ca)
3Universidade Federal de Pernambuco (sial@ufpe.br)
4CPRM (masf@re.cprm.gov.br)

δ44/40Ca(seawater) values of Neoproterozoic cap-carbonates in NW Canada and NE Brazil overlying glacigenic units are reported. While cap-carbonates (Rapitian and Jaccoca Fms) overlying ca 0.74 Ga Rapitian diamictites display δ44/40Ca(seawater) values increasing from −1.9‰ to −0.7‰, cap-carbonates (Raventhroat-Hayhook and Acaua Fms) overlying ca 0.635 Ga Marinoan diamictites display δ44/40Ca(seawater) values decreasing from -0.9‰ to –1.8‰, followed by a progressive up-section increase to values near 0‰. The δ44/40Ca(seawater) values displayed by the post-Marinoan cap-carbonates are undistinguishable from those of their correlative Kailber and Maiberg Fms (NW Namibia, Kasemann et al., 2005). We suggest that changes in the δ44/40Ca(seawater) values of the studied cap-carbonates reflect changes in the Ca-isotope composition of their coeval seawater. The similar δ44/40Ca(seawater) values displayed by coeval carbonates from a deep to shallow marine profile (lower Hayhook Fm) suggest a homogeneous Ca-isotope composition of oceans. Differences in the degree of diagenetic overprint of these samples along with the sub-greenschists facies of metamorphism of the Brazilian cap carbonates suggest preservation of the sedimentary Ca-isotope compositions even after diagenesis and burial. The global nature of the δ44/40Ca(seawater) values, along with varying Ca-isotope compositions with stratigraphy displayed by the post-Marinoan and Post-Rapitian cap-carbonate indicate that Ca-isotope stratigraphy can be used to correlate cap-carbonate successions worldwide.

Macroscopic and infrared spectroscopic investigation of the synergistic effect between small organic ligands and desferrioxamine-B on the dissolution of goethite

Anna A. Simanova, Per Persson and John S. Loring
Department of Chemistry, Umeå University, Umeå, Sweden
(anna.simanova@chem.umu.se, per.persson@chem.umu.se, john.loring@chem.umu.se)

In several recent papers, Kraemer et al. [e.g. 1-2] have suggested that the dissolution of goethite by desferrioxamine-B (des-B) is enhanced in the presence of small organic ligands such as oxalate that actively shuttle iron from the goethite surface to bulk solution. The goal of the present study was to further an understanding of this phenomenon in both the oxalate- and malonate-goethite-des-B systems using macroscopic and spectroscopic methods. All experiments were performed at 25 °C in the absence of visible and ultraviolet light. The amount of oxalate and malonate adsorbed and the concentration of Fe(III) dissolved were studied after a reaction time of one week at total ligand concentrations of both 0.1 and 1 µmol/m² and covering the pH range 3 to 9.5. Several different types of in situ infrared spectroscopic experiments were performed at constant pH values of both 4 and 6, total oxalate and malonate concentrations of 1 µmol/m², and des-B concentrations of between 0.1 µmol/m² and 1 µmol/m². First, spectra were collected to monitor the adsorption and surface speciation of oxalate and malonate on the goethite surface in the absence of des-B as a function of time, and the desorption of these ligands was followed spectroscopically to clarify the relative stabilities of the different types surface complexes. Second, spectra were collected as a function of time after the simultaneous addition of 1 µmol/m² concentrations of both oxalate or malonate and des-B to identify the complexes present at the goethite surface. Third, oxalate and malonate were reacted with goethite in the absence of des-B, and then spectra were collected as a function of time after repeated 0.1 µmol/m² additions of des-B every 24 hours. These experiments have revealed the type of surface complex responsible for the synergistic effect between these small organic ligands and des-B on the dissolution of goethite. The results are also discussed with respect to their broader implications toward mechanisms for ligand-promoted mineral dissolution.

Variable Calcium isotopic fractionation factor in natural carbonated water

Neil G. Sime and Albert Galy
Department of Earth Sciences, Cambridge University, UK
(neilsime@yahoo.co.uk; albert00@esc.cam.ac.uk)

Carbonates precipitated inorganically under laboratory conditions are fractionated relative to the coexisting solution by up to about -1‰ in their 44Ca/42Ca ratio [1,2]. Such Ca isotopic fractionation (44/42α_carb) is dependent upon the rate of carbonate precipitation with a temperature dependency as a knock-on effect [2] and has been attributed to kinetic effects. The mechanism by which Ca gets enriched in the light isotope in carbonate is rather controversial [1,2] but the experimental approach can be reconciled with the data obtained for biomineralisation. Evidence for a kinetic effect behind the preferential incorporation of light isotopes in inorganic carbonate is more elusive since studies at catchment scale [3-5] are complicated by the role of the vegetation and the incorporation or release of Ca by the biomass.

Here we report 44/42Ca for paired dripping water and speleothems previously studied for Mg isotopic fractionation [6]. The 44/42α_carb ranges from 0.9998 to 0.9988 while the 44/42Ca of the dripping water are either indistinguishable from the values of the country rock or enriched toward heavier values by up to 0.22‰. The largest 44/42α_carb is found in a slow dripping speleothem while fast dripping stalagmites precipitate carbonate weakly fractionated. Qualitatively, our data support Lemarchand et al. [2] model but with a much greater 44/42α_carb value for very low rate of carbonate precipitation. While this data is not direct evidence for an equilibrium fractionation of Ca isotopes, it is worth noticing that the incorporation of O and Mg isotopes in all of these speleothems occurs at equilibrium [6] and clearly suggests that the mechanisms responsible for Mg and O isotopic fractionations are distinct from those responsible for Ca isotopic fractionation.

Lithospheric geodynamics with thermo-chemical density anomalies and mineral phase transitions switched on

N.S.C. Simon, Y.Y. Podladchikov and L.H. Rüpke

Physics of Geological Processes, University of Oslo, P.O. Box 1048 Blindern, N-0316 Oslo, Norway, (n.s.c.simon@fys.uio.no)

Density is an important physical property of rocks, which e.g. determines the isostatic response of the lithosphere to deformation. The density of a piece of mantle depends on pressure, temperature and composition. These three parameters inevitably change during geological processes such as rifting, but can also vary in apparently passive settings, e.g. at the lithosphere-asthenosphere boundary. The density distribution of the shallow mantle is non-linear and discontinuous due to complex mineralogy and, most importantly, phase transitions. The two shallow phase transitions that have the strongest effect on density are the plagioclase-in transition above ~50 km and the garnet-in reaction below ~40 – 100 km. The depth of these phase transitions strongly depends on the bulk composition of the mantle. The depth of the plagioclase-in boundary is mostly pressure dependent and predominantly controlled by bulk Na2O/Al2O3, whereas the garnet-in transition has a steep and curved Clapeyron slope with a strong depth-dependence on bulk Cr2O3/Al2O3.

In an extending lithosphere, the density changes in the lithospheric column due to phase transitions can cause significant deviations from purely thermal subsidence. The amount of subsidence depends on the composition of the mantle, in addition to classical parameters such as the thickness of the crust, the initial geotherm and the amount of stretching. The phase-transition effect is most pronounced for thin crust, strong mantle thinning/upwelling and relatively fertile mantle compositions rich in aluminum and sodium, and can match the effect of thermal expansion. This could explain the pronounced syn-rift uplift and accelerated post-rift subsidence observed in some basins. The incompatible nature and strong mobility of sodium may lead to large changes in bulk Na2O, and therefore density, during minor melting (Na extraction) or metasomatism (Na addition).

Densification of portions of the mantle, e.g., due to melt infiltration and shifts in the location of phase boundaries, might also contribute to the formation of gravitational instabilities and small scale convection, e.g. at the lithosphere-asthenosphere boundary. The combination of 2-D finite element deformation modeling and thermodynamic phase diagram calculations allows us to evaluate and quantify the feedback between geochemical variations and lithospheric deformation.

Elemental and Sr isotope investigations of human tooth enamel by laser ablation-(MC)-ICP-MS: Successes and pitfalls

Antonio Simonetti1, Michele R. Buzon2 and Robert A. Creaser1

1Dept. Earth & Atmospheric Sciences, University of Alberta, Edmonton, AB, T6B 1S6, Canada
(antonio.simonetti@ualberta.ca)
2Dept. Sociology & Anthropology, Purdue University, West Lafayette IN 47907-2059, USA (mbuzon@ucalgary.ca)

Sr isotope analysis of human tissue has proven to be an important tool for examining ancient human migration. Previous studies have typically conducted Sr isotope measurements by TIMS; however, Sr isotopic measurement by solution mode MC-ICP-MS greatly increases sample volume throughput with little (if any) detriment to the quality of individual analyses (e.g. Buzon et al., in press). Recent studies have also reported reliable Sr isotope measurements and elemental concentrations within geologic and biologic samples at high spatial resolution using various LA-(MC)-ICP-MS instrument configurations. The relatively rapid nature of an individual laser ablation Sr isotope analysis (i.e. minutes) could possibly revolutionize (if successful) the manner in which migration studies of ancient civilizations are conducted in the future.

We investigated the elemental and Sr isotope ratios of tooth enamel from remains at the New Kingdom period Egyptian colonial site of Tombos (Sudan) by both laser ablation and solution mode-(MC)-ICP-MS analysis. Elemental abundances for both solution and laser ablation modes of analysis were obtained using a ELAN6000 quadrupole ICP-MS. Sr isotope measurements obtained in both solution and laser ablation modes were acquired with a NuPlasma MC-ICP-MS instrument. Laser ablation analyses were conducted using a UP213 system (New Wave Research).

Elemental abundances determined by both solution mode and laser ablation-ICP-MS analysis yield comparable values; however, 87Sr/86Sr values obtained by laser ablation are higher compared to their solution mode counterparts. This discrepancy is related to the production of a molecular interference- Ca+P+O (overlaps 85Sr); hence the higher 8Sr/86Sr values recorded during ablation analyses. Laser ablation studies of enamel may provide relatively precise 8Sr/86Sr values rather quickly but cannot be used for accurately deciphering historical population migrations (Simonetti et al. in press).

Characterizing degassing and magma recharge from measurement of short-lived U-series isotopes in volcanic gases and lavas

KENNETH WW SIMS¹ and PIERRE-JEAN GAUTHIER²

¹Department of Geology and Geophysics – Woods Hole Oceanographic Institution Woods Hole, MA 02543, USA (ksims@whoi.edu)
²Laboratoire Magmas et Volcans – Observatoire de Physique du Globe de Clermont-Ferrand (CNRS, UBP) – 5 rue Kessler – 63000 Clermont-Ferrand, France (P.J.Gauthier@opgc.univ-bpclermont.fr)

Magma recharge and degassing are directly linked to volcanic activity. Determining the timescales of these shallow level processes is fundamental to our understanding of physical eruption dynamics and hazard assessment.

At many quiescent but potentially dangerous volcanoes, persistent degassing is the most common manifestation of volcanic activity. While it is generally agreed that these gas fluxes are mostly sustained by the exsolution of volatiles that were initially dissolved in the magma at depth, it has been unclear whether these gases originated from small ascending magma batches (ultimately recycled at depth once degassed) or large magma reservoirs beneath active volcanoes. Setting constraints on magma residence times in shallow degassing reservoirs and/or feeding systems is critical to distinguish between these two end-member models. Measurement of radioactive disequilibria between short-lived ²²²Rn, ²¹⁹Pb, ²¹⁸Bi, and ²¹⁰Po in gases and tephras collected from inside the Santiago Crater of volcano Masaya (Nicaragua). To our knowledge these are the first measurements of ²²²Rn from magmatic gases. Masaya’s (²¹⁸Po/²¹⁰Pb) and (²²²Rn²¹⁰Pb) are best explained by ²²²Rn enrichment and subsequent decay in gas bubbles of a magma body having a residence time between 3 and 150 years. Our measurements of radioactive disequilibria in Masaya's gases also display significant variability through time (periodically since 2000) that are correlated with observed variations in activity and gas fluxes at the surface. Taken together, these observations suggest that degassing occurs in a large magma reservoir beneath the active Santiago crater and that input of deep pristine magma into this reservoir controls the eruptive activity at the surface.

Anthropogenic signatures in sediments of the fast growing urban area of Natal (NE-Brazil) – A study of heavy metals and organic components

In this study the effect of anthropogenic discharges on the composition of sediments in the Potengi – Jundiaí river system near the fast growing city of Natal, NE-Brazil, is investigated.

In general, the sediments of the Rio Potengí – Jundiaí river system in the studied area are not severely polluted. Rather they represent an incipient stage of anthropogenic accumulation. A previous study (Sindern et al. 2006) has shown that heavy metals such as Zn, Pb, Cu, Cd and in part also Sn, Hg and Ag have enhanced values relative to reference elements such as Al and Fe. Sources are domestic and animal waste, combustion products and hydrocarbons. These heavy metals are mainly bound to organic matter.

The elements Cr, Ni and V are characteristic of weathering heavy minerals in crystalline rocks exposed in the catchment area of the river system and are not significantly added from anthropogenic sources.

Additionally, a comprehensive spectrum of organic compounds was identified in sediment as well as water samples of the Potengi-Jundiaí river system. Individual organic components were characterized dominantly to be of biogenic origin. However, huge amounts of indicative substances, e.g. fatty acids, suggest a significant emission of natural organic matter as the result of anthropogenic waste discharge. This might reflect incomplete of insufficiently working waste water treatment. Further on, well known xenobiotics, such as plastiziers, pharmaceuticals or pesticides, were detected only to a minor extend, although this type of anthropogenic contamination has frequently been found in riverine systems. The anthropogenic impact on the organic emission within the riverine system differs significantly from the organic signature of rivers from other regions, e.g. Europe or North America.

Geochemistry and PGE potential of Bangur Gabbro from the Baula-Nuasahi Mafic Ultramafic Complex, Orissa (India)

RAVI SHEKHAR SINGH AND S. N. CHARAN
National Geophysical Research Institute, Hyd., India
(ravishekhar3@yahoo.com, nirmalcharan@yahoo.com)

Geological set-up
The Baula-Nausahi mafic ultramafic complex comprises (1) Gabbro-Anorthosite unit, (2) Peridotite unit (with three chromite bands Ganga, Lakshmi and Sankar), (3) Pyroxenite unit and (4) Bangur Gabbro (~3.1 Ga) (Auge et al. 2003).

Geochemistry
The Zr/TiO\textsubscript{2}*0.0001 vs Nb/Y diagram shows these gabbros in the field of basalt. SiO\textsubscript{2}, Na\textsubscript{2}O and Al\textsubscript{2}O\textsubscript{3} show negative trend while MnO and Fe\textsubscript{2}O\textsubscript{3} show positive trend with MgO which indicates the differentiation trend of magma and is reflected in mineralogy. Trace element pattern of Bangur gabbro shows the positive Rb and Y anomaly and negative Nb anomaly. The positive anomaly of Rb and Y can be attributed to the development of secondary amphiboles due to alteration.

The metal ratio diagram shows the PGE potential of Bangur Gabbro as almost all the samples plots in the field of Layered complex. So the samples plotted above the extrusive rocks field also show enough potential as the chrome-spinel in Bangur gabbro may have affected the ratio.

Discussion and Conclusion
The hydrothermal processes have lead to the formation of secondary minerals as well as remobilization of Base metal sulphide. The metal ratio diagram shows the potential for PGE and supports the further investigation to delineate the mineralized zone within Bangur gabbro.

The Alteration Mineralogy and Mass Change of Volcanics from Zigana (Gümüşhane, NE-Turkey)

F. SIPAHI, M. B. SADIKLAR AND B. PRACEJUS
Jeoloji Müh., KTU, MF, Tr-61080, Trabzon;
(sadiklar@ktu.edu.tr, sipahi@ktu.edu.tr)

The Late Cretaceous volcanic rocks around Zigana Mountain (Gümüşhane) at the eastern part of Black Sea Region (NE-Turkey) belong to the east Black Sea metallogenic province, and have intensive hydrothermal alteration although weathering alteration is limited. The basement of the study area is formed by the Late Cretaceous basalt, andesite and their pyroclastics. These rocks are overlaid by the Late Cretaceous aged dactic rocks, namely Dacite-I and Dacite-II described by [1] and [2]. These volcanic rocks are bimodal in character and have tholeitic to calc-alkaline affinity, and have developed in volcanic arc environment. The Late Cretaceous rocks are the host of VMS and vein type deposits in the study area and region.

Volcanic rocks in the study area have been altered to the sericite/illite-chlorite facieses, and contain sericite/illite, chlorite, quartz, carbonate minerals (ankerite and calcite), iron-oxide, and rare kaolinite, smectite and epidote as the alteration products. Sericitization/illitization is the most common type of the hydrothermal alteration associated with the Zigana Volcanics, and chloritization is the second. Pyritisation is seen all volcanics, and the most commonly in dacites. In some fields, limonitisation is occasionally present. Epidotization is rare, and especially seen at basalt and andesite. Isocon method was applied to estimate the mass gains and losses of the Zigana Volcanics as a result of hydrothermal alteration. According to this, basalt and andesite, Dacite-I, and Dacite-II have 2-61 % mass gain, 71 % mass gain and 42 % mass loss, and 44 % mass gain and 32 % mass loss, respectively. Namely, both mass gain and mass loss have occurred in volcanics during the hydrothermal alteration of the parent materials. Illitization-chloritization-kaolinitization increase generally from least altered rock to highly altered rock, whereas carbonatization decreases. The relation between metals such as Cu, Pb, Zn and sericitization/illitization, chloritization and silisification shows that fluids which cause sericitization and chloritization did not increase the amount of these metals and, in fact, it can be said that this fluids are poor in these metals. This also shows that they developed under different hydrothermal conditions.

This study was supported by DAAD scholarship.

Results of FTIR studying microdiamonds from gneisses and calc-silicate rocks from mine Kumdi-Kol, Northern Kazakhstan

E. SITNIKOVA AND V.S. SHATSKY
Institute Geology and Mineralogy, Siberian Branch of the RAS, 3prosp. Koptyuga, Novosibirsk, 630090, Russia
(sentyabruna@uiggm.nsc.ru, shatsky@uiggm.nsc.ru)

Statistically representative selection of microdiamonds from gneiss and calc-silicate rocks of the Kumdy-Kol deposit was first time studied by means of FTIR spectroscopy. Grayish yellow diamonds of the calc-silicate rocks are about 10-90 mkm in size and have cuboidal morphology. The morphology of microdiamonds from gneiss is more versatile. The crystals of octahedral, cuboctahedral and cuboidal morphologies were found there. They also have yellow color with grayish tint. The size of the gneiss microdiamonds varies between 15 and 150 mkm. The size of studied diamonds were about 60-150 mkm.

The selected diamonds have been studied with Bruker VERTEX-70 FTIR spectrometer equipped by Hyperion IR-microscope. IR spectra demonstrate that all of the studied diamonds contain nitrogen defects, which are manifested through the absorption at 1135 cm⁻¹ (C-defects) and 1282 cm⁻¹ (A-defects). Concentrations of nitrogen in the diamonds from different rocks are similar and vary from 700 to 2500 ppm (+20%). The nitrogen aggregation in the studied crystals varies from 30 up to 50% (+6-18%). The absorption at 3107 cm⁻¹ indicates the presence of hydrogen defects. The intensity of absorption at 3107 cm⁻¹ in gneiss diamonds is 5-20, while in calc-silicate rock diamonds - 2-10. Our data indicate that the studied microdiamonds belong to the Ib-IaA type.

IR spectra of diamonds from gneiss and calc-silicate rocks differ from each other in additional absorption lines. The spectra of calc-silicate rock diamonds testify to the presence of carbonate (1430 cm⁻¹) and silicate (1090 cm⁻¹) inclusions, water (banding vibrations at 1630 (1650)+5cm⁻¹ and stretching at 3420 cm⁻¹). The spectra of the gneiss diamonds do not demonstrate the presence of carbonates, silicates and/or water.

The differences of inclusion assemblages in microdiamonds from gneiss and calc-silicate rocks are the evidence of the extremely low mobility of the fluids/melts in the course of UHP metamorphism.

“Blood Coltan”: Fingerprinting of columbite-tantalite ores

M.A. SITNIKOVA¹, F. MELCHER¹, T. OBERTHÜR¹, F. HENJES-KUNST¹, A. GERDES², H. BRÄTZ³ AND D. W. DAVIS⁴

¹BGR, Stilleweg 2, D-30655 Hannover, Germany

⁴Department of Geology, University of Toronto, 22 Russell Street, Toronto ON M5S 3B1, Canada (dond@geology.utoronto.ca)

The term “Blood Coltan” was coined for columbite-tantalite ores in the Congolese civil war, as their sale supported the conflict, especially in the eastern provinces of the DRC. Following the United Nations initiative to fingerprint the origin of conflict materials, the German Ministry for Economic Cooperation and Development decided to fund this pilot study on fingerprinting coltan ores.

So far about 160 samples have been obtained from the world’s major coltan producing areas. Special attention is directed toward the Ta-Nb-Sn provinces in Africa: DR Congo, Rwanda, Mozambique and Namibia.

Using state of the art analytical tools, we are investigating a wide range of mineralogical and chemical parameters obtained from columbite-tantalite ores, in an attempt to distinguish between different ore provinces, down to the individual deposit scale.

Methods employed include XRF (bulk major and trace elements), XRD (structure), ore microscopy, fully automated electron microscopy (Mineral Liberation Analysis), electron microprobe analysis (major and minor), laser ablation-ICP-MS (trace elements, isotopes), and TIMS (U-Pb dating).

Elevated concentrations of U, and low amounts of common Pb in columbite-tantalite, facilitate the application of the U-Pb system to date columbite-tantalite. Consistent results of TIMS and LA-ICP-MS analyses in three different laboratories prove that columbite-tantalite yields concordant and reliable ages. In the samples analyzed so far from Africa, four age populations are evident: Archaean (>2.6 Ga), Palaeoproterozoic (1.9-2.1 Ga), early Neoproterozoic ("Kibaran"; 0.98-0.93 Ga), and early Palaeozoic (ca. 0.5 Ga). The bulk of the current Central African columbite-tantalite production is from Kibaran pegmatites associated with late “G4” tin granites. Trace element concentration patterns, mineral assemblages, and zoning characteristics in these pegmatites are clearly different from rare element pegmatite-hosted Ta mineralization in Alto Ligonha, Mozambique.
Study of trace elements reactivity in polluted soils: Measure of Cd, Zn, Cu and Pb lability by using DGT and isotopic dilution methods

Y. Sivry1, L. Denaix2, M. Fabregue1, Dr J. Riotte1, C. Zouten1, V. Sappin-Didier2 and B. Dupré1

1LMTG-UMR 5563 UR, 154 CNRS, Univ. P. Sabatier, IRD, Observatoire Midi-Pyrénées-14, av. Edouard Belin-31400 Toulouse, France; (sivry@lmtg.obs-mip.fr)
2INRA-UMR Transfert sol plante et cycle des éléments minéraux dans les écosystèmes cultivés-71, Av. Edouard Bourlaux BP 81-33883 Villeneuve d’Ornon, France

Industrial production and more precisely the metallurgy led to the dissemination of chemical contaminants in the environment. According to the metallurgical processes, this contamination can be more or less strong and induce, locally, grounds, water and plants pollutions.

In this study we try to quantify the labile pool of various trace elements in cultivated gardens, located around an industrial area.

The concentrations of heavy metals (As, Cu, Zn, Cd and Pb) measured in various cultivated vegetables are significatively higher than the european reference values (EC466/2001). The accumulation in plants differs in leaf, roots and fruits vegetables and is clearly correlated with the pH of the soils. In order to describe the heavy metal soil/plant exchanges, we tried to determine the concentrations of metals in the labile pool of the soils and to relate it to phytoavailability.

An isotopic dilution method (ID) using spiking with stable isotopes [1] and [2] has been performed in these polluted soils to determine the labile pool whereas a Diffusive Gradient in Thin film (DGT) method realised in the same soils permitted to mimic the heavy metal uptake by the roots of the plants [3]. The comparison between these two complementary methods allowed to describe the soil-solution transfer and demonstrated the different behaviours of the measured metals: relationships between labile pool measured by DGT and phytoaccumulation are observed for some of them, such as cadmium or zinc, but not for lead.

The kinetic aspects of the soil/solution exchanges were also described by performing ID and DGT, from 1h to 2 weeks. Modelization of these kinetiks gave us the parameters describing the exchange properties and the desorption of the metal from soil to solution. These parameters varied with metal concentration, pH or organic carbon content in the soils.

Organic microanalysis by time-of-flight secondary ion mass spectrometry

PETER SJÖVALL

SP Technical Research Institute of Sweden, Chemistry and Materials Technology, P.O. Box 857, SE-501 15 Borás, Sweden, (peter.sjovall@sp.se)

Time-of-flight secondary ion mass spectrometry (TOF-SIMS) is based on the analysis of positive or negative secondary ions emitted from a solid surface during bombardment by energetic ions. The technique has during the past decades become a well established surface analysis technique in materials science, in particular in the field of semiconductors and polymeric materials [1]. This is due to the attractive combination of high analytical sensitivity (in terms of absolute detection limits) and excellent imaging capability, with lateral resolution in the ~100 nm range. The application of the technique to more complex materials and molecular analysis was, however, for a long time hampered by the fact that the ionization process on which the technique is based lead to extensive fragmentation of and low yields (sensitivities) for organic anlyte molecules of masses higher than a few 100 u. This was in turn due to the properties of the primary ions used for accomplishing the sputtering and ionization of the sample under study.

During the last few years, there has been a strong development around TOF-SIMS for the analysis of organic materials and molecules. In particular, the development of new cluster primary ion sources (e.g., Au3+, Bi127+, C60+) have lead to dramatic improvements (typically by a factor 100-1000) in the detection sensitivity for organic molecules in the range from a few 100 u to 2000 u [2]. Due to the developments in instrumentation, in combination with a rapidly growing data base of reference spectra and the use of multivariate statistical tools for spectrum interpretation, TOF-SIMS is now emerging as a highly useful analytical tool for organic microanalysis, for example, in the field of biomedicine.

The presentation will give an introduction to TOF-SIMS, and illustrate the capabilities of the technique to more complex materials and molecular analysis was, however, for a long time hampered by the fact that the ionization process on which the technique is based lead to extensive fragmentation of and low yields (sensitivities) for organic anlyte molecules of masses higher than a few 100 u. Fluid inclusions, REE and sulfur isotope geochemistry of the Lavrion carbonate hosted ore deposit, SE Attica, Greece

N. SKARPELIS1, V. LÜDERS2 AND D.A. BANKS3
1Department of Geology & Geoenvironment, University of Athens, 157 84 Zografou, Greece (skarpelis@geol.uoa.gr)
2GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany (volue@gfz-potsdam.de)
3School of Earth Sciences, University of Leeds, Woodhouse Lane, Leeds LS2 9JT, UK (eardab@earth.leeds.ac.uk)

The Pb-Ag-Zn sulfide mineralization of the ca. 3000 year old mining district of Lavrion, comprises mainly mantos and skarn-type massive sulfides. The area is a part of the Attico-Cycladic Belt (ACB). Late Miocene granitoid dykes and a granodiorite stock intruded the footwall of the detachment fault that separates the Basal Unit from the overlying Cycladic Blueschist Unit. Late Miocene porphyritic S-type granitoid rocks occur as sills along or within the hangingwall close to the detachment fault. The manto-type ores are spatially associated with the detachment fault, shear bands within marbles, and the shear contacts between marbles and the intercalated metaclastics of the Basal Unit, indicating that the most important structural control of the Lavrion mineralization is related to the large-scale back-arc Miocene extension in the Aegean. The mineralizing event postdated the mylonitic deformation stage of the marbles, as proved by the alignment of ore bodies with the mylonitic foliation planes or by their crosscut relationship. Wall-rock alteration is characterized by carbonatization and minor silicification. Ore deposition involved mainly marble dissolution and replacement, and open space filling.

Fluid inclusion studies provide evidence for deposition of sulfides of the manto-type mineralization at temperatures of about 280°C from fluids having salinities between 14 and 17wt% NaCl eq. Quartz and fluorite deposition occurred at lower temperatures (250 to 125 °C) from fluids having highly variable salinities (1-19 wt% NaCl eq.). The δ34SCTD values of galena, sphalerite and pyrite range between -4.8 to +3.99 per mil. Most paired samples of sphalerite-galena, sphalerite-pyrite and galena-pyrite show either reversed fractionations or unreasonably high temperature values, indicating either sulfur isotope disequilibrium or noncontemporaneous precipitation of sulfides. Chondrite-normalized REE patterns in fluorites show slightly increasing LREE and decreasing HREE contents. All fluorite samples possess weak negative Ce and pronounced positive Eu anomalies. A meteoric water influx late into the granodiorite stock is documented by the fluid inclusions in quartz of widespread extensional quartz veins. There is no clear evidence whether a direct genetic link exists between the manto-type massive sulfides and the Late Miocene igneous activity in the footwall of the detachment or along the detachment fault. Ag-rich sulfide mineralization forming tension gashes within hydrothermally altered hornfelses postdates contact metamorphic phenomena.

Adsorption energy trends on UO2 and ThO2 surfaces

F. N. SKOMURSKI, R. C. EWING, AND U. BECKER
Department of Geological Sciences, University of Michigan, Ann Arbor, Michigan, U.S.A. (fskomurs@umich.edu, rodewing@umich.edu, ubecker@umich.edu)

Determining the interaction of adsorbates such as water and oxygen with surfaces of uranium and thorium dioxide is important for the long-term storage of these isostructural nuclear fuel materials. The semi-conducting versus insulating nature of UO2 and ThO2, respectively, makes comparison of surface-adsorbate interactions with these materials possible as a function of electronic structure in addition to surface structure. Previously, the quantum mechanical code CASTEP was used to calculate surface energies for UO2 and ThO2, and the (111) surface was found to be the most stable relative to the (110) and (100) surfaces in both cases (Skomurski et al., 2006). In this study, CASTEP was used to investigate the interaction of water and oxygen with UO2 and ThO2 slabs of finite thickness representing each crystallographic orientation. The effect of model set-up on adsorption energy trends is discussed for single versus double-sided models in a periodic setting.

On a defect-free (111) surface, the adsorption of molecular water is found to be more favorable than dissociated water for both UO2 and ThO2. On the more reactive (110) surface, however, the opposite trend is favored. The adsorption of molecular and atomic oxygen is investigated as a function of spin configuration to determine the very first steps of oxidation on UO2 surfaces. On both the (111) and (110) surfaces, the adsorption of atomic oxygen leads to oxidation of near-surface uranium atoms. Investigations into possible transition state spin configurations for oxygen interacting with the substrate are discussed. A co-adsorption case for water and oxygen is tested on both UO2 and ThO2 surfaces. On the UO2 (111) surface, the presence of water is found to enhance the oxidation of near-surface uranium atoms, a phenomenon attributed to the semi-conducting nature of UO2 as this trend is not observed on the insulating ThO2 surface. Finally, the distance dependence of this “surface proximity effect” (Rosso and Becker, 2002) is tested as a function of distance between adsorbates on the (110) surface. By using quantum mechanical methods to investigate the very first interactions of oxygen and water with actinde oxide surfaces, we start to develop a mechanistic understanding of processes that ultimately affect oxidation and dissolution rates on the macroscopic scale.

Garnet growth in the Zermatt-Saas Fee eclogites

S. SKORA1, L.P. BAUMGARTNER1, N.J. MAHLEN2 AND C.M. JOHNSON2

1Institut de Minéralogie et Géochimie, Université de Lausanne, l’Anthropole, 1015 Lausanne, Switzerland (Susanne.Skora@unil.ch, Lukas.Baumgartner@unil.ch)
2Department of Geology and Geophysics, University of Wisconsin, 1215 W Dayton St, Madison, WI 53706, USA (mahlen@geology.wisc.edu, clarkj@geology.wisc.edu)

Different approaches have been used to infer the growth-limiting mechanism. The radius rate relations of e.g. Kretz (1973) rely on major element compositional zoning as time markers assuming that all porphyroblasts are precipitating the same chemical composition at any point in time. Comparison of chemical contour lines in variably sized garnets is used to distinguish between the different rate laws. A second approach is based on the 3-D spatial distribution of porphyroblasts. It assumes that depletion halos developing around early porphyroblast in the diffusion-controlled case will inhibit nucleation within the halos. This is supposed to lead to an ordered distribution while a random distribution is to expect for the interface-controlled case.

Application of the radius-rate concept to garnets of the eclogites of the Zermatt-Saas Fee ophiolite (ZSF, Western Alps, Switzerland/Italy) suggests that all garnets precipitated the same amount of radius per time interval, hence were grown limited by an interface-controlled growth mechanism. Approximately bell-shaped crystal size distributions suggest continuous nucleation and growth throughout the garnet growth history. Preliminary 3-D spatial distribution data using the nearest neighbour method is used to distinguish between the different rate laws. A second approach is based on the 3-D spatial distribution of porphyroblasts. It assumes that depletion halos developing around early porphyroblast in the diffusion-controlled case will inhibit nucleation within the halos. This is supposed to lead to an ordered distribution while a random distribution is to expect for the interface-controlled case.

Investigation of the interaction between green rust sodium sulfate and aqueous selenium

L. L. SKOVBJERG AND S. L. S. STIPP
NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen Ø, Denmark (lskovbjerg@geol.ku.dk; stipp@geol.ku.dk)

Selenium is an important trace nutrient in the body at low concentrations but becomes toxic at high concentrations. It is a natural compound in many rocks and sediments in various concentrations, but selenium is also produced as a decay product in radioactive waste. It exists in various redox states of which the higher, selenate (VI) and selenite (IV) are mobile in the aquatic environment. Inorganic reduction to elemental, insoluble selenium is one pathway to minimize the bioavailability of selenium in areas of increased levels.

Green rust is an Fe(II)-containing compound, known for its capability of reducing a large number of oxidized elements and compounds. It belongs to the family of layered double hydroxides (LDHs) with layers of Fe(II)-Fe(III) hydroxide, separated by interlayers of water, anions and for some types also cations (poster by Christiansen et al.). The reduction of selenate and selenite by green rust has been studied during the last decade. We have focused our investigations at the nanoscale level to understand the mechanism of the reactions. We use transmission electron microscopy (TEM), atomic force microscopy (AFM) and X-ray diffraction (XRD) to observe the particles at various times during the reactions.

Our results suggest that the mechanism of reaction is dependent on the type of green rust as well as the oxidation state of selenium. We used a green rust type which had SO42- incorporated in the interlayers. When SeO42- was added, we observed signs of intrusion into the interlayers. However, when SeO32-, which has a different steric nature, was added, interlayer exchange was not observed. In both cases, the oxidised species were reduced to insoluble elemental selenium. Previous studies on chromate (Skovbjerg et al., 2006) showed that the reduction mechanism is important for the mobility of the reduced contaminant, but in the case of selenium it appears not to be of relevance.

REE distribution in volkhovites – New type of the tektite-like glasses

S. G. SKUBLOV

Institute of Precambrian Geology and Geochronology RAS, St-Petersburg, Russia (skublov@mail333.com)

Volkhovites are the tektite-like glasses of mafic and ultramafic composition; for the first time we have discovered them among fluvial-glacial sediments of Valday glaciations (10-65 thousand years) at the right side of the river Volkhov (North-West Russia). Volkhovite particles are characterized by small size (0.1-3.0 mm), varied microtektite aerodynamic (spherules, drop-shaped, dumbbell-like) and irregular forms, and the perfect safety indicating their postglacial age (Skublov et al., 2007).

Volkhovites can be separated into four groups: Ca-enriched, Mg-enriched, Mn-enriched and K-enriched. REE distribution was studied in volkhovites locally by ion microprobe Cameca IMS-4f (IMI RAS, Jaroslavl, Russia). REE patterns for K-volkhovites and Australasian microtektites are very similar.

We suggest that volkhovites were formed as a result of outburst of the fluidisite slag-stone-melt-mud-gas mixture from the crust deep levels up to surface (Skublov et al., 2007).

Figure 1: Chondrite-normalized REE patterns for mean values for different types of volkhovites. Dotted line indicates the mean value for the normal Australasian microtektites (Glass et al., 2004).

Increasing number of geological applications requires the use of well-characterized and widely available reference materials for in situ analysis. We have established a new natural zircon standard (“Plešovice”) for U-Pb dating and Hf isotopic analysis by laser ablation ICP-MS.

The ID-TIMS U-Pb age of the Plešovice zircon has been determined to 336.9±0.2 Ma (95% confidence limits; mean 206Pb/238U age). The U-Pb ages obtained by LA ICP-MS (3 labs) and SIMS techniques show larger spread but within their analytical uncertainties they are consistent with the TIMS age. Hafnium isotopic composition of the Plešovice zircon appears to be homogenous within and between grains. Combined laser ablation and solution MC ICP-MS analyses gave a mean 176Hf/177Hf value of 0.282481±0.000013 (95% confidence limits, 87 analyses). Cathodoluminescence and BSE imaging and chemical analyses revealed that discrete zones in the Plešovice zircon are enriched in trace elements and especially in U and Th. Raman spectroscopy suggests that these highly radiation-damaged areas have not undergone any annealing. However, our LA ICP-MS analyses did not indicate any Pb-loss but the high intensities of measured U signal require that these areas are avoided during routine U-Pb isotopic analysis.

The morphologically varied freshwater carbonate microbialite structures in Pavilion Lake, B.C. Canada represent an opportunity to investigate the processes leading to their formation and potential associated biosignatures that will contribute to our understanding of geo-microbe interactions and to our ability to interpret the geologic record. A primary question in such systems is determination of the primary carbon sources and cycling. In some systems, such as Mono Lake, carbonate structures are proposed to be the result of abiotic precipitation due to supersaturation resulting from groundwater-surface water mixing. Alternatively, modern stromatolites such as those in Shark Bay and the Bahamas are proposed to form via significant biological influence using bulk DIC.

Determination of the $\Delta^{14}$C of dissolved inorganic carbon (DIC) sources and mid-depth microbialite carbonate demonstrated that microbialite carbonate was significantly depleted in $\Delta^{14}$C with respect to bulk surface water indicating either contributions of geologically derived carbon or significant time since precipitation. Assuming surface carbonate was recently precipitated, comparison to local and regional groundwater $\Delta^{14}$C indicates that regional $\Delta^{14}$C depleted groundwater DIC sources provide 12% of carbonate carbon.

$\Delta^{14}$C of the detrital wood sample resulted in an estimated constant growth rate of 3 to 6 cm/thousand years, approximately double a previous U/Th based estimate.

The $\Delta^{14}$C of a deep water carbonate sample was highly depleted indicating that either groundwater was making a larger contribution to this carbonate or that this carbonate was precipitated significantly earlier than the mid-depth carbonates.

Modeling marine Carbon and Phosphorus cycling during Cretaceous Oceanic Anoxic Events

C.P. SLOMP, P. KRAAL AND I. TSANDEV

Faculty of Geosciences, Utrecht University, Budapestlaan 4, 3584 CD, Utrecht, the Netherlands, (slomp@geo.uu.nl)

Phosphorus (P) is a key nutrient and may control rates of primary productivity and organic carbon (C) burial in the oceans. Changes in phosphorus (P) availability thus may have played an important role in the initiation, formation and termination of Cretaceous oceanic anoxic events (OAEs). Besides redox-dependent changes in the recycling efficiency of sediment P, as deduced from elevated organic C/total P ratios in black shales, the marine P cycle can be affected by variations in sealevel, oceanic circulation and chemical weathering.

In this study, we use a model for the coupled marine cycles of P and C to examine the relative role of these various factors in determining changes in P availability and organic C burial during OAEs. We focus on OAE-2 (~94 Myrs BP; 500 kyr duration) and specifically study (1) possible triggers for the OAE, such as enhanced weathering and reduced oceanic circulation, (2) factors leading to its termination and (3) the relative role of the continental shelves and open ocean.
Abiotic Nitrogen reduction in Hadean hydrothermal systems

A. SMIRNOV\textsuperscript{1,2}, D. HAUSNER\textsuperscript{3}, R. LAFFERS\textsuperscript{1}, F. M. MCCUBBIN\textsuperscript{4}, D.R. STRONGIN\textsuperscript{5}, AND M.A.A. SCHOOSEN\textsuperscript{1}

\textsuperscript{1}Department of Geosciences, SUNY Stony Brook, Stony Brook, NY 11794, USA (asmirnov@gl.ciw.edu)
\textsuperscript{2}Geophysical Laboratory, 5251 Broad Branch Road, NW, Washington, DC 20015, USA
\textsuperscript{3}Department of Chemistry, Temple University, PA 19122, USA

One of the outstanding questions in Astrobiology is the source and formation mechanisms of NH\textsubscript{4}\textsuperscript{+} which presumably was required for reactions of prebiotic synthesis and origin of life. The uncatalyzed reduction of abundant N\textsubscript{2} to NH\textsubscript{4}\textsuperscript{+} is prohibitively slow due to the strong triple bond in the molecule. However, NO\textsubscript{3}\textsuperscript{-} and NO\textsubscript{2}\textsuperscript{-} present in the Hadean Ocean as result of atmospheric reactions may have been more susceptible to reduction. We have experimentally tested the hypothesis, which suggests that Ni, Fe metals and alloys formed as a result of hydrothermal (HT) serpentinization processes in the Hadean oceanic crust could have acted as catalysts and/or reactants in reactions leading to abiotic NH\textsubscript{4}\textsuperscript{+}.

Our results show NO\textsubscript{3}\textsuperscript{-} and NO\textsubscript{2}\textsuperscript{-} were converted into NH\textsubscript{4}\textsuperscript{+} more rapidly than N\textsubscript{2}, and the reduction process had a strong temperature dependence. Metals, especially Ni were found to be more effective than alloys in reducing N\textsubscript{2} with yields usually not exceeding few percent. Based on the experimental results we have estimated NH\textsubscript{4}\textsuperscript{+} yield of Hadean HT systems from to be approximately $10^{10}$-$10^{12}$ mol.yr\textsuperscript{-1} which is comparable to values estimated by Brandes et al., 1999 ($10^{10}$-$10^{11}$ mol.yr\textsuperscript{-1}) and Schoonen and Xu (2001) ($10^{9}$-$10^{10}$ mol.yr\textsuperscript{-1}) in HT systems as well as Summers and Chang (1993) for NO\textsubscript{2}\textsuperscript{-} reduction by Fe\textsuperscript{2+}. Our estimate only includes N\textsubscript{2} to NH\textsubscript{4}\textsuperscript{+} reaction yield and therefore if NO\textsubscript{2}/NO\textsubscript{3}\textsuperscript{-} were present in the advected seawater, the yields would have been proportionally higher considering their high conversion rates to NH\textsubscript{4}\textsuperscript{+} in the presence of metals/aleys.

We have also considered iron meteorites as possible sources of N since they commonly coain reduced N species such as nitride (N\textsuperscript{3-}) which could have reacted to form NH\textsubscript{4}\textsuperscript{+} during dissolution in the Hadean Ocean. When compared, however, with HT production, the meteoritic NH\textsubscript{4}\textsuperscript{+} flux during the Late Heavy Bombardment is approximately 6 orders of magnitude smaller.

Melt segregation and near source fractionation: Examples from small scale basaltic systems

IAN E M SMITH

Geology programme, School of Geography, Geology and Environmental Sciences, University of Auckland, New Zealand (ie.smith@auckland.ac.nz)

Basaltic magmatic systems, expressed at the earth’s surface as volcano fields, are characterised by very low rates of magma production (< 1.0$^4$ km\textsuperscript{3} /year) over relatively long time scales (up to 10\textsuperscript{7} years); these are tiny igneous provinces contrasting with Large Igneous Provinces that represent the other extreme in the spectrum of mantle derived magmatism. Tiny igneous provinces are the result of very small degrees of partial melting from a mantle source. In the Auckland volcanic field of Northern New Zealand, sampling of stratigraphically defined eruption sequences typically shows compositional trends in small magma batches that cannot be accounted for by fractionation involving low pressure mineral assemblages in a shallow pre-eruption environment. Detailed study of several individual volcanic centres in the Auckland field has defined two styles of compositional variation. 1). Least evolved compositions (as defined by geochemical parameters such as Mg-number and incompatible element content) are erupted first followed by more evolved compositions. This is interpreted to reflect magma extraction from a source in which a thermal gradient has produced a range of melting proportions with the greater proportion melt leading the extraction process. 2). The eruption sequence is initiated by relatively evolved compositions followed sequentially by progressively less evolved compositions. This trend is interpreted as the result of high pressure fractionation immediately above the source in a part of the conduit where melt is thermally connected to its surroundings and side wall crystallisation controls fractionation. The fact that these well defined compositional variations can be observed in stratigraphic sequence shows that the fractionated magma column rose very rapidly and without mixing once it left the source region. Further, such subtle compositional trends are probably only preserved because of the extremely small volumes of melt involved. In the Auckland volcanic field there is evidence for these extraction/fractionation processes occurring in both garnet and spinel peridotite facies giving rise to a range of alkaline to sub-alkaline basalt compositions. There is also evidence for compositionally distinct small magma batches coexisting independantly and rising simultaneously to the surface demonstrating the inherent instability of small scale mantle based magmatic systems.
Purification of sterols and alkenones for compound specific hydrogen isotopic analysis using HPLC

RIENK H. SMITtenBERG*, VALERIE F. SCHWAB AND JULIAN P. SACHS

University of Washington, School of Oceanography. Box 355351, Seattle, WA 98195, USA.
(smitten@u.washington.edu; vfschwab@u.washington.edu, jsachs@u.washington.edu)
*moving to ETH Zürich, Geological Institute. Universitätsstrasse 16, 8092 Zürich, Switzerland.

Here we present two variations of a method for purifying sterols and alkenones out of total lipid extracts using an HPLC-MS coupled to a fraction collector. The presented methods reduce the amount of work needed and simplify the procedure to obtain fractions pure enough for compound specific irm-GC/MS analysis, compared to traditional wet chemical techniques. This allows a higher throughput of samples so that high-resolution paleoclimatic or paleoenvironmental proxy records based on compound-specific isotope measurements can be obtained more efficiently. The presented method was developed for hydrogen isotope analysis, and introduces no isotopic fractionation. The method could also be used in other cases where purification of lipid biomarkers out of total lipid extracts is required.

Figure 1: Gas Chromatograms of:
A) Total lipid extract of a Chesapeake Bay sediment and fractions as purified by semi-preparative HPLC. Individual alkenones are separated from notoriously co-eluting alkenoates.
B) Neutral fraction of a sediment from Palau (West Pacific) and collected fractions containing various alcohol classes.

Continental temperatures from the Paleocene-Eocene boundary in the Big Horn Basin, WY from carbonate clumped isotope thermometry

K.E. SNELL1, J.M. EILER2, D. DETTMAN3 AND P.L. KOCH1

1University of California Santa Cruz, Earth and Planetary Science Dept. (ksnell@pmc.ucsc.edu)
2California Institute of Technology, Div. of Geological and Planetary Sciences (eiler@gps.caltech.edu)
3University of Arizona, Dept. of Geosciences

We used carbonate clumped isotope thermometry to constrain growth temperatures of paleosol carbonates and fossil unionid bivalves collected from the Big Horn Basin (Wyoming) from sections that span the Paleocene-Eocene boundary. Long-term global warming of ~10°C occurred from the Late Paleocene to the Early Eocene. The Paleocene-Eocene Thermal Maximum (PETM) is an extreme thermal event of short duration (< 200 ky) superimposed on the long-term warming trend, and has been identified globally in the ocean sediment record and on the continents in sedimentary basins. The Big Horn Basin is one such basin that has been extensively studied with multiple climatic and biotic proxies in an attempt to characterize the PETM. Therefore, it is an ideal case study for the new paleothermometry technique we use here.

Temperature estimates for the paleosol carbonates capture the pattern of temperature change through time suggested by other paleotemperature proxies, but are consistently higher than previous estimates. Temperature estimates from the fossil mollusk shells, however, are too high to reflect original climatic conditions and do not mimic the stratigraphic change in temperature seen in other proxies. These samples were buried to > 1 km and subsequently exhumed. Our results suggest the paleosol carbonate samples were not dramatically reset by burial metamorphism, whereas the mollusk fossil carbonate was reset by re-crystallization or other processes. We speculate that carbonate that originally forms as calcite is more resistant to resetting during burial metamorphism than carbonate initially formed as metastable aragonite. Although X-ray diffraction analyses detected primary aragonite and no calcite in these fossil mollusks, trace metal analysis and more detailed SEM and/or XRD studies may be required to identify sufficiently unaltered fossil mollusks, if they exist (Came et al., in revision, 2007). We conclude that the soil carbonate data constrain continental climate across the Paleocene to Eocene transition. In addition, the contrast between soil carbonates and fossil mollusks provides an important first case study of the relative ability of different forms of carbonate to retain primary temperatures as measured by clumped isotope thermometry.

Melt inclusions and host olivines: What do they tell about mantle processes and sources?
ALEXANDER V. SOBOLEV

1Vernadsky Institute of Geochemistry, Moscow, Russia, (sobolev@geokhi.ru)
2Max-Planck-Institut für Chemie, Mainz, Germany

Host olivines and magmatic (melt and fluid) inclusion studies have had significant impact on petrology and geochemistry of mantle-related igneous processes in recent years. This includes better understanding of melting processes, source heterogeneities, and volatile contents of parental melts. At the same time, new results have shown possible processes (such as magma mixing and interaction with crustal materials) which appear to compromise the idea that melt inclusions represent simple primary liquids (e.g. Danyushevsky et al., 2003). Here I present a summary of last 5 years studies of our group concerning compositions of melt inclusions and host olivines from the mantle plume, LIP and MOR environments.

Melt inclusions in olivines are likely trapped during relatively fast growth of crystals in the environments of significant temperature and (or) compositional gradients such as magma mixing. Compositional variability of melt inclusions far exceeds variability of lavas representing end-members commonly present in bulk rock in highly attenuated form. Melt inclusions of variable compositions coexisting in a single olivine phenocryst are often trapped sequentially at different depths. This suggests complicated multistage crystallization and trapping process rather than nearly simultaneous trapping of locally heterogeneous melts.

Data suggest that each volcanic plumbing system or particular lava represents dynamic mixing of numerous parental melts and products of their fractionation and (or) interaction with crystal mashes and melts in shallow conduits. Some inclusions approach primary melt compositions much better then any studied rocks. These inclusions show extreme compositional ranges far exceeding those of bulk surface lavas. They are usually trapped in the earliest crystals formed in the deepest parts of plumbing system. The compositional and isotopic ranges of the recovered parental melts suggest highly efficient open system melting; fast melt transport and compositional heterogeneity of mantle sources in all volcanic environments studied so far. In particular the concentrations of Mn, Ni, Ca, Zn and Sc of early olivine phenocrysts from wide range of mantle derived melts are not consistent with common peridotitic source and suggest significant amount olivine-free hydride pyroxenite source formed by melting and reaction of recycled crustal component in the convecting mantle (Sobolev et al., 2005, 2007).

Recycled oceanic crust as a source of Siberian flood basalts
A.V. SOBOLEV1,2, N.A. KRIVOLUTSKAYA1, D.V. KUZMIN2 AND A.W. HOFMANN2

1Vernadsky Institute of Geochemistry, Moscow, Russia, (sobolev@geokhi.ru)
2Max-Planck-Institut für Chemie, Mainz, Germany

Recent study (Sobolev et al., 2007) has shown that Gudchikhinskaya suite (Gd2) from the base of Siberian flood basalts in Norilsk region likely formed by melting of olivine-free hybrid pyroxenite, produced by reaction of melts from recycled crust and peridotite. Here we present new data on major and trace element compositions and volatile contents in parental melts for Gd2 basaltic suite recovered from the study of homogenised melt inclusions in olivine phenocrysts by EPMA, LA-ICP MS and SIMS. We show that the composition of trapped melt varies from similar to tholeiitic OIB (e.g. Mauna Loa, Hawaii) with notable depletion in Pb, U, Th and Rb to those enriched in these elements (Fig.1). Abundances of these elements correlate with concentrations of Si, K (positively) and Nb, Ti (negatively). This suggests significant contamination of melt by continental crust during magma fractionation. All melts are severely undersaturated by S and contain low water concentrations.

The composition of melts unaffected by crustal contamination indicate oceanic crustal component. This suggests that the recycled oceanic crust was a major source of Siberian flood basalts at the initial stage of LIP formation.

Figure 1: Average compositions of melt inclusions in olivine from Gd2 picrites (2 samples) compared with continental crust (Rudnik, 2003) and typical Mauna Loa melt (Sobolev et al., 2005) normalized to primitive mantle (Hofmann, 1988).

Evidence for correlation of late CFBs from East Greenland and the Faeroe Islands (North Atlantic Igneous Province)

N. SOAGER AND P.M. HOLM

Institute of Geography and Geology, University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen, Denmark (mina@soeager.dk)

The Faeroe Islands formed early as part of the North Atlantic Igneous Province (NAIP) and is composed of a 4-5km thick basaltic lava sequence erupted before and during continental breakup ~56-55 Ma ago (Storey et al. 2007). The present dataset represents the syn-breakup part of the sequence and comprises both enriched high-Ti plume related basalts and depleted MORB-like low-Ti basalts. The Faroese lavapile has earlier been correlated geochemically with the East Greenland Paleogene lavaseries from Kangerlussuak and Blosseville Coast by Larsen et al. (1999), where the Faroes Middle and Upper Formations were correlated with the Milne Land Formation (MLF) from East Greenland. New data from the southern island of Søndøy on the Faroe Islands shows that thin counterparts of the East Greenland Geikie Plateau Formation (GPF) and Rømer Fjord Formation (RFF) are present on the Faeroe Islands in the very top of the sequence. The correlation is based on variations in Zr/Nb and 206Pb/204Pb and is also consistent with petrological observations that GPF and RFF lavas are mainly aphyric and RFF lavas have lower depleted MORB-like low-Ti lavas can be modelled as mixtures between a MORB source and a component identical with the NAEM composition of Ellam and Stuart (2000). The proposed Icelandic depleted plume end-member ID1 (Thirlwall et al. 2004) does not seem to be present in the Paleogene lavas which is an argument against its existence.

Occurrence and origin of igneous fragments in chondritic breccias

A.K. SOKOL1,3, M. CHAUSSIDON2, A. BISCHOFF1 AND K. MEZGER3

1Institut für Planetologie, Münster, Germany (sokola@uni-muenster.de; bischoa@uni-muenster.de)
2CRPG, Nancy, France (chochoc@crpg.cnrs-nancy.fr)
3Institut für Mineralogie, Münster, Germany (klaush@nwz.uni-muenster.de)

The ordinary chondrite breccias Adzhi-Bogdo (LL3-6) and Study Butte (H3-6) contain igneous-textured inclusions that are best described as alkali-granitoids in Adzhi-Bogdo (Bischoff et al., 1993) and andesite in Study Butte (Fredriksson et al., 1989). Both the granitoids and the andesite appear to have been formed by melting and magmatic differentiation on a parent body and indicate mixing of achnodratic fragments with chondritic components.

Al-Mg isotope data for these igneous-textured clasts reveal no evidence for radiogenic 26Mg and indicate that the formation of these igneous clasts, the incorporation into the parent body regolith, and the lithification must have occurred late, after almost all 26Al had decayed (Sokol et al., 2007).

Oxygen isotope ratios of plagioclase, quartz and pyroxene in the fragments were measured in situ with the CRPG-CNRS Cameca IMS 1270 ion microprobe. On a three-O isotope diagram all fragments fall in the range of ordinary chondrites (Fig 1). These results imply that the fragments derive from an ordinary chondrite precursor and that the granitic fragments may have formed on the same parent body as the surrounding host rock material. The andesite seems to derive from a LL chondrite in contrast to its host rock (which is H3-6). This in turn indicates that melt formation and extreme differentiation occurred on ordinary chondrite parent bodies in the early stage of solar solar system formation. Alternatively, the fragments may have formed on another parent body but within the same oxygen isotope region of the solar nebula. In this case, they may represent projectile fragments within the chondritic breccias.

New approaches to geochemical exploration for deep-seated and covered mineral deposits

S.V. SOKOLOV, A.G. MARCHENKO, S.S. SHEVCHENKO, V.YU. MAKAROVA AND V.O. ILCHENKO

A.P. Karpinsky Russian Geological Research Institute
(VSEGEI), St.-Petersburg, Russia
(sergey_sokolov@vsegei.ru,
alexey_marchenko@vsegei.ru,
sergey_shevchenko@vsegei.ru,
yuliya_makarova@vsegei.ru,
vadim_ilchenko@vsegei.ru)

At present, because of the urgent need to carry out exploration for deep-seated mineral deposits, as well as deposits within areas covered by drifts, it is necessary to create and develop new geochemical techniques which are deep-penetrating ones and enable revelation of such concealed ore deposits. Routine geochemical prospecting surveys are not effective enough in such terrains due to low contrast or absence of geochemical anomalies related to ores.

Among the deep-penetrating geochemical methods based on the phenomenon of jet-flow vertical migration of chemical elements from the deep to the surface resulting in superimposed dispersion halos formation, is the Method of Analysis of Superfine Fraction (MASF) developed in VSEGEI that uses extraction and analysis of superfine fraction of soils (<3-10 μm) where superimposed dispersion halos occur. These halos are predominantly created by the process of secondary fixation of mobile forms of elements due to the sorption of metals from the gaseous and water upward flows by clays, Fe and Mn hydroxides, and other natural substances. MASF surveys use sampling of definite horizons of soils and/or stream sediments, extraction of superfine fraction from samples by means of special technology, determination of contents of indicator elements using ICP-AES, ICP-MS, AAA with specific sample preparation, and geochemical data processing and interpretation with the help of original algorithms.

Another perspective technique is the geochemical prospecting using water-extractable and weak-acid-extractable forms of chemical elements (mobile ions) from soils and stream sediments. Results of our survey carried out in the Far East region has shown that most reliable prediction of gold mineralization can be distinguished by getting together data obtained by both mentioned deep-penetrating geochemical techniques.

Nisa granitic massif: SHRIMP zircon U-Pb age and source constraints

A.R. SOLA1, I.S. WILLIAMS2, A.M.R. NEIVA3

1Dep. Geologia, INETI, Portugal, (rita.sola@ineti.pt)
2RSES, ANU, Australia, (ian.williams@anu.edu.au)
3Dep. Cências da Terra, Univ Coimbra, Portugal, (neiva@ct.uc.pt)

The Nisa granitic massif crops out over an area of 1000 km² in SW Iberia. It is a zoned batholith dominated by a rim consisting of very coarse-grained porphyritic two mica S-type monzogranite-syenogranite and a discontinuous core of very fine-grained 1-type tonalite-granodiorite. To constrain the age relationships and petrologic processes responsible for this zonation, SHRIMP 206Pb/238U zircon ages were obtained for the monzogranite and tonalite. Zircons from the monzogranite are typical of granitic rocks and can be broadly classified into three texturally and chemically distinct types: 1) high-U, low Th/U overgrews (307.4 ± 4.0 Ma); 2) moderate U and Th/U zircon with concentric zoning occurring both as inner overgrowths and whole grains (305.4 ± 6.2 Ma) and 3) texturally discordant cores (309.0 ± 4.6 Ma and inherited). It was impossible to identify in advance, on any textural basis, which cores were ‘young’ or inherited. Despite textural and compositional contrasts the three “young” zircon types have mutually indistinguishable ages. Zircons 1) and 2) represent different stages of igneous zircon growth and zircon 3) must represent an earlier stage of growth. Either the protolith of the monzogranite contained some zircon slightly older than the monzogranite itself or zircon grew in two stages, separated by a period of zircon undersaturation. The former hypothesis seems to be unrealistic in the regional geological context. The latter would be possible if the magma was reheated soon after cooling to the point of zircon saturation. This is consistent with the dissolution features found in some of both older and younger cores. There is a very marked chemical contrast between zircons 1) and 2), as Th/U in 1) is almost 10x lower than in 2), which is compatible with saturation of monazite at a late stage of crystallization and/or the presence of U-rich fluid soon after the monzogranite was intruded. The inherited old cores fall broadly into Neoproterozoic, near concordant ages (506–661 Ma), and Paleoproterozoic and older, mostly discordant ages (1.85–2.55 Ga). There is a noticeable absence of Mesoproterozoic ages, which is significant in a regional geodynamic context. In contrast, zircons from the tonalite have banded zoning that is typical of zircon from mafic igneous rocks, and inherited cores were not found. Further, their Th/U is generally >1, higher than in zircon from the monzogranite. Their age, 306.2 ± 3.0 Ma, overlaps the ages of the three generations of zircon from the monzogranite, but zircon features suggest different sources for these two granitoids. The tonalite protolith might have been a more refractory level that melted soon after the crystallization of the “young” zircon cores from the monzogranite due to an increase in temperature (causing zircon dissolution). Tonalite in the core of the batholith probably intruded immediately after the dominant monzogranite rim.
Land ocean interactions in a coastal embayment, Kaneohe Bay, Hawaii: Nutrient dynamics, productivity, and CO$_2$ exchange between seawater and atmosphere

R. F. SOLOMON$^1$, C.E. OSTRANDER$^1$, E. HEINEN DE CARLO$^1$, M.A. MCMANUS$^1$, F.T. MACKENZIE$^1$, K.E. FAGAN, C. SABINE$^2$ and R.A. FEELY$^2$

$^1$Department of Oceanography, University of Hawaii, Honolulu, HI 96822, USA; (edecarlo@soest.hawaii.edu)
$^2$NOAA PMEL, 7600 Sand Point Way NE, Seattle, WA 98115 USA

Human activities throughout the past two centuries have generated large increases in the atmospheric content of greenhouse gases, leading to higher global mean surface temperatures. The warming of oceans may increase the frequency of storms, which facilitate the transfer of nutrients, sediment, and pollutants from rivers into coastal ecosystems. Increased oceanic CO$_2$ concentrations attributable to anthropogenic input lower the saturation state of seawater with respect to carbonate minerals, can cause “ocean acidification” and have been argued by some to negatively impact calcification (e.g., Kleypas, 1999; Orr, 2005). Coastal areas and estuaries, however, may be either net annual sources or sinks of atmospheric CO$_2$ (-41 to 7.3 Mole C m$^{-2}$ yr$^{-1}$, Mackenzie and Lerman, 2006).

We present here results from 18 months of observations at CRIMP-CO$_2$, a collaborative effort in Kaneohe Bay, Hawaii between UH Manoa and NOAA/PMEL. This buoy was the first coastal buoy of the NOAA/PMEL-CO$_2$ program. CRIMP-CO$_2$ has documented the response of bay waters to pulsed inputs throughout a La Niña winter season (2005-06) and the much drier winter of 2006-07. The evolution of bay waters following storm-derived inputs was studied, along with the impacts of blooms and physical forcing on the air-sea exchange of CO$_2$. Physical forcing strongly influences system response, in particular stratification and mixing, hence controls both the duration of blooms and attendant changes in CO$_2$ concentration. Southern Kaneohe Bay often becomes a CO$_2$ sink following storm inputs (0.2-0.7 m Mole C m$^{-2}$ hr$^{-1}$), but remained a net source of CO$_2$ to the atmosphere (-1.06 Mole C m$^{-2}$ yr$^{-1}$) throughout our study period. This result is similar to estimates from Hog Reef flat in Bermuda and from the Scheldt Estuary plume (-1.2 and -1.1 to -1.9 Mole C m$^{-2}$ yr$^{-1}$, respectively, Mackenzie and Lerman, 2006).

Diamonds, xenoliths and kimberlites:
A window into the Earth’s Mantle.

UNESCO IGCP 557

HOLGER SOMMER$^1$, KLAUS REGENAUER-LIEB$^2$ AND CHRISTOPH HAUZENBERGER$^3$

$^1$Department of Geology, University of Botswana, Private Bag 0022, Gaborone, Botswana (sommerr@mopipi.ub.bw)
$^2$CSIRO Exploration & Mining, PO Box 1130, Bentley, WA 6102, Australia (klaus.regenauer-lieb@csiro.au)
$^3$Institut für Erdwissenschaften, Universität Graz, Universitätsplatz 2/I, A-8010 Graz, Austria (christoph.hauzenberger@uni-graz.at)

The principal aim of this study is to develop a dynamic process based understanding for the formation of the e- and p-type diamonds. A joint study of the petrology and geodynamics of diamond bearing rocks is thus understood as a space-time window for unravelling deep processes in the Earth’s Upper Mantle. Our assessment aims particularly at the migration paths of hydrogen in nominally OH-free minerals in xenoliths, their geological/geodynamic setting as well as their petrological evolution. Recently, a 3-D dimensional modelling tool for understanding the geometry of a subduction zones was developed (Morra, et al., 2006). The new method comprises a novel Finite-Element/Boundary Element method (FEM/BEM) coupled to a thermodynamic solver (PERPLEX). The primary target of the code was to give a quantitative tool for modelling mantle tomography and geodynamics using the constraint of phase equilibria. Although the simulations are mainly geared at subduction/collision environments, both methods can be used in a much broader sense and thus provide a unique opportunity to test geodynamic settings for diamond formation in a truly quantitative manner. The strength of the FEM-BEM method of Morra and Regenauer-Lieb (2006), lies in the fact that the physical parameters derived from thermodynamic calculations provide a robust tool for predicting a geodynamic processes. In our approach, density contrasts and mineral chemical compositions are used for driving geodynamic processes occurring in a subduction zone. Material parameters, are equally derived and complemented by the best of our knowledge on rheological properties of rocks from laboratory data. We propose to compare the predicted phases with in situ observations using multi-scale laboratory analyses complemented by a high resolution synchrotron based FT-IR analysis to derive passage of aqueous fluids through the lithosphere. This latter technique has proven to be very powerful to map the formation of mineral inclusions in mantle minerals such olivine. The project is carried out under the auspices of an international UNESCO IGCP557 collaboration involving a large group of international scientists.

High sea bed methane emission rates at Hikurangi margin (New Zealand) associated with extremely dense populations of ampharetid polychaetes

S. SOMMER¹, P. LINKE¹, O. PFANNKUCHE¹, D. BOWDEN², J. GREINERT³ AND M. HAECKEL¹

¹Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, Germany, (ssommer@ifm-geomar.de, plinke@ifm-geomar.de, opfannkuche@ifm-geomar.de, mhaeckel@ifm-geomar.de)
²National Institute of Water & Atmospheric Research, Wellington, New Zealand (d.bowden@niwa.co.nz)
³Institute of Geological & Nuclear Sciences Ltd, Lower Hutt, New Zealand, (j.greinert@gns.cri.nz)

Occurrence of gas hydrates and gas seepage from Hikurangi margin sediments has been inferred from BSR structures, methane derived carbonates, gas flares in the water column, and the presence of chemosynthetic bivalve mollusks. Apart from these geophysical indications and sporadic observations by fishermen and scientific dredge samples, detailed biogeochemical studies are missing. We determined the in situ sea bed methane emission and associated fluxes of oxygen, nitrate, sulfate and sulfide at 3 different locations along the Hikurangi margin in water depths ranging from 662 to 1104 m using GEOMAR lander technology. Highest sea bed methane emissions of up to 203 mmol m⁻² d⁻¹ were associated with extremely high abundances of ampharetid polychaetes (10³20 ind. m⁻²), highly elevated total oxygen uptake rates (up to 98 mmol m⁻² d⁻¹) and steep pore water gradients of methane, oxygen, sulfate and sulfide. Although members of the family Ampharetidae have been also reported from other cold seep sites and whale falls, this is to the best of our knowledge the first record where these polychaetes constitute key organisms of a cold seep environment. The distribution of the ampharetids was restricted to spatially highly confined patches of darkened sediment at the fringe of extended carbonate concretions. Close to these sites expulsion of free gas from the sea bed has been observed. They live in tubes of organic material that penetrate about 3 cm deep into the sediment. Density and spatial arrangement of their tubes, that extend a few millimeters into the water column, likely affects the current regime of the bottom contact water and therewith physical sediment properties and in consequence the exchange of solutes across the sediment-water interface. Micro gradients of oxygen and sulfide indicate further solute transport along the tubes. Both mechanisms might largely affect methane carbon turnover and release from this particular environment.

Sequential oxidation of arsenite by both permanganate and the reaction byproduct

K.S. SONG¹,², G. LEE¹, S.Y. KIM² AND C.H. EUM²

¹Department of Earth System Science, Yonsei University, Seoul, Korea (ghlee@yonsei.ac.kr)
²KIGAM, Daejeon 305-350, Korea (kssong@kigam.re.kr, sykim@kigam.re.kr, cheum@kigam.re.kr)

Arsenic contamination of soil, surface- and groundwater is of serious concern over the world because of its toxicity and carcinogenicity. One of the most effective ways to remove As from water is to oxidize it to less mobile and less toxic As(V), which can be subsequently immobilized by sorption to various sorbents. This study investigates the effects of permanganate on the oxidation of As(III) at pH 4 and 8 at varying doses of As(III) (10 or 100 µM) and permanganate (1 – 170 µM) in 0.01 M NaNO₃. The solution pH was adjusted to the desired values using 10 mM of either monobasic or dibasic phosphate buffer with 10 mM HNO₃.

The oxidation of As(III) by permanganate at the stoichiometric ratio of As(III) to Mn(VII) (i.e., 3:2 for As(III) oxidation to As(V) with an assumption of Mn(VII) reduction to Mn(IV)-oxide) or at excessive Mn(VII) concentrations is instantaneous at both pH's. In addition, the ratio of oxidized As(III) to reduced Mn(VII) is ca. 2:1, indicating the reaction product is probably Mn(III)-oxide/oxyhydroxide. When As(III) dose exceeds Mn(VII) concentration at pH 8, the excess As(III) is further oxidized by the primary reaction product, which is thereby reduced to dissolved Mn(II). This subsequent heterogeneous reaction between the excess of As(III) and the manganese solid byproduct is slower than the primary reaction. These results indicate that permanganate may be an effective and efficient reagent for As(III) oxidation in water treatment processes.
Study on 3-D crustal structure in the area along Yangtze River: The significance to multi-metal mineralization
S.Y. Song and E.G. Gao
CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University Science and Technology of China, Hefei 230026, China (grg@ustc.edu.cn)

Introduction
The complex structure characteristics of the area along the Yangtze River in Anhui Province is located in the convergent collision belt formed by two big tectonic plates, which are North China Plate and Yangtze plate. Plenty of mineral sources were generated in the duration of the frequent magmatic activities in this area. Therefore, it has a significant meaning in the exploring mineral sources to get a comprehensive view of the 3-D crustal structure. Based on the inversion and integrated interpretation of six geophysical profiles across this area, we obtain the 3-D characteristics about the crustal structure in Anhui Province along Yangtze River.

Data Processing and Results
Taking the crustal structure of Yangtze Plate as the frame, and combining with the geological strata or tectonic units, the initial model containing the different blocks was designed. Taking the exsisting partially seismic profile interpretation as the constraint condition, gravity and magnetic robust iterative inversion and the 3-D crustal structure integrated interpretation are carried out in the six geophysical profiles across the entire area. Several conclusions were obtained as follows: (1) The crustal structure has the obvious three layers overally, namely the upper crust, the mid-crust and the lower crust. (2) The upper crust, with a violent changing structure, has deposited the relative thicker cap rock. The partial area may hit 10km, with the character of the low velocity, low resistivity, low density and low magnetism (V: 5.7~5.8 km/s, \( \rho_s: 1000~1500 \)Ωm, \( \sigma_s: 3.0~3.2 \times 10^3 \)kg/m\(^3\), J: 10\(^{-8}\)~10\(^{-7}\)A/m). (3) The mid crust has the top depth generally below 10 km and the bottom depth generally about 20 km, with the characteristics of high velocity, high resistivity, high density and high magnetism (V: 6.0~7.0 km/s, \( \rho_s: 1000~1500 \)Ωm, \( \sigma_s: 2.9~3.0 \times 10^3 \)kg/m\(^3\), J: n×A/m), differently from the upper crust. (4) The lower crust, with an average of 12 km depth, has the character of high velocity, high resistivity and high density (V: 6.8~7.6 km/s, \( \rho_s: 10^3~10^4 \)Ωm, \( \sigma_s: 3.0~3.2 \) kg/m\(^3\)). The Curie surface is in this layer. This study has significance to multi-metal mineralization.

Historical variations in zinc stable isotope compositions of smelter polluted sediments
Jeroen E. Sonke\(^1\), Yann Sivry\(^1\), Jerome Viers\(^1\), Stéphane Audry\(^1\), Leon Dejonghe\(^2\), Luc André\(^3\), Jürgen Elckerlyc\(^4\), Jörg Schäfer\(^5\), Gérard Blanc\(^6\) and Bernard Dupré\(^1\)

1LMTG, Toulouse, France (sonke@lmtg.obs-mip.fr)
2Geological Survey of Belgium, RBINS, Brussels, Belgium
3Royal Museum of Central Africa, Tervuren, Belgium
4Department of Earth Sciences, UC Santa Cruz, USA
5Universitee Bordeaux I, Talence, France

Two case studies were carried out to investigate the use of zinc stable isotopes as tracers for industrial smelter sources and processes: 1) two organic sediment cores obtained 800 m from the former pyrometallurgical zinc smelter of Lommel (Belgium), which received exclusively atmospheric inputs, and 2) two dam lake sediment cores taken 15 km downstream and 30 km downstream of the former pyro/hydro-metallurgical zinc plant of Viviez (France), which received predominantly riverine dissolved Zn and particulate Zn inputs. Zinc isotopic compositions were measured on the LMTG Thermo-Finnigan Neptune MC-ICPMS in Toulouse and expressed as per mille deviations from the JMC 3-0749L standard. In case 1 atmospheric pre-industrial deposits have \( \delta^{66}Zn = +0.31\pm0.09 \)‰ (2sd). Deposits dated from 1900-1930 have \( \delta^{66}Zn = +0.29\pm0.06 \)%o (2sd), and sediments dated from 1956-1995 shift to lighter isotopic compositions of \( \delta^{66}Zn = +0.13\pm0.08 \)%o (2sd) in 1968. 42 ZnS minerals from ore import dominating Australian and African mines yield, together with literature ZnS data, a grand average of \( \delta^{66}Zn = +0.16\pm0.07 \)%o 2se, n=83 for ZnS. Emission control since 1955 is a likely cause for the \( \delta^{66}Zn \) sediment shift. In case 2 the polluted riverine sediments dated from 1952-2002 have elevated \( \delta^{66}Zn \) of +0.75 to +1.32‰ relative to the geochemical background \( \delta^{66}Zn = 0.33\pm0.06 \)‰ (2sd). Mine tailing slag samples also had elevated \( \delta^{66}Zn \) ranging from +0.18 to +1.49‰. In summary we show that 1. Bulk ZnS ore minerals have homogeneous \( \delta^{66}Zn \). 2. Zinc refinery processes fractionate Zn isotopes: slags are enriched in heavy isotopes. 3. near-field (<1 km) atmospheric deposition resembles ZnS ores, far-field carries isotopically light Zn, and mine tailing drainage carries heavy Zn.
**Diffusion profiles of Li in plagioclase/clinopyroxene and plagioclase/olivine intergrowths**

I. Sonntag¹, T. Ludwig² and R. Altherr³

¹Mineralogisches Institut, Universität Heidelberg, INF 236, (iris.sonntag@min.uni-heidelberg.de)

Diffusion in magmatic systems occurs during crystal growth, magma mixing and ascent. In some magmatic crystals diffusion profiles are preserved. These profiles provide information about the timescales of magmatic processes. It is known that Li diffuses very rapidly in plagioclase and clinopyroxene (Giletti and Shanahan 1997, Coogan et al. 2005, Parkinson et al. 2007) and that Li diffuses in plagioclase two to three times faster than in clinopyroxene (Coogan et al. 2005).

This study is focused on the diffusion of Li between intergrown plagioclase/clinopyroxene and plagioclase/olivine. These intergrowths are observed in andesitic and dacitic rocks from the volcanic island Nisyros (Greece). Plagioclase phenocrysts in the andesitic lavas are cloudy zoned with slightly higher An content in the cores, while olivine and clinopyroxene phenocrysts are not zoned. In the dacitic lavas plagioclase phenocrysts have complexly zoned (‘splotchy’) cores and low An rims, while clinopyroxene phenocrysts show nearly no zoning. Both intergrowths of phenocrysts were analysed for Li concentration. Concentration profiles across the minerals were measured using a Cameca ims3f ionprobe with ~ 5 µm lateral resolution.

Li concentration in the dacitic sample jumps at the border of the intergrowth from 10 µg/g in the plagioclase to 44 µg/g in the clinopyroxene and then drops steadily over a distance of 100 µm to 5 µg/g in the clinopyroxene core. Similar patterns are observed for plagioclase/clinopyroxene pairs in other dacitic and andesitic samples. In intergrowths of plagioclase and olivine in andesitic samples, the same Li increase on the border of the crystals is found (7 µg/g in the plagioclase to 13 µg/g in the olivine rim and a slow decrease to 5 µg/g in the core). Preliminary Li isotope measurements reveal negative δ⁷Li values (~ -26‰) in clinopyroxene rims to zero values in the core. Isotope and concentration profiles are estimated to be caused by diffusion at ~ 1000°C and on timescale of only hours.

⁴Institute for Study of the Earth’s Interior, Okayama University, Misasa, Tottori 682-0193, Japan (tatsukix@misasa.okayama-u.ac.jp)

Jadeitite (jadeite rock) occurs rarely in a few serpentinite bodies from worldwide subduction complexes. Geochemical and CL-textural data show that such jadeite crystallizes directly from multiply sourced Na-, Al, and Si-bearing fluids. Both jadeite and lawsonite eclogite occur together in a few serpentinite-matrix mélanges of Guatemala. Also a rare rock, lawsonite eclogite forms under wet, extreme P/T conditions.

Each rock type shows complex fluid-rock interactions. Relationships of jadeite-forming fluids and host rocks are all but unknown—such contacts are rarely preserved. In the Sierra de las Minas, a 3 m-wide pit exposes such a contact, with jadeite and serpentinite respectively altered to albite and meta-ultramafic rocks. At the paleocontact, Zr, U, Hf, Pb, Ba, Sr, Y and Cs are greatly enriched in albite relative to the other rocks. Enrichments coincide with the appearance of and/or increase in abundance and/or grain size of zircon, titanite, celsian and REE-rich epidote in albite. All contain albite inclusions—many appear poikiloblastic—suggesting nucleation/growth of “trace-element-rich grains in albrite.”

Lawsonite eclogite records another fluid-rock system. For example, sample 2-14 (Jalapa dept.) is LREE-rich, with La 50× and Sm 30× Chondrite. It contains lawsonite grains as: 1) 100-300 µm, subidiomorphic inclusions in cores of 3-5 mm garnet; 2) 200-400 µm, irregular grains in garnet; 3) 100-300 µm idiomorphic matrix, partly consumed by amoeboid titanite; 4) 100-300 µm, idiomorphic matrix, with 100-200 µm garnet; and 5) 300-600 µm idiomorphic late veins. Each textural type shows distinct LREE abundances and fractionations, as well as Sr contents and zoning (all by LA-ICPMS). Mass balance suggests only lawsonite (1) reflects “protolith” LREE values. The others manifest LREE redistribution, or deposition of exotic REE.

These data show that Guatemalan serpentinite-matrix mélanges yield field examples of the mobility of “immobile” elements under low-T (300-450°C), high to very high-P (~8-~23 kbar) conditions, in chemically distinct fluids.
Improved in situ measurements of lead isotopes in silicate glasses by LA-MC-ICPMS using multiple ion counters

A.K. SOUDERS AND P.J. SYLVESTER

A new technique that improves the spatial resolution and detection limits of the measurement of lead isotope ratios in silicate glasses with < 15 ppm total Pb by laser ablation-multicollector magnetic sector-inductively coupled plasma mass spectrometry (LA-MC-ICPMS) is presented. The method allows for the concurrent, static measurement of 206Pb, 207Pb, 208Pb, along with 204Hg and 235U, in six Multi-Ion Counters (MICs) fitted on a Finnigan NEPTUNE MC-ICPMS. Use of a collector array consisting only of MICs eliminates the need for cross calibration between Faraday cups and ion counters, as employed in previous methods reporting 204Pb values by LA-MC-ICPMS. Standard-sample-standard bracketing using BCR-2G as the calibrant is used to correct for instrumental mass bias. Accuracy and precision of the method was evaluated by replicate analyses of various MPI-DING reference glasses, with low Pb concentrations (1.38 to 11.6 ppm total Pb) and well-determined isotopic ratios. Typical spot sizes for in situ analyses ranged from 40-69 microns, providing better spatial resolution than previous LA-MC-ICPMS reporting 204Pb. Ablations for all analyses were carried out using a 193 nm ArF GeoLas laser at a repetition rate of 10 Hz and a pulse energy of 5 J/cm². Mercury derived from argon gas is a chronic problem for ICPMS measurements of the minor 204Pb isotope because of the isobaric intereferece by 204Hg. Due to the high sensitivity of the MICs, the Hg-correction of the measured 204Pb mass was significant, especially for samples with < 5 ppm total Pb. Two different methods were used to correct for Hg on the 204Pb mass with the results agreeing within error for each method on all lead isotope ratios. Measured lead isotope ratios for the MPI-DING KL2G (2.07 ppm Pb) and ATHO (5.67 ppm Pb) agree within 0.10% and 0.16% respectively of the accepted values. For MPI-DING KL2G (2.07 ppm Pb) and ML3B (1.38 ppm Pb), measured Pb ratios involving 204Pb agree within 1% of the accepted values with typical precisions of < 2.9% RSD (2 sigma). Measured 208Pb/206Pb and 207Pb/206Pb ratios for KL2G and ML3B are within 0.40% of the accepted values with typical precisions are < 0.75% RSD (2 sigma). The results for KL2G and ML3B demonstrate improvement over previous LA-MC-ICP-MS data in terms of both detection limits and spatial resolution, while retaining similar levels of accuracy and precision. The new method provides the capability of making quantitative in situ lead isotope measurements on tiny objects of geologic interest such as mineral growth bands, melt inclusions, and accessory minerals, even where they are lead poor.

Mineral phase identification of coral skeletal microstructure

K. SOWA, T. WATANABE, Y. SETO, S. MOTAI AND T. NAGAI

Mineral phase identification of the coral skeletal microstructure is important for reconstructing the paleo-climate. Especially, Porites sp. is widely used a paleo-climatic proxy. To reconstructing the paleo-environment, those chemical compositions have been studied as coral thermometry. For example, Sr/Ca ratio in coral skeletons is sensitive to the paleo-environment variant so that Sr/Ca ratio has the possibility as the accuracy archive. However, there are one assumption is that trace elements in coral aragonite originate from solid solution. Gregor et al. (1997) reported that the as much as 40% of strontium (Sr) in coral aragonite existed as a strontianite which was not the solid solution by using X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS). On the other hand, Finch et al. (2003a, 2003) and Allison et al. (2005) showed no evidence of the presence of strontianite or its intermediate state in coral aragonite. They attempted to seek out the strontianite in coral samples using EXAFS. However, XANES and EXAFS could not identify the mineral phase directly. In addition, few studies have referred to mineral phase in coral skeletons with micro scale. X-ray diffraction analysis (XRD) with synchrotron radiation plays a role in detecting the mineral phase identification of coral skeletal microstructure for their strong energy, which enables phase identification with small range of X-ray spots: X-ray spot sizes of this study are 15µm and 40µm.

We performed XRD analysis with synchrotron radiation for coral, Porites sp., living/fossil microstructure. The experiment conducted with imaging plate (IP) on BL-18c at Photon factory, KEK (HIGH ENERGY ACCELERATOR RESEARCH ORGANIZATION), Tsukuba, Japan. A monochromatic incident X-ray beam with a wavelength of 0.616Å was used and was collimated to a diameter of 15µm or 40µm. The two-dimensional IP data were integrated and conducted to one dimensional intensity data.

The size of the centre of calcification (COC) is approximately 30µm in diameter in the samples of this study. That size corresponds to the X-ray spot sizes of this study in 15 or 40µm in diameter, so we got the different mineral structural information between the COC and fibres. All diffraction peaks of COC and fibres can be explained as aragonite, and no significant difference of cell parameters can be observed. This indicates that COC and fibres consist of aragonite: this study could not detect calcite phase.

Survival times of anomalous melt inclusions; Constraints from REE diffusion in olivine and chromite

C. Spandler1, H. St.C. O’Neill2 and V. S. Kamenetsky3

1Institute of Geological Sciences, University of Bern, Bern 3012, Switzerland; Spandler@geo.unibe.ch
2Research School of Earth Sciences, Australian National University, Canberra, 0200, Australia
3ARC Centre of Excellence in Ore Deposits and School of Earth Sciences, University of Tasmania, Hobart, 7001, Australia

It is widely assumed that incompatible element diffusion through olivine and chromite is very slow and hence melt inclusions (MI) hosted in these minerals do not experience diffusive re-equilibration with the external magma. However, at present there are no data on diffusion coefficients for most trace elements in olivine or chromite.

We have conducted experiments at one atmosphere to determine diffusion coefficients for REE in forsteritic olivine and chromite. Clean samples of olivine and chromite that contain well-characterized MI suites were annealed with REE-doped (Pr, Ho, Tb, Lu) synthetic melts for up to 25 days at 1300-1450°C and under controlled fO2. Diffusion profiles were measured across sections of the crystal/synthetic melt boundary by laser-ablation ICP-MS and by electron microprobe. Element concentrations were then fitted to the diffusion equation to obtain diffusion coefficients. Calculated diffusivities for REE are relatively fast (D = 10-15 m²/s at 1300°C), whereas P and Al diffusion appears to be very slow (D <10-18 m²/s at 1300°C).

MI in the olivine and chromite crystals have distinct enrichments in the REE that were doped in the external melts. The systematic degree of enrichment of Lu>Ho>Tb>Pr and correlation between degree of enrichment and MI size and/or experiment duration are all consistent with re-equilibration of these inclusions via lattice diffusion through the host crystal.

Applying our diffusion coefficients to the equations of Qin et al. [1], we calculate that the REE compositions of olivine- or chromite-hosted MI will completely re-equilibrate with external magma in years to decades. These timescales are consistent with the REE enrichment observed in the experimental MI, and are significantly shorter than the times estimated for magma extraction from the mantle or residence in the lower crust. Therefore, anomalous MI must be trapped in the upper crust shortly before eruption. Our results show that the assumption of chemical isolation of incompatible elements in olivine and chromite-hosted MI is not valid, and hence calls for re-evaluation of the popular interpretation that anomalous MI represent preserved samples of unmodified mantle melts.

Biogeochmical insight on the origin of carbonaceous matter in metalliferous lowest Cambrian black shale, South China

J.E. Spangenberg1 and H.E. Frimmel2

1Institute of Mineralogy and Geochemistry, University of Lausanne, BFSH-2, CH-1015 Lausanne, Switzerland, (Jorge.Spangenberg@unil.ch)
2Institute of Mineralogy, University of Würzburg, Germany, (hartwig.frimmel@mail.uni-wuerzburg.de)

Early Cambrian black shale deposits in the Yangtze Platform in South China are, in places, strongly enriched in Ba (~470 Mt barite and witherite), Ni, Mo, V, Co, Cr, Au, U, As, Pb, Zn, Cu, Re, and PGE. Several models have been put forward for explaining the extreme metal enrichment of the ~0.50-0.52 Ga old black shale. These include enrichment by diagenetic fluids, hydrothermal exhalation, extraterrestrial impact, synsedimentary enrichment from seawater, and discharge of petroleum into the basin. This communication presents the first results of a molecular and isotopic organic geochemical study of the metalliferous carbonaceous shale. The new biogeochemical data provide further insight into the source of the hydrocarbons and the formation of the organic matter-metal association.

The TOC content of the analysed samples is between 0.7 and 8.2 wt%. The Rock-Eval parameters were not reliable in most samples because of the low S1 and S2 peaks. The massive aspect of the samples without altered surfaces and coating of metal oxyhydroxides suggest indigeneity of the organic extracts. The δ13C and δ15N ratios of the kerogen range respectively from –31.5 to –35.4‰ V-PDB and from –1.4 to 0.6‰ V-Air. The δ34S values of the organic-solvent soluble molecular sulphur of black shale samples range between 13.9 and 15.8‰ V-CDT, similar to the values obtained for sulphides.

The distribution of saturated HC is characterized by: n-alkanes in the C11–C31 range (maximum at C16) with bimodal distribution with further maxima at C22 or C26 in some samples, slight even-over-odd dominance), moderate to large i-C18 to i-C21 isoprenoid peaks, pronounced unresolved naphthenic humps in the n-C15-22 range, generally pristane and phytane in roughly equal proportion, and alkylcyclohexanes in the range C11 – C26. Some bitumens contain C25-C35 hopanes and C27-C29 steranes, with the latter dominating over the former. Aromatic HC such as alkylbenzenes, naphthalene, and alkynaphthalenes were detected only in very minor concentrations. The δ13C values of n-alkanes and isoprenoids vary between –33 and –25‰. In all samples pristane and phytane are depleted in 13C by up to 6‰ compared to C17 and C18 n-alkanes. All these results are best explained by derivation of hydrocarbons from algal and bacterial mats that were deposited in a saline, anoxic marine environment.
**Chlorine Partitioning: The behavior of Cl in the presence of sulfide-silicate melts and aqueous fluid**

HEATHER A. SPARKS\(^1\), JOHN MAVROGENES\(^{12}\), JEREMY WYKES\(^2\) AND JÖRG HERMANN\(^1\)

\(^1\)Research School of Earth Sciences, Australian National University, Canberra ACT 0200 Australia
(Heather.Sparks@anu.edu.au)
\(^2\)Department of Earth and Marine Sciences, Australian National University, Canberra ACT 0200 Australia

Can sulfide melts exsolve halogen rich fluids? Several ore deposits around the world (eg. Broken Hill, Stillwater, Sudbury and Bushveld) have occurrences of halogen-rich minerals in association with the ore. To help better understand these occurrences, piston cylinder experiments were performed to investigate the partitioning behavior of Cl between coexisting haplogranite and Pb-Fe-Zn-sulfide melts at 0.5 GPa pressure and 810ºC temperature.

In water undersaturated experiments where a Cl doped haplogranite glass was used as the silicate starting material, the Cl was found to partition strongly into the sulfide melt. Here Cl may be acting as a flux within the sulfide melt resulting in lowering its eutectic temperature. Not only is Cl dissolved in the sulfide melt, but as the sulfides crystallize the residual sulfide melt progressively enriches in Cl. In water saturated experiments where Cl was doped into the sulfides, Cl was noticeably absent from both quenched sulfide melt and silicate glass, suggesting strong partitioning into the coexisting aqueous fluid. The results indicate that the partitioning preference of Cl, when in equilibrium with sulfide-silicate melts and aqueous fluid, decreases in the order aqueous fluid - sulfide melt - silicate melt.

These experimental results can be applied to understand the cooling of sulphur- and chlorine-bearing magmatic systems. Initially, Cl will partition into a sulfide melt that coexists with a hydrous silicate melt. Once an aqueous fluid exsolves from the silicate melt – due to decomposition or crystallization at the solidus – Cl will partition into the newly formed fluid causing the sulfides to freeze and crystallize rapidly. The escaping Cl-rich fluid might lead to extensive halogen alteration in the country rocks of the intrusion. The concepts investigated in this study may have significant implications for understanding the evolution of magmas giving rise to copper porphyry deposits and aid in our understanding of halogen-alteration and halogen-rich minerals in major sulfide deposits.

**Planktonic foraminifera: Calcifying microenvironments, diffusive boundary layers and a peek at the event horizon**

H. J. SPERO

Department of Geology, University of California Davis, Davis California, USA (spero@geology.ucdavis.edu)

The planktonic foraminifera, *Orbulina universa*, should be considered the proverbial white rat for researchers studying biomineralization in the marine realm. This protozoan produces a spherical test in a single brief (several hours) calcifying event, that involves organic matrix secretion, rapid calcite precipitation and spine elongation. Chamber thickening in subsequent days is intimately linked to diurnal physiological oscillations related to symbiont photosynthesis and host assemblage respiration which controls large shifts in microenvironment pH (7.8 – 8.8) and [O\(_2\)] (~80-220% air saturation) (Rink, et al., 1998). Interestingly, microelectrode measurements of Ca\(^{2+}\) at the chamber surface show concentrations that are 10% higher than ambient seawater, while [CO\(_2\)] measurements on *O. universa* under dark and light conditions suggest \(\Sigma\)CO\(_2\) varies between ambient (~2 mMol/kg) and ~5 mMol/kg respectively in the boundary layer near the calcifying shell (Köhler-Rink and Kühl, 2005). Together these data point to an active calcium and carbon concentrating mechanism in this species, and may help explain how *O. universa* can calcify in seawater at pH between 7.4 and 8.8 (Bijma, et al., 1999).

Laboratory experiments and stable isotope and trace/minor elemental analyses of *O. universa* demonstrate that shell geochemistry is influenced by physiologically-controlled boundary layer chemistry. Elemental ratio banding, possibly related to the diurnal cycle, as well as observations of non-equilibrium calcite precipitation, provide insight into aspects of calcification that were previously poorly constrained. Together, these observations may provide clues for novel applications of foraminifera geochemistry for paleoenvironmental reconstructions.

Trace elements in garnets of diamondiferous xenoliths from the Nurbinskaya pipe, Yakutia

Z. V. SPETSIUS1, W.L. GRIFFIN2, S.Y. O’REILLY2, AND V.I. BANZERUCK1
1YaNIGP CNIGRI, ALROSA Co. Ltd., Mirny, Yakutia, 678170, Russia, (spetsius@cnigri.alrosa-mir.ru)
2GEMOC ARC National Key Centre, Macquarie University, NSW 2109, Australia, (wgriffin@els.mq.edu.au)

Rare earth elements (REE) and other trace elements were analyzed by LAM-ICPMS in garnets of about 150 mafic and ultramafic diamondiferous xenoliths from the Nurbinskaya pipe. Most garnets are homogeneous in terms of major- and trace-element contents. Garnets from ultramafic xenoliths define two groups, one with sinusoidal REE N (chondrite normalised) patterns (10 harzburgites, two lherzolites) and one with flat MREEN (lherzolites, some websterites).

Most eclogitic garnets have LREE-depleted patterns (Ce N as low as 0.1), and no Eu anomalies. Heavy rare earth elements are variably enriched; most LuN varies 20-50. Most websteritic garnets show REE patterns similar to this but they are typically enriched in LREE with Ce N (0.2-0.5). Garnets with nearly flat HREE and small positive Eu anomalies are common in coesite-bearing eclogites and those containing kyanite and/or corundum [1]. Another group of garnets (n=9) from eclogites and websterites have small negative Eu anomalies. These types of pattern commonly are interpreted as evidence of the reaction of plagioclase to garnet and used to support the origin of mantle eclogites by subduction of oceanic crust [1, 2], but may be simply a redox feature. Garnets from highly aluminous eclogites show convex REE patterns enrichment in LREE and strong depletion of in HREE (YbN<5). Garnets of corundum-bearing eclogites commonly have positive slopes within the LREEN, peaking at Sm and then slowly decreasing to about chondritic abundance for Lu. LAM-ICPMS analysis could be used to show how different populations within an eclogite xenolith series can document the heterogeneous evolution of the lithospheric mantle beneath cratonic areas.

Latest-stage exhumation history of the Central Alps

C. SPIEGEL1, N. DÖRR1, M. RAHN2 AND M. DANIŠÍK1
1Institute of Geosciences, University of Tübingen, Germany (cornelia.spiegel@uni-tuebingen.de, ninadoerr@gmx.de, martin.danisik@uni-tuebingen.de)
2Swiss Federal Nuclear Safety Inspectorate, Villingen, Switzerland (Meinert.Rahn@hsk.ch)

The European Alps, like many other Cenozoic orogens, show a pronounced increase in erosion rages since ~5 Ma. In a recent paper, Willett et al. (2006) proposed that this accelerated erosion was due to enhanced precipitation subsequent to the Messinian salinity crisis and marked the transition from orogenic construction to orogenic destruction.

In this study, the latest-stage exhumation history of the Central Alps was investigated by using zircon fission track (ZFT), apatite fission track (AFT) and apatite (U-Th)/He (AHe) thermochronology along the eastern margin of the Lepontine Dome. The study area covers basement nappes east and west of the Forcola fault, a major Alpine normal fault bordering the Lepontine Dome to the east.

ZFT ages from both east and west of the Forcola fault range between 25 and 16 Ma, with youngest ages occurring close to the fault system. These ages reflect a period of enhanced exhumation related to the onset of orogen-parallel lateral extension of the Alps. The area east of the Forcola yielded AFT ages between 17 and 5 Ma and AHe ages between 7.5 and 6 Ma, whereas the area west of the Forcola yielded AFT ages between 9 and 4 Ma and AHe ages between 6.6 and 3.4 Ma. The age difference between basement nappes east and west of the Forcola normal fault indicates that the fault system has been active (or re-activated) during the Latest Miocene to Pliocene, much later than previously assumed. Late Neogene reactivation, however, has also been observed for the Simplon normal fault west of the Lepontine Dome, which is supposed to be conjugated to the Forcola fault. Age-elevation relationships reveal that the area west of the Forcola fault experienced a period of rapid exhumation between approximately 5.5 to 4 Ma, and that exhumation rates slowed down after ~4 Ma. The period of rapid exhumation is temporally consistent with the increase in deposition rates in the foreland basins, whereas the end of rapid exhumation coincided with the end of deformation in the Jura mountains. These temporal relations support the idea of a Pliocene shift from orogenic construction to orogenic destruction and thus to a decrease of the actively deforming area of the Alps.

Spatial record of recent anthropogenic changes in the sedimentary soils of the Netherlands; Opportunities for a knowledge-based soil legislation framework

J. SPIJKER1, G. VAN DER VEER2 AND G. MOL3

1National Institute of Environment and Health, P.O. Box 1, 3720 BA, Bilthoven, The Netherlands, (Job.Spijker@rivm.nl)
2Department of Earth Sciences, Universiteit Utrecht, P.O. Box 80.021, 3584 CD, Utrecht, The Netherlands, (G.Vanderveer@geo.uu.nl)
3Soil Science Centre, Alterra, PO Box 47, 6700 AA, Wageningen, The Netherlands, (Gerben.Mol@wur.nl)

Much of our knowledge about recent environmental changes – such as the increased anthropogenic emission of various metals – has been inferred from sedimentary records. These paleorecords, however, mainly focus on environmental changes through time. To generalize such changes in a spatial context, geochemical baseline surveys are required.

Using the data from the Geochemical Soil Survey of the Netherlands (Van der Veer, 2006), a geochemical baseline model was developed. The baseline model, based on covariability in pristine sediments, revealed a substantial overall enrichment of metals including Cd, Cu, Hg, Pb and Zn. These enrichments reflect the accumulation of metals in the topsoil compartment as a result of ongoing diffuse input from various anthropogenic sources. The enrichment, generally a factor 2-3 above natural concentrations, varies on a local as well as a regional scale.

Besides tracking environmental changes in a spatial context, the model furthermore offers unique possibilities to derive soil quality standards for a knowledge-based soil legislation framework. In this presentation we will show how the model can be used to derive soil quality standards, and how to take the natural variation of soils, as well as the diffuse enrichment, into account.

Bionergetics of the buried seafloor

ARTHUR J SPIVACK

Graduate School of Oceanography, URI, Narragansett, RI, USA, (spivack@gso.uri.edu)

Major questions in subsurface biosphere research are related to bioenergetics. How much energy is required to support a given amount of biomass? And what is the minimum energy yield of reactions that are biologically utilized? Beyond these, there are related issues, such as, the energetic rules that govern the distribution of subsurface life, in particular, the controls on the distribution and rates of the various energy producing metabolic reactions and the possibility that some buried marine ecosystems rely on radiolytic H2 as their principle electron donor.

In situ metabolic rates and energy yields of diverse microbial activities in sediments of the eastern equatorial Pacific have been determined based on sedimentary pore fluid chemical profiles. Fe and SO42- reduction, and methanogenesis co-occur. These are energetically favorable throughout the sediment column with relatively constant energy yields. Based on this, minimum biologically utilizable energies of reaction can be inferred and it appears that this ecosystem operates as a thermodynamic homeostat.

When combined with reaction rate estimates, based on a numerical solution to the diffusion/reaction continuity equation, these data allow the calculation of an average maintenance energy that is orders of magnitude lower than observed in the laboratory. Based on this, it is inferred that in marine sediments, radiolytic H2 could support approximately 105 while approximately 104 could be supported in a water-saturated sediment that has a U, Th, and K similar to that estimated for the Martian crust.
Plate-tectonic controls on intraplate volcanism in New Zealand

P. SPRUNG, S. SCHUTH AND C. MÜNKER

1Institut fuer Mineralogie, University of Muenster, Germany
(sprungp@uni-muenster.de)
2Mineralogisch-Petrologisches Institut, University of Bonn, Germany

Cretaceous to recent intraplate volcanism in the New Zealand microcontinent provides an ideal case to explore possible factors that exert control on this type of volcanism. Located in the vicinity of the active Australian-Pacific plate boundary, the New Zealand microcontinent exhibits intraplate volcanic activity that is associated with various tectonic regimes: behind an active arc, in domains with predominant strike-slip motion, and in areas that are virtually unaffected by recent plate-tectonic activity.

Based on major-, trace-element-, and Hf-Nd-Pb-Sr isotope compositions of a representative set of near-primitive samples, distinct end member compositions corresponding to different tectonic regimes can be recognized: (1) HIMU-like signatures (206Pb/204Pb up to 20.57, “decoupled” Hf-Nd systematics; e.g., Chatham Islands), (2) dilute HIMU-like trace element signatures and depleted, asthenospheric isotope compositions (εHf: +9.9, εNd: +7.0; North Island), and (3) compositions having affinities to subducted sediments (87Sr/86Sr: 0.7037, 206Pb/204Pb: 18.99, 207Pb/204Pb: 15.67; South Island). The HIMU- and sediment-like signatures are interpreted to originate from a veined lithospheric mantle, reflecting a variable overprint by an ancient, possibly Cretaceous mantle plume and by Phanerozoic subduction zone enrichment.

Variations in the average melting depths of the magmas are manifested in a variable impact of residual garnet (e.g., Gd8/Yb8: 1.84 - 4.74). Changes in relative melting depths reflect variations in lithospheric thickness [1]. The geodynamic setting (lithospheric thickness, heat flow, degree of extension) controls the proportions of asthenospheric and lithospheric source components. For the South Island, magma compositions provide “snapshots” of a decreasing lithospheric mantle plume and by Phanerozoic subduction zone enrichment.

The Podili alkaline complex, Prakasam alkaline province, Andhra Pradesh, southern India

M. SRINIVAS AND A. G. S. REDDY

1Department of Geology, Post-Graduate College of Science, Osmania University, Saifabad, Hyderabad-500004, Andhra Pradesh, India
2Central Ground Water Board, Southern Region, Hyderabad-500 029, Andhra Pradesh, India

The Podili alkaline complex in Prakasam alkaline province of Andhra Pradesh, in the southern India, is one among the cluster of alkaline complexes with a near NE-SW disposition pervading the cratonic corridor that is terminated by intracratonic sedimentary Cuddapah Basin in the west and Eastern Ghat Mobile belt in the east.

This N-S trending complex (12 km²) has a close spatial and temporal association with granites and gabbros that represents the manifestations of basic, acidic and alkaline magmatism.

Alkaline syenite, and subordinate quartz syenite constitute the important lithounits of the complex. The syenites are leucocratic dominated by microcline mesoperthite, plagioclase feldspar, quartz. The mafic minerals are alkali pyriboles and biotite with subordinate magnetite, sphene and apatite. The mafic minerals attribute to the alkaline and hydrous nature of parental liquids.

The syenites are of different degrees of silica saturation, and alkali syenites in particular carry normative nepheline and acmite, an indication of the peralkaline trait possibly inherited from the parental alkaline magma, either by prolonged differentiation or lowest degree of partial melting of an enriched/fertile mantle source.

Soil contamination due to heavy metals from tannery industries: A case study of Jajmau (Kanpur) and Unnao industrial areas, Uttar Pradesh, India

S. Srinivasa Gowd, N.N. Murthy and Pradip K. Govil
National Geophysical Research Institute (NGRI), Hyderabad, India

Environmental geochemical studies were carried out in and around Jajmau (Kanpur) and Unnao industrial areas, to find out the extent of chemical pollution in soil due to waste disposal from tannery industries. There are more than 2500 tanneries in the country and nearly 80% of them are engaged in the chrome tanning process. In Uttar Pradesh, Jajmau (Kanpur) and Unnao (80°18’ – 80°30’ E longitude and 26°25’ – 26°34’ N latitude) are prominent centers for leather processing and there are two clusters of tannery industries (about 450) along the banks of river Ganga. Geologically the study area is covered by alluvium of Quaternary age consisting of older alluvium of middle to upper Pleistocene and newer alluvium of Holocene and the climate of the study area is semi-arid type.

Fifty-three soil samples were collected from Jajmau (Kanpur) and Unnao industrial areas from top 10 cm layer of the soil and were analyzed for heavy metals by using Philips PW 2440 X-ray fluorescence spectrometer. The data reveals that the soil in this area is significantly contaminated, and shows very high concentrations of chromium ranging from 162 to 60819 mg/kg (14535 mg/kg average). Other heavy metals such as Ba ranges 44-781 mg/kg (295.7 mg/kg average), Cu 1.7-126 mg/kg (42.9 mg/kg average), Pb 22-68 mg/kg (40.4 mg/kg average), Sr 47-151 mg/kg (105.3 mg/kg average), V 1.3-209 mg/kg (54.4 mg/kg average) and Zn 44-688 mg/kg (159.9 mg/kg average). High concentrations of these toxic/heavy metals are contributors for the degradation of human health in the study area and people suffer from occupational diseases such as asthma, chromium ulcers and skin diseases. Distribution and correlation of heavy metals in soil along with possible remedial measures are discussed.

New constraints on the origin of short-lived radioactive nuclides in the early solar system

Gopal Srinivasan1, Marc Chaussidon2* and Addi Bischoff3

1Department of Geology, University of Toronto, Toronto, ONM5S3B1, Canada; (srini@geology.utoronto.ca)
2CRPG-CNRS, BP20, 54501 Vandoeuvre-lès-Nancy, France; (chocho@crpg.cnrs-nancy.fr)
3Institut für Planetologie, Wilhelm-Klemm-Strass 10, 48149 Münster, Germany; (bischoa@uni-muenster.de)

The presence of several short-lived radioactive nuclides (10Be, 26Al, 26Cl, 41Ca, 53Mn, 60Fe) in the early solar system is established from the presence of their decay products in constituents of primitive meteorites such as Ca-Al-rich inclusions (CAIs). These nuclides are either (i) the products of stellar nucleosynthesis (as demonstrated by the presence of 60Fe) and were injected in the protosolar cloud before or during its collapse or (ii) the result of interactions of energetic particles (as demonstrated by the presence of 10Be) with gas and dust either in the protosolar nebula or in the presolar cloud. As shown by X-ray observations of young stellar objects, one obvious source of an intense flux of accelerated particles in the protosolar nebula is the young active Sun. CAIs being the oldest solids formed in the solar system, they may have formed close to the young Sun and may contain a record of these irradiation processes. Understanding the origin of short-lived radioactive nuclides is thus fundamental not only for early solar system chronology but also for deciphering the astrophysical context of the formation of the first solids in the early solar system.

We report Li, B and Mg isotopic analyses by ion microprobe ( Cameca ims 1270) of a set of various CAIs from the CH chondrite Acfer 182 and CV3 chondrite Efremovka, including some hibonite-rich CAIs which because of their refractory composition are considered to be among the earliest CAIs. The hibonite-rich CAIs have lower 26Al/27Al ratios (<1.1±0.5×10-5) than the classical type B CAIs from Efremovka (e.g. CAI E66 which has a 26Al/27Al ratio of 5.49±0.15×10-5). The 10Be/9Be ratios are lower by a factor of two in hibonite-rich CAIs compared to Efremovka type B CAIs (e.g. 10Be/9Be=1.2±0.3×10-5 in E65). These data show that 26Al and 10Be are likely decoupled in the early solar system. The low 26Al/27Al ratios in hibonite-rich CAIs may reflect the steady state abundance of 26Al in the local interstellar medium. The hibonite-rich CAIs show a systematic slight but significant 6Li enrichment indicative of the presence of a component produced by spallation. This can be used to put a higher limit on the amount of 10Be which could have been produced in the presolar molecular cloud by trapping of galactic cosmic rays.
Water structure and exchange kinetics are important to a number of fundamental geochemical processes. For example, the rate of dissolution of isosstructural materials often correlates with the rate of water exchange on the aqueous cation. However, thus far most computational studies have focused on structure of the mineral surface. Water structure and kinetics are less often studied, yet are necessary to understand such basic properties of the interface such as adsorption energy. In this work, we use an existing molecular dynamics potential model [1] to estimate the water structure and exchange kinetics of aqueous barium ion on the barite \{001\} surface.

Water exchange kinetics were using a correlation function as well as the potential of mean force and a reactive flux. The latter methods involve calculating a transition state theory rate constant through integrating a free energy of activation estimated from a radial distribution function and a transmission coefficient estimated via a reactive flux. It was found that using only the barium-oxygen distance to constrain the reaction coordinate resulted in unphysical results and a solvent organization parameter is necessary. Using these methods, water structure and exchange kinetics surrounding aqueous barium ion fall within the range of experimental estimates. Water-barium distances for the surface ions on the \{001\} barite surface are very close to those of the aqueous ion, yet the rate constant is significantly faster. This increase in exchange rate is attributed to a relatively hydrophobic, high energy interface.

The calculated water structure of the overall interface is relatively complicated, with up to five distinguishable oxygen positions interacting with both surface sulfates and bariums. This complex structure contrasts to the fit of experimental X-ray reflectivity data, which can only justifiably include a single ordered layer of water that matches unsaturated barium-oxygen bonds. It is unclear at this point how to reconcile of this discrepancy, but there are substantial uncertainties in both the experimental and computational water structures.

This study is the first time the kinetics of water exchange on aqueous barium ion and barite surfaces have been examined using a reactive flux method and as such, represent a significant expansion of this new and hitherto relatively unexplored method to systems of geochemical interest.

Continental erosion averaged over space and time

JANE W. STAIGER1 BRANDON MCELROY2 AND LESLEY P Berg3

1National Center for Earth-surface Dynamics, Saint Anthony Falls Laboratory, University of Minnesota, Minneapolis, Minnesota, USA; (jstaiger@umn.edu)
2Dept. of Geology, University of California-Davis. (rustad@geology.ucdavis.edu)
3Department of Geology and Geophysics, University of Minnesota, Minneapolis, Minneapolis USA; (lperg@umn.edu)

Matching rates of denudation at all temporal scales have been used to infer erosional steady state in various mountain belts. What variation in erosion rates is significant or expected from one temporal and spatial scale to another and over a range of tectonic regimes?

Under ideal conditions, the cosmogenic nuclide flux out of a basin can be used to measure the denudation rates that average over millennia for the entire drainage area. Erosion rates measured over shorter timescales (e.g. sediment yield, reservoir infill) show greater variance due to the stochastic nature of erosion and surface process interactions. Short-term measurements miss rare events in a predictable way and because of this property, rates of surficial processes measured over increasingly longer time intervals can incorporate longer intervals of process inactivity, thus producing a different apparent rate of deposition and erosion (Sadler, 1981; Gardner et al., 1987).

We use a new (available from the author) compilation of all previously published and new cosmogenic nuclide-derived denudation rates and sediment-flux measurements for the same basins to evaluate this variability. Despite anthropogenic effects, the majority of sediment fluxes are less than long-term rates of erosion, contrary to that predicted by Gardner et al. (1987).

What controls Sulfur isotope fractionation in modern estuarine sediments?

M.C. STAM1, P.R.D. MASON1, A.M. LAVERMAN1, C. PALLUD2 AND P. VAN CAPPELLEN1

1Department of Earth Sciences, Utrecht University, The Netherlands; (m.stam@geo.uu.nl, mason@geo.uu.nl, anniet@geo.uu.nl, pvc@geo.uu.nl)
2Department of Geological and Environmental Sciences, Stanford University, USA; (cpallud@stanford.edu)

Sulfur isotopes are a promising tool for tracing sulfate reduction in sedimentary rocks, and for providing constraints on one of the oldest metabolic process on Earth. However, the relationship between isotopic fractionation and parameters such as sulfate reduction rate, temperature and availability of organic matter remains unclear, with conflicting results from pure culture and natural population studies [1,2,3]. Here, we use flow through reactors that contain undisturbed slices of sediment to measure sulfate reduction rate under quasi-steady state conditions. Flow through experiments were run to investigate the control of temperature, sediment depth, organic matter content, sulfate concentration and the effects of inhibitors on sulfate reduction rate and sulfur isotope fractionation. Samples were collected at a brackish location of a temperate estuarine sediment (Western Schelde, The Netherlands).

Our results indicate an inverse relation between sulfate reduction rate (SRR) and sulfur isotope enrichment factor under optimum temperatures (20 and 30°C). This trend disappears at low rates (<10 nmol cm⁻³ h⁻¹) and for non-optimum temperatures (10 and 50°C). Large fractionations (>20‰) were observed only at low SRR (<10 nmol cm⁻³ h⁻¹). Sediment depth as well as organic matter content did not significantly affect isotope fractionation.

This study demonstrates that the degree of isotope fractionation can be used to infer SRR in natural populations as well as in pure cultures providing that the bacterial population is thriving under optimal conditions.

History of seafloor hydrothermal activity in the SW Pacific Bare Zone using fish teeth strontium isotope dating of metalliferous sediments

A.M. STANCIN, J. D. GLEASON, R. M. OWEN, D. K. REA, AND J. D. BLUM

Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109-1005 (astancin@umich.edu)

A 2 million km² region virtually devoid of sediment has been identified in the remote SW Pacific Basin (February/March 2005 drill site survey cruise - Rea et al., 2006). This region, informally termed the "South Pacific Bare Zone" comprises ocean floor dating back to the Late Cretaceous. Seismic profiling, piston cores and gravity cores reveal the full extent of barren crust – an area nearly the size of the Mediterranean Sea. Within the Bare Zone, a small (1km²) abyssal valley with 24 m of sediment was identified and sampled with a large diameter piston core, leading to recovery of 8.35 meters of metalliferous sediment at 5082 m water depth. Fish-teeth Sr-isotope stratigraphy reveals a continuous record of sedimentation 31Ma to present, with an average linear sedimentation rate at this site of 0.27 mm/kyr. However, the fish teeth age-depth profile and INAA geochemistry show an exponentially decreasing hydrothermal flux, with sedimentation rates approaching <0.05 mm/kyr between 17 Ma and the present. The origin of the main pulse of hydrothermal activity is uncertain, but may be related to a series of late Eocene/early Oligocene ridge jumps and propagating rifts that accompanied large-scale plate tectonic reorganization of South Pacific seafloor. The fish teeth Sr isotope age-depth profile and pelagic clay geochemistry also reveals that the terrigenous component at this site registers a very low eolian flux, increasing in proportion to the hydrothermal component upcore. Primary dust sources were likely Australia and New Zealand, consistent with Nd-Sr-Pb isotopes of detrital extracts. The unusual conditions of Cenozoic non-deposition that characterize this area of the South Pacific make this the first record of its kind, providing unique insight into hydrothermal activity and eolian sedimentation since the early Oligocene. The utility of the fish teeth Sr isotope method for dating marine hydrothermal cores should be explored further.

s.basu@suerc.gla.ac.uk).
\(^3\)GEUS, Øster Voldgade 10, DK-1350 Copenhagen K,
Denmark (ilm@geus.dk).

Recently, several studies have shown an apparent link between high \(^3\)He/\(^4\)He and depleted mantle (Stuart et al., 2003; Class and Goldstein 2005) which is inconsistent with prevailing orthodoxy where high \(^3\)He/\(^4\)He reflects a lack of mantle degassing and depletion. Here we present 28 new \(^3\)He/\(^4\)He analyses from Tertiary picrites of Baffin Island and West Greenland and have identified 21 samples with \(^3\)He/\(^4\)He >35\(^R\) (the highest value observed in recently erupted basalt). Whole rock \(^{143}\)Nd/\(^{144}\)Nd for these samples show a significant peak at depleted values (mean of 0.513024), as observed in an earlier study (Stuart et al., 2003), but an interesting feature of the new data is the scatter in \(^{143}\)Nd/\(^{144}\)Nd down to 0.512876, a value which although not chondritic is certainly less depleted than observed in Baffin Island and West Greenland picrites. Whole rock Pb isotope data show significant variations which are consistent with incorporation of radiogenic Pb of crustal origin but critically there is no relationship between Pb and Nd isotopes. Thus, if crustal contamination is the cause of Pb isotope variation, it was not responsible for the range in \(^{143}\)Nd/\(^{144}\)Nd.

In addition, major and trace element compositions of olivine hosted melt inclusions allow us to compare melt inclusion compositions from olivines of various sizes, that record different stages of magma evolution, to provide better resolution on the effects, if any, and timing of potential crustal contamination. We conclude that variations in \(^{143}\)Nd/\(^{144}\)Nd are likely to derive from heterogeneity in the mantle sources tapped by the Baffin Island and West Greenland picrites and that these new data do not support the concept of a discrete depleted-high \(^3\)He/\(^4\)He end-member in the mantle.

What controls iron isotope fractionation in an acid mining pile?

M. STAUBWASSER\(^1\), F. VON BLANCKENBURG\(^2\) and A. SCHIPPERS\(^3\)

\(^1\)Institut of Mineralogy, Leibniz-University Hannover,
Germany (m.staubwasser@mineralogie.uni-hannover.de)
\(^2\)Institut of Mineralogy, Leibniz-University Hannover,
Germany (fvb@mineralogie.uni-hannover.de)
\(^3\)BGR, Hannover, Germany (axel.schippers@bgr.de)

This study explores the potential use of Fe isotope analysis in long-term risk assessment of acid mine drainage generating mining piles. Balci et al. (2006) have demonstrated the enrichment of heavy Fe isotopes in Fe oxidation products with respect to Fe(II)\(_{aq}\) during growth of Acidithiobacillus ferrooxidans in batch culture-experiments. They argued that inorganic equilibrium fractionation between Fe(III)\(_{aq}\) and Fe(II)\(_{aq}\) is the controlling reaction as described earlier by Welch et al. (2003). These authors have shown that in equilibrium the isotopic difference is \(\Delta^{56}\)Fe\(_{Fe(III)-Fe(II)}\) ~ 2.9‰. Here, we present Fe isotope ratios measured on sequentially leached tailings material sampled from a 25 m drill core into an active pile at Selebi-Phikwe, Botswana, and of an additional analog column bio-leaching experiment in the laboratory. Throughout the drill core, reactive solid Fe(III) is enriched in the heavy isotopes (average \(\delta^{56}\)Fe = −0.15‰) with respect to pyrrhotite (average \(\delta^{56}\)Fe = −0.40‰). This is in general agreement with the batch experiments of Balci et al. (2006). The fraction of exchangeable and soluble Fe shows very low \(\delta^{56}\)Fe values down to −2.4‰. Such extreme values can only occur in a small residual pool after the majority of dissolved Fe has been removed by precipitation. Our results can best be explained if the total reaction is broken down as follows. Fe dissolved from pyrrhotite is partitioned by microbial Fe(II)-oxidation into a mixed Fe(III)\(_{aq}\) and Fe(II)\(_{aq}\) pool which quickly equilibrates isotopically. Precipitation of solid Fe(III) occurs with perhaps additional fractionation from the Fe(III)\(_{aq}\) in the mix. Our data suggest that the mixed reservoir initially consisted mostly of Fe(III)\(_{aq}\) whose \(\delta^{56}\)Fe would be close to the initial pyrrhotite. The strongly fractionated residual derives from the remaining small pool of Fe(II)\(_{aq}\). However, low \(\delta^{56}\)Fe values cannot be sustained unless resupply of unfraccionated, freshly dissolved Fe from pyrrhotite is sluggish. Although showing complex results, the bio-leaching experiments appear to confirm that the ratio of Fe(II)\(_{aq}\) to Fe(III)\(_{aq}\) in the fluid, and thus the overall metal sulfide oxidation activity in the pile, is the main factor that controls the isotopic composition of soluble Fe.

The hydrothermal Wenzel deposit, South Germany: Implications for the formation of Kongsberg-type silver deposits

SEBASTIAN STAUDE, THOMAS WAGNER AND GREGOR MARKL

Institut für Geowissenschaften, Universität Tübingen, D-72074 Germany; (sebastian.staude@uni-tuebingen.de, thomas.wagner@uni-tuebingen.de, markl@uni-tuebingen.de)

The post-Variscan Kongsberg-type Wenzel deposit near Wolfach, Schwarzwald, Germany, the type locality of the Ag-Sb alloy dyscrasite, was investigated by ore microscopy, electron microprobe analysis, stable isotope and fluid inclusion analysis. Three mineralization stages could be distinguished in the vein. Whereas the first stage is a typical sulfide mineralization including galena and tetrahedrite, the second and third stage show a sulfide-poor association of Ag-Sb alloys with Fe-, Co- and Ni-arsenides and -sulfarsenides in a calcite matrix. The main ore minerals of this stage are allargentum and dyscrasite.

Seven distinct generations of calcite were distinguished. The δ¹³C (V-PDB) and δ¹⁸O (V-SMOW) values of these generations show a positively correlated trend that evolves from -13.0 to -4.0 ‰ and from 12.3 to 23.6 ‰, respectively.

Fluid inclusion data of stage I fluorite and quartz show homogenization temperatures of 100-180 °C at salinities of 17-26 wt.% NaCl eqv. Fluid inclusions in stage II calcite display similar, but more restricted values of 110-150 °C and 25-28 wt.% NaCl eqv., respectively. The stage III fluid inclusions of calcite show similar homogenization temperatures, but different salinities. Earlier Ag-Sb-alloy bearing calcite of this stage contains inclusions with salinities of 27-30 wt.% NaCl eqv., whereas later ore-free calcite crystals show lower salinities of 3-10 wt.% NaCl eqv. The initial ice melting temperatures of most fluid inclusions range between -45 and -60 °C and are typical of an H₂O-NaCl-CaCl₂ fluid.

Based on all available geochemical data and phase equilibrium constraints in the system Ag-Ca-Na-C-Si-Cl-O-H, we favor a model in which basement-derived near-neutral-pH hydrothermal fluids remobilized older Ag-Sb-bearing mineralizations. Mixing of these fluids with more alkaline formation waters from the Mesozoic cover rocks resulted in the precipitation of the silver alloys in an enrichment zone at P-T conditions of 120-150 °C and approximately 200 bars. A significant pH shift from near-neutral to alkaline is able to explain the abundant association of silver alloys with calcite gangue and the general absence of quartz in the enriched ore zone. This conceptual model can be applied to similar ore deposits world-wide, where rich ores of native silver and silver alloys are hosted by calcite-rich and quartz-poor gangue mineral assemblages.

Interpreting reaction rates at the field scale

C. STEEFEL AND L. LI

Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720 (CSteefel@lbl.gov)

Interpreting reaction rates and associated rate formulations (rate constants, catalytic and inhibitory effects, reaction affinity) at the field typically requires explicit consideration of transport. This is because overall rates may be either locally transport-controlled in the case of heterogeneous systems, or even globally transport-controlled if sufficiently large length scales for reaction are considered. The potential role of physical and chemical heterogeneity has been discussed, but is still not routinely evaluated at the field scale. Heterogeneity may introduce a scale dependence to field-scale rates even in the case where the pore fluids remain far from equilibrium due to either transverse concentration (and therefore rate) gradients, or as a result of longitudinal gradients that develop where the extent of reaction is large. These two effects can be quantified in models of the field-scale system respectively by 1) comparing results from 2D or 3D representations with those from 1D continuum models, and 2) by comparing results from 1D models with those from well-mixed flowthrough reactor models. The analysis indicates that well-mixed reactor models, implicit in the so-called “Inverse Models” to the extent that they are used to determine rate constants, should be used with considerable caution at the field scale.

Another effect associated with the presence of heterogeneities that complicates the interpretation of field-scale rates has to do with the determination of hydrologically accessible reactive surface area. Some regions within the reactive domain may be largely inaccessible because of their low permeability, or mass transfer from the low to high permeability regions (where the bulk of the flow occurs) may be rate-limited. An approach that uses the retardation of a reactive tracer to quantify the hydrologically accessible reactive surface area is presented and is combined with an example involving the weathering of smectite to kaolinite at the Shale Hills site in Pennsylvania, USA.

The complexity of many multicomponent reaction networks presents another significant obstacle to the interpretation of rates at the field scale. Problems are usually manifested when an incomplete data set has been collected at the field scale, in which case potentially important pathways may be neglected altogether. In this regard, combining major and minor element aqueous and solid phase chemical analyses with isotopic analyses offers a powerful approach for delineating all of the important pathways within a field-scale reaction network. Successful examples of such an approach will be provided.
Magma sources in the Icelandic Western Rift Zone (WRZ): Crustal and mantle input

R. C. J. STEELE, M. F. THRILLWALL, C. J. MANNING, M. A. M. GEE, M. REGELOUS AND D. LOWRY

Department of Geology, Royal Holloway, University of London, Egham, Surrey, TW20 0EX, UK

Low δ18O Icelandic rift basalts have been interpreted as a result of contamination by low δ18O crust, or as derived from an unusual, low δ18O mantle source. In the Reykjanes Peninsula (RP) δ18O values ≥ +4.2 ‰ have been interpreted as mantle derived, while lower values were thought to reflect contamination [1]. (230Th/238U) disequilibrium has also been used as an indicator of crustal contamination in both rift, and off-rift zones in Iceland [2]. Since the magnitude of (230Th/238U) disequilibrium varies radially with proximity to the proposed centre of the Iceland plume [3], variations in this sample.

The WRZ is an ideal area to study the extent to which low δ18O and (230Th/238U) disequilibrium indicate crustal contamination, due to their eruption during post/last-glacial time minimizing the need for an age correction. Further, the rift zone is orientated tangentially to the assumed location of the centre of the plume, and thus variations in extent of disequilibrium cannot be strongly controlled by distance to the plume.

A study of new O-Sr-Nd-Pb data from the WRZ demonstrates δ18O as low as +3.79 ‰ in primitive lavas (9.5 % MgO, 143Nd/144Nd 0.513046). The WRZ data appear compatible with varying degrees of crustal contamination in terms of δ18O and 143Nd/144Nd. However, assuming the WRZ assimilant has a δ18O OL of +1.2 ‰ [1] then 35 % bulk assimilation is required to produce the lowest δ18O OL sample of 3.79 ‰ from the mantle mean of 5.2 δ18O OL. This is difficult to reconcile with the relatively low degrees of fractional crystallization, shown by the 9.52 % MgO found in this sample.

Isotopic data from Hengill central volcano, located at the triple junction between the WRZ, RP, and the south Iceland seismic zone (SISZ), plot at the enriched end of WRZ Nd-Sr-Pb trends, showing the sources are isotopically linked. δ18O OL from Hengill is 3.83 - 4.5 ‰, with 5.91 - 8.73 % MgO. This range is present in rocks with homogenous Nd-Sr isotope ratios, showing that Hengill is much more consistent with assimilation producing the low δ18O signature.

The hydrolysis and cloro complexation of iron(III) in hydrothermal solutions

A. STEFANSSON1, T.M. SEWARD2 AND I. GUNNARSSON1

1Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland
2Institut für Mineralogie und Petrographie, ETH-Zentrum, Universitätstrasse 16, 8092 Zürich, Switzerland

A knowledge of the stability of iron(III) hydroxide and chloride complexes in hydrothermal solutions is important for quantitative interpretation of the transport and precipitation of iron by crustal fluids. It is generally accepted that iron is predominantly transported as iron(II) species in reduced hydrothermal fluids in the Earth’s crust. However, boiling (phase separation) occurs ubiquitously in hydrothermal systems with the partitioning of hydrogen into the volatile (less dense) phase. The redox state of the residual liquid (or denser phase) and pH changes, such that iron(III) may become the predominant oxidation state of iron. A knowledge of the complex equilibria involving Fe3+ is therefore important in understanding the transport and precipitation chemistry of iron by fluids in the crust at high temperatures and pressure.

The complexation of iron(III) with hydroxy and chloride ligands has been studied as a function of solution composition (salinity and pH) in hydrothermal solutions to 300°C at saturated water vapour pressure. Two experimental methods have been applied, uv-vis spectrophotometry using a high-temperature, flow-through gold-lined optical cell and hematite solubility using flow-through and static autoclave systems. The strong ligand-to-metal charge transitions of the uv-vis spectra of iron(III) hydroxy and cloro complexes at wavelengths below 400 nm were used to obtain molar absorptivities, ε, and equilibrium formation constants using principle component analysis and non-linear least squares treatment of the hematite solubility measurements were used to obtain solubility constants. Based on the experimental result iron(III) was found to hydrolyse to form FeOH2+, Fe(OH)3(aq) and Fe(OH)4+ with increasing pH and FeCl2+, FeCl3+, FeCl4-(aq) with increasing chloride concentration in acid solutions. Iron(III) hydroxide complexes were found to predominate in dilute and alkaline hydrothermal solutions whereas with increasing chloride concentration and temperature iron(III) chloride complexes become increasingly important species in oxidised acid solutions.
A 3.3 Ga Mo-Cu porphyry-style deposit at Spinifex Ridge, East Pilbara, Western Australia: Re-Os dating of Paleoarchean molybdenite

H.J. Stein1,2, M.E. Barley3, A. Zimmerman1 and B. Cummins4

1AIRIE Program, Department of Geosciences, Colorado State University, USA; (hstein@warnercnr.colostate.edu)
2Geological Survey of Norway, 7491 Trondheim, Norway
3University of Western Australia, Crawley WA 6009
4Moly Mines Ltd, 46-50 Kings Park Rd, W. Perth WA 6005

Here we show that the Re-Os chronometer is robust for Paleoarchean molybdenites. Prior to this study, AIRIE’s oldest dated molybdenite was from the 3128 ± 13 Ma Sergeevske porphyry Au-Cu-Mo deposit, Ukraine. The youngest is from the 2.120 ± 0.007 Ma Boyongan porphyry Cu-Au deposit, Philippines. Thus, molybdenite chronology can be readily used across the full span of geologic time [1].

The Spinifex Ridge (Coppins Gap) Mo-Cu deposit is located immediately north of the variably deformed Mount Edgar batholith in the 3.52-2.85 Ga East Pilbara granite-greenstone terrane. Mo-Cu mineralization, estimated at 481 million tons carrying 0.06% Mo and 0.08% Cu, is associated with high-level quartz-plagioclase porphyry intruded into Warrawoona Group basalts and rhyolites, and porphyritic granodiorite bodies [2]. Quartz veins with molybdenite and chalcopyrite are most abundant where both granodiorite and quartz-plagioclase porphyry are present.

Two molybdenite samples ascertain the timing of porphyry-style Mo-Cu mineralization at Spinifex Ridge. The drill core samples (SRD053, 227.2 and 227.6 m) represent main-stage stockwork ore hosted in potassically altered porphyry. Molybdenite was analyzed by NTIMS using a Carius tube digestion and double Os spike. Re-Os ages are 3298 ± 11 for a 1.5 cm quartz vein with irregular molybdenite selvages and 3284 ± 11 Ma for a 0.2 cm molybdenite clot adjacent to a similar vein. Ages are indistinguishable within their 2-sigma uncertainties, and agree with SHRIMP U-Pb zircon ages [3] for the Mount Edgar batholith (3314 ± 13 Ma, Coppin Gap suite; 3304 ± 10 Ma, Boodallana suite).

Ore zone geometry inclusive of silicified, brecciated borders to the quartz-plagioclase porphyry suggest that the entire intrusive-mineralization system was strongly tilted by regional listric faulting that accompanied uplift of the batholith. The Re-Os dates present a maximum age for that faulting and a minimum age for the hosting quartz-plagioclase porphyry. The geology supports formation of the Spinifex Ridge Mo-Cu deposit in a weakly extending brittle regime at ~3.3 Ga, similar to magmatic-tectonic conditions that produce Mo-Cu porphyry-style deposits today.

UV femtosecond laser ablation applied to stable Fe isotopes in BIFs

G. STEINHOEFEL, I. HORN AND F. VON BLANCKENBURG

Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, 30167 Hannover, Germany
g.steinhoefel@mineralogie.uni-hannover.de
i.horn@mineralogie.uni-hannover.de
fvb@mineralogie.uni-hannover.de

Here we present in situ stable Fe isotope measurements in Precambrian banded iron formations (BIFs) using our in-house built laser ablation system which consists of a frequency-quadrupled fs laser operating at a wavelength of 196 nm and a multicolonlector-ICP-MS. The short pulse length turns the ablation process away from thermal pathways preventing artificial fractionation and minimizing matrix dependency (Horn and von Blanckenburg, 2007). The accuracy of this method has been verified for different types of matrices giving a reproducibility of 0.1‰ (2SD) for the $^{56}$Fe/$^{54}$Fe ratio (Horn et al., 2006). BIFs are fine-grained chemical sediments which are the product of initial precipitation from seawater and subsequent diagenetic and metamorphic processes. All of these processes involve redox reactions, dissolution and precipitation of Fe resulting in fractionation of Fe isotopes. In order to investigate these processes, we have determined the Fe isotope composition of single Fe-oxide and Fe-carbonate crystals by spot analyses at 30 microns resolution in different thin sections of low-grade metamorphosed BIFs. Small-scale isotopic variations of up to 0.9‰ in $\delta^{56}$Fe within single layers exist for hematite as well as for magnetite. Furthermore we detect isotopic zonation in magnetite crystals as small as 30 microns which becomes heavier in their Fe isotope composition towards the rim. These heterogeneities suggest variable relocation of Fe on a sub-millimeter scale during diagenesis and metamorphism. Fe-carbonates have also been investigated. Although crystal sizes are often less than 25 microns and Fe contents are low giving only low Fe signal intensities, we have found that variations in chemical composition have little influence on the Fe isotopic composition. Both, Fe-oxides and Fe-carbonates show constant average Fe compositions over all layers within a thin section. Since also magnetite and Fe-carbonate exhibit a constant relative difference of ca. 0.9‰, either a diagenetic process with the same precursor material must have established these isotope equilibrium fractionations or, alternatively, fluid sources were distinct but pathways to the Fe-carbonate and Fe-oxide were steady with time. These results illustrate that the study of stable Fe isotopes at high spatial-resolution have the potential to gain a better understanding on the mechanism of BIF formation and the Precambrian Fe cycle.

Potassium partitioning in the lowermost mantle from ab-initio computations

G. STEINLE-NEUMANN1, K.K.M. LEE2 AND S. AKBER-KNUTSON3

1Bayerisches Geoinstitut, University of Bayreuth, Germany, (g.steinle-neumann@uni-bayreuth.de)
2Department for Physics, New Mexico State University, Las Cruces, NM, USA and Bayerisches Geoinstitut, University of Bayreuth, Germany, (kanani@physics.nmsu.edu)
3Scripps Institution of Oceanography, University of California at San Diego, La Jolla, CA, USA, (sofia@ucsd.edu)

Partitioning of radioactive isotopes in the Earth’s interior is of great importance to the thermal and dynamic state and evolution of the Earth as radioactive decay provides an important source of energy for mantle dynamics. As a consequence, enriched (or depleted) reservoirs in the mantle can influence the energy balance in geodynamics. The recently discovered phase transition in MgSiO3 from perovskite (pv) to post-perovskite (ppv) in the lowermost mantle provides the possibility for an enriched or depleted zone at the base of the mantle. Therefore, the partitioning of radiogenic isotopes among the phases of the lower mantle is of central importance in geochemistry and geodynamics of the deep Earth. Here we take a first step in addressing this issue by considering the partitioning of potassium between pv and ppv by performing ab-initio computations.

We have set up computations for a coupled substitutions of K and Al or Fe$^{3+}$ (M ion) for 2 Mg on the A site, and evaluate the energetics of a (Mg$_{30}$K,M)$_{Si_{32}O_{96}}$ composition in the pv and ppv structure. We compare the energetics of the following reactions for both pv and ppv to compute the enthalpy of formation:

\[
(Mg_{30}K,M)_{Si_{32}O_{96}} + 2MgO \rightarrow Mg_{32}Si_{32}O_{96} + 1/2 K_2O + 1/2 M_2O_3.
\]

The computations are performed with the VASP package using the projector augmented wave method for the static lattices of the high pressure phases in the reaction above. We use the generalized gradient approximation to the exchange and correlation potential. Structures are optimized for internal and external degrees of freedom at constant volume, and we assume that the M and K ions are at A positions directly adjacent to one another. Computations are performed for a wide compression range, reaching pressures of the CMB.

Slightly above 100 GPa we predict that $D_{K}<1$, implying that K partitions preferably into the ppv phase. Increased temperatures would decrease the magnitude of preferred differentiation. This makes a K enriched layer at the base of the mantle a possibility. It is clear, however, that the effect of other phases stable in the lower mantle (Ca-pv and mw) must be considered in a full assessment of K distribution in the lower mantle.
Biogeochemical cycling of rare earth elements in surface soils

M. Steinmann¹, P. Stille² and M.C. Pierret²

¹EA 2642 Géosciences, Université de Franche-Comté, F-25030 Besançon, France (marc.steinmann@univ-fcomte.fr)
²CGS, CNRS, UMR 7517, EOST, F-67084 Strasbourg, France (pstille@illite.u-strasbg.fr, pierret@illite.u-strasbg.fr)

Stille et al. (2006) have suggested in a study on the Strengbach catchment in the Vosges mountains (eastern France, http://ohge.u-strasbg.fr) that preferential absorption of light REE (LREE) by vegetation may contribute to LREE depletion of stream water. New REE data on soil solutions recovered on the same site from 10 to 70 cm depth show similar to vegetation an enrichment of the LREE. Strontium and neodymium isotope data from these solutions indicate that up to 90 % of Sr and Nd are derived from vegetation litter. This origin of the REE in the surface soil is in strong contrast to the underlying regolith, where the mobile REE essentially originate from the dissolution of apatite derived from the granitic bedrock (Aubert et al., 2001). The Sr isotope record from tree rings of 3 spruce specimens planted 90-100 years ago on the study site yields valuable information on the formation of these different REE pools. The data demonstrate that the spruce mainly absorbed Sr from granite-derived minerals during the first years after plantation. But rapidly the isotopic compositions of the tree rings are shifted to values typical for atmospheric deposits. We interpret this evolution by transformation of the initial mineral soil into a surface soil rich in organics issued from the decomposition of vegetation litter. This new surface soil contained in the beginning mainly regolith-derived Sr inherited from vegetation. This initial Sr was then continuously removed by soil water runoff and replaced by atmospheric Sr. We are actually analyzing Nd isotopic compositions on the same spruce samples in order to confirm this hypothesis for the REE. This scenario thus suggests that vegetation and surface soil form an almost closed biogeochemical cycle for the REE, accumulating preferentially LREE issued from vegetation litter. This cycle is modified by inputs from atmospheric sources and leaching of remaining soil minerals, and outputs by surface and soil water runoff. Local stream water is in contrast to surface soil and vegetation depleted in LREE indicating that surface soil water is not the dominant source for stream water. This is in agreement with Nd-Sr isotope data from Stille et al. (2006) showing that stream water REE are mainly derived from alteration of apatite within the mineral soil. We suggest that the formation of a LREE enriched reservoir in the surface soil has together with preferential scavenging of the LREE by adsorption and precipitation during groundwater flow contributed to the formation of a LREE depleted groundwater pool within the underlying regolith. This groundwater is the main source for stream water at low stream flow.

The mobility of actinides and ⁹⁰Sr from bomb test fallout in a karstic area, Jura Mountains (Switzerland)

Philipp Steinmann¹, Laurent Pourcelot² and Pascal Froidevaux¹

¹University Institute of Radiation Physics, University Hospital Center and University of Lausanne, Grand Pré 1, CH-1007 Lausanne, Switzerland; (philipp.steinmann@chuv.ch; pascal.froidevaux@chuv.ch)
²Institut de Radioprotection et de Sûreté Nucléaire IRSN, CEA Cadarache Bat 153, 13108 St Paul Lez Durance, France; (laurent.pourcelot@irsn.fr)

The presence of artificial radioisotopes of plutonium, americium and strontrium is mainly due to the atmospheric tests of nuclear bombs before 1964. Present day inventories of these radionuclides in soils of the Jura Mountains (Switzerland) are often less than expected. Apparently, there has been leakage from the soils (especially the thin soils) into the karst of this region of carbonate rocks.

With the goal to assess this possible long-range migration in a natural setting we analyzed the radioisotopes - in upland soils (soil profiles and soil solution profiles near Col de Mollendruz, Switzerland, 1200 m a.s.l.), - in a karstic source at a distance of ca. 5 km (water and aquatic mosses, 660 m a.s.l.), and - in cave deposits from the same area. The mean soil inventories (0-25 cm) for thick soils are 1.3 kBq/m² and 0.12 kBq/m² for ⁹⁰Sr and Pu, respectively. These radioisotopes have significantly diffused towards deeper soil layers (40 cm depth or more) and they are also present in measurable amounts in the soil solution (< 0.22 µg/m, i.e. dissolved and colloidal). These findings highlight the potential of long-range transport in colloidal form. The calculated distribution coefficients K₄ are on the order of 10⁰⁰⁰; 3'000; and 1'500 for Pu, Am, and Sr, respectively.

The radioisotopes appear in the waters of the karstic source and in aquatic mosses collected close to the source. The plutonium activity found in the filtered (<0.45 µm) source water is 4 and 22 µBq/l for ⁹⁰Sr and Pu, respectively. The radioisotopes have significantly diffused towards deeper soil layers (40 cm depth or more) and they are also present in measurable amounts in the soil solution (< 0.22 µ, i.e. dissolved and colloidal). These findings highlight the potential of long-range transport in colloidal form. The calculated distribution coefficients K₄ are on the order of 10⁰⁰⁰; 3'000; and 1'500 for Pu, Am, and Sr, respectively.

Taken together our results demonstrate the long-range transport (km-scale) of Pu, Am, and ⁹⁰Sr in a natural karstic environment with no radioisotope contamination other than "global fallout".
Solute exchange across the sediment water interface in an acidic pit lake

R. STELLMACHER AND M. KOSCHORRECK
Helmholtz Centre for Environmental Research – UFZ, Brückstraße 3a, D-39114 Magdeburg, Germany (roman.stellmacher@ufz.de; matthias.koschorreck@ufz.de)

Solute exchange across the sediment-water interface affects the water quality in mining pit lakes. Fluxes are supposed to be affected by advective groundwater flow. However, benthic solute fluxes in such lakes have mostly been determined by sediment core incubations in the laboratory or by calculation from pore water profiles.

In the present study direct solute flux measurements were carried out in situ in acidic Mining Lake 111 in the Lausitz lignite mining area, Germany. Three sites were chosen to represent A) groundwater inflow conditions B) the lake profundal and C) a reference littoral site. A volume of lake water and the sediment below were enclosed using an opaque benthic flux chamber. Oxygen decrease in the chamber was directly measured using an optode, whereas parameters such as total inorganic carbon (TIC) and dissolved Fe$^{2+}$ were analyzed in a series of water samples withdrawn from the chamber.

Sites B and C showed oxygen consumption rates between 5 and 15 mmol m$^{-2}$ d$^{-1}$ while oxygen loss from the chamber at site A equaled rates between 19 and 35 mmol m$^{-2}$ d$^{-1}$. TIC fluxes from the sediment varied closely around 5 mmol m$^{-2}$d$^{-1}$ at sites B and C, but reached up to 100 mmol m$^{-2}$d$^{-1}$ at site A. Further a distinct increase of ferrous iron in the chamber was detected only at site A, i.e. in the groundwater inflow area.

Our results reveal significant differences in benthic solute fluxes depending on groundwater inflow and setting in the lake. The groundwater inflow area is characterized by high oxygen consumption and high inflow of TIC and dissolved iron. To our knowledge these are the first measurements of this kind, providing valuable practical experience for the use of benthic flux chambers in pit lake research.

FTIR water observation in minerals from diamond inclusions and matrix of diamondiferous eclogite

A.S. STEPANOV, D.A. ZEDGENIZOV AND V.S. SHATSKY
Russian Federation, Novosibirsk, Institute of Geology and Mineralogy. (stepanovas@uiggm.nsc.ru)

The series of recent observations have recovered that nominally anhydrous minerals (NAM) in the Earth’s mantle may contain significant amount of water. There are some evidences that water plays an important role in diamond formation. Here we present the first data on water content in clinopyroxenes (Cpx) in the matrix and diamond inclusions (DI) from diamondiferous eclogite xenolith from Udachnaya kimberlite pipe (Yakutia, Russia, description in [1]).

The water content has been estimated from unpolarized FTIR spectra of slices of the rock and polished plates of diamonds with DI. Spectra from individual DI have been obtained by subtraction of diamond absorption in the point near inclusions. The thickness of rock slices was measured by micrometer and thickness of inclusions was determined by up and bottom focusing under microscope with reference to refractive index.

The strong band at 3450 cm$^{-1}$ and two weaker bands at 3620 and 3740 cm$^{-1}$ are observed in FTIR spectra of Cpx from the matrix of eclogite. Most Cpx inclusions in diamonds show single absorption band at 3450 cm$^{-1}$ and only one inclusion has additional band with the maximum at 3600 cm$^{-1}$ (may be attributed to OH band in chlorite [2]). Water content in Cpx has been estimated by using calibrations from [3]. Water concentrations are 60-90 ppm in Cpx from the matrix and 80-150 ppm in Cpx from diamond inclusions. Neither Grt DI nor Grt from the matrix do not show any water absorption in their FTIR spectra.

Specific results of this study are: (i) the major phase containing water in the eclogite is Cpx; (ii) water content in the matrix and DI from eclogite is not significantly different. It may testify that water content in eclogite did not change during period between diamond formation and ascent of xenolith to the surface by kimberlite magma.

This work was supported by the Siberian branch of the Russian Academy of Science.

$^3$Geological Survey of Western Australia, Department of Industry and Resources, 100 Plain St., East Perth, Western Australia 6004, Australia (simon.bodorkos@doir.wa.gov.au; arthur.hickman@doir.wa.gov.au)
$^4$Department of Geosciences, University of Oslo, Postbox 1047, Blindern N-0316, Oslo, Norway (fernando.corfu@geo.uio.no)

SHRIMP and other ion probes are routinely utilized to determine $^{207}$Pb/$^{206}$Pb ratios of zircons, but only in special cases can the accuracy of the measurements be claimed to be better than a few %. A great deal of attention is placed on calibrating $^{206}$Pb/$^{238}$U ratios, yet for $^{207}$Pb/$^{206}$Pb this is seldom the case. Any systematic bias in $^{207}$Pb/$^{206}$Pb of zircon is considered insignificant relative to the low precision of the individual spot analyses, a reasonable assumption based upon the generally well-known characteristics of the large ion probe. Nevertheless, as several individual $^{207}$Pb/$^{206}$Pb measurements are typically pooled to improve overall precision to the ±1-5 ‰ level for Paleoproterozoic or older zircons, the accuracy of the composite ratio should be a concern.

There are several potential sources of bias in ion probe $^{207}$Pb/$^{206}$Pb measurements of zircon, including instrumental mass fractionation, peak shape, detector performance, isobaric interferences, common Pb correction, and the method of data processing. Although it is important to understand and potentially control these individual factors, it is critical to be able to measure the overall bias. Unfortunately, there appear to be no ion probe zircon reference materials developed expressly for $^{207}$Pb/$^{206}$Pb calibration. Our data obtained from analyzing the Proterozoic U-Pb zircon QNG suggest that systematic errors of several ‰ may exist between sessions on the same instrument and between different instruments. However, this zircon is not a suitable Pb-isotope standard for several reasons, and the validity of the results is uncertain. We have developed an Archean (ca. 3.5 Ga) $^{207}$Pb/$^{206}$Pb zircon reference material, and TIMS data indicate homogeneity. The goal is to incorporate analyses of this material as a routine part of SHRIMP zircon sessions in order to monitor and potentially correct for any systematic error in the $^{207}$Pb/$^{206}$Pb ages.
Fungal transformation of lignite in overburden dumps

E. STIEBITZ AND A. KASSAHUN

Groundwater Research Institute Dresden, Meraner Strasse 10, 01217 Dresden, Germany (estiebitz@gfi-dresden.de)

Acidity in overburden dumps of open cast lignite mines poses a considerable environmental threat. Despite the persistence of the dump organic material (lignified organic matter), microbial acidity attenuation processes such as iron sulphide formation by microbial sulphate reduction were observed within several dumps (Storch et al.; 2007). Fungi are known for their ability to liquefy lignite (Ward; 1985). Therefore, autochthonous acidotolerant fungi may provide bacterial substrates by transformation of lignite into water soluble organic matter.

Methods

Autochthonous fungal strains were isolated from dump material of the Plessa field site (Lusatia, Germany). The sediment was placed on Sabouraud glucose agar and incubated at 20°C. After formation of a thick hyphae mat identical dump material was placed on this mat. A few days later bioliquefaction of lignite particles started.

Results

The autochthonous fungi (Mucor hiemalis) transformed lignite particles into black and shiny droplets of very high organic carbon contents (~15 g/L). The liquid product was analysed by gel chromatography to consist of humic substances (a), building blocks (b), low molecular weight substances (c), neutral substances (d), and polysaccharides (e). The liquefied organic matter is highly polar and water soluble. HPLC analysis (Schmalz et al.; 2002) of the water dissolved droplets revealed the predominance of carboxylic and carboxylic functional groups. Carbonic acids are well known substrates for sulphate reducing bacteria (Widdel; 1988).

Isotopic fractionation of Uranium in low-temperature environments

C.H. STIRLING1,2, M.B. ANDERSEN3,2, R. WARTHMANN2 AND A.N. HALLIDAY4,2

1Dept. Chemistry, Univ. Otago, New Zealand (cstirling@chemistry.otago.ac.nz)
2Dept. Earth Sciences, ETH Zürich, Switzerland (warthmann@erdw.ethz.ch)
3Dept. Earth Sciences, Univ. Bristol, UK (morten.andersen@bris.ac.uk)
4Dept. Earth Sciences, Univ. Oxford, UK (alexh@earth.ox.ac.uk)

Uranium is the heaviest naturally occurring element and mass-dependent isotopic fractionation between 235U and 238U, which scales with δM/M2, is not normally considered significant given the small ~1% difference in mass. It is therefore usual to assume that 238U/235U is constant in the terrestrial environment and equal everywhere to 137.88 at the present day. Importantly, isotopic fractionation of the very heavy elements has recently been investigated for mercury and thallium in the context of mass-independent nuclear field shift effects1, which do not scale with δM/M2, and are predicted to have permil-level effects on the heavy masses, including uranium.

We have developed experimental protocols for the precise measurement of 238U/235U and 238U/234U by multiple-collector ICPMS (MC-ICPMS) to investigate potential isotopic fractionation in uranium. Using multiple-Faraday protocols and a high-purity 238U:236U double spike to internally monitor instrumental mass bias effects, we are able to resolve variations in 238U/235U and 238U/234U at the 0.4 and 0.3 epsilon level (2σ, 1 epsilon = 1 part in 10,000), respectively. Measurements for samples formed in a range of low-temperature environments reveal sizeable, permil-level natural variability in 238U/235U2. Present experiments are focussed on the isotopic fractionation of uranium during the biologically-mediated reduction of U(VI) to U(IV).

Our new observations indicate that uranium isotopic fractionation of 238U/235U may offer the potential to monitor biological pathways and redox processes occurring during mineralization, weathering, and the transition between the U(IV) and U(VI) oxidation states, offering new insight into the processes at work. Moreover, variability in 238U/235U will have a direct bearing on the U-series and U-Th-Pb chronometers, when applied to samples formed in low-temperature environments, as these chronometers currently assume an invariant 238U/235U equal to 137.88.

In the early nineties of the last century rivers of North-Rhine Westphalia were examined by Veizer and members of his working group (Flintrop et al., 1996). Their motivation for having a close look on these – and on other more eminent – rivers was primarily the search for the missing carbon-dioxide sink. In addition, they provided a documentation of the pollution situation. We revisited some of these rivers, looking for possible changes that occurred during the past 15 years, and visited additional rivers with the focus not on the carbon budget but more on the pollution state.

In order to isolate occuring in-river processes and to identify sources of river constituents we analysed the isotopic compositions of $\delta^2$H and $\delta^{18}$O of water, $\delta^{13}$C of dissolved inorganic carbon, $\delta^{34}$S and $\delta^{18}$O of sulphate, and $\delta^{15}$N and $\delta^{18}$O of nitrate. Isotopic work was supplemented with measurements of common physical parameters and concentrations of major anions and cations.

The different geographic settings of the rivers are mirrored by their isotopic composition of water. Respective regional trends are affected by processes as evaporation and mixing of different water masses. Compared to previous work, salt pollution (i.e. ions commonly attributed to an anthropogenic origin) has decreased. This holds true especially for potassium and nitrate, but also for sodium and chloride. The isotopic composition of nitrate in the river Ruhr identifies organic fertilizers and sewage as the main sources, with some evidence for denitrification processes. Compared to 1991, sulphate concentration has increased in the downstream part of the Lippe. Low $\delta^{34}$S values suggest a higher contribution from pyrite oxidation as the likely cause. This could indicate changes in mining activity and related groundwater hydrology. For dissolved inorganic carbon we found higher concentrations characterized by lower $\delta^{13}$C-values in all rivers compared to results from the early 1990s, caused by differing meteorological situations and in-river carbon cycling.

Cosmogenic nuclide calibration – A progress report from the CRONUS project

JOHN STONE

Department of Earth and Space Sciences, University of Washington, Box 351310, Seattle, WA, 98195 (stone@geology.washington.edu)

One goal of the overall CRONUS project (CRONUS-Earth, CRONUS-EU and contributors from countries outside the US and EU) is to derive cosmogenic nuclide production rates from well-characterised geologic sites. We aim to generate a network of natural calibration data that span a wide range of altitudes, latitudes and exposure periods, including as many nuclides and target minerals as possible at each site. This talk will provide a status report on geological calibration of $^{10}$Be, $^{26}$Al, $^{36}$Cl and $^{3}$He production rates, reviewing published data and presenting initial CRONUS results from sites in North America, Scotland and Antarctica.

The geological calibration effort is closely integrated with work on altitude-latitude scaling schemes, which provide the framework for comparing production rates between different latitudes, altitudes and exposure periods. All published scaling schemes can reconcile existing $^{10}$Be calibration data to within approximately 10% (1 sd). Assigning appropriate scaling errors is more complicated, however, because examination of the misfit between scaled production rate estimates and calibration data shows that there are systematic effects (biases in latitude and/or altitude) for all calibration schemes, as well as random error. The systematic component is minimal close to calibration sites, but may be large (and is unknown) at latitudes and altitudes far from calibration data. Additional calibration sites are needed to provide denser coverage, especially in latitude and exposure duration. Low latitudes are poorly represented in the data so far, and old sites are required to test the predictions of time-dependent scaling schemes which attempt to correct for paleomagnetic variations.
Age of magnetite–apatite deposits and geochemistry of host rocks, Bafq District, Central Iran

H.-G. Stosch1, R.L. Romer2 and F. Daliran1

1Universität Karlsruhe, Institut für Mineralogie und Geochemie ( stosch@img.uka.de, farahnaz.daliran@img.uni-karlsruhe.de)
2GeoForschungsZentrum Potsdam ( romer@gfz-potsdam.de)

Major hydrothermal/metasomatic Kiruna-type REE-apatite-magnetite ores (2x109 t) of the Bafq district in East Central Iran are hosted by Early Cambrian rhyolitic rocks and occur locally also in late spilitic basalts. This intimate association within a 150 km N–S striking structural zone, bordered by crustal faults, suggests a genetic link between magma generation and ore formation. The exact age of the mineralization, however, has not yet been determined. The tectonic setting of granitoids and rhyolites has been controversially discussed (rift setting versus magmatic arc environment) with Ramezani and Tucker (2003) favoring a collisional setting based on the chemical signature of the felsic magmatic rocks and paleogeographic reconstructions.

Our current study deals with the age of the mineralization and the geochemistry of the host rocks.

Petrographic investigations indicate that the rhyolites have been subjected to a broad-scale alkali metasomatism and an ore-related metasomatism that have modified their original composition, thus complicating the interpretation of geochemical data. Indeed, our major and trace element data do not yet permit an unambiguous interpretation of the geotectonic environment. However, we note that volcanism in the southern sector of the Bafq District is essentially bimodal with intermediate (andesitic) rocks being rarely encountered and mafic rocks being subordinate to felsic ones.

Clear apatite crystals were separated from three apatite-magnetite deposits. The nine analyzed samples yield apparent 206Pb/238U ages between about 527 and 539 Ma and thus fall entirely within the age range of the felsic magmatic rocks dated by Ramezani and Tucker (2003) [525–547 Ma]. This confirms field evidence that the ore formation was closely related to the Early Cambrian magmatic event (Daliran, 2002).

Tracing the mineralogy of oceanic basalt sources

A. Stracke1 and M. Willbold2

1ETH Zürich, Institut für Isotopengeologie, Clausiusstr. 25, 8092 Zürich, Switzerland (stracke@erdw.ethz.ch)
2University of Bristol, Department of Earth Sciences, Bristol, BS8 1RJ, United Kingdom (M.Willbold@bristol.ac.uk)

Subduction of oceanic crust has introduced considerable quantities of basalt into the Earth’s mantle, which, in the form of eclogite or pyroxenite, have often been proposed to constitute part of oceanic basalt sources. Isotopic evidence for mafic constituents in oceanic basalt sources remains ambiguous because their inferred isotopic composition is highly model dependent. Identification of pyroxenite derived melts on the basis of their major element composition is complicated by second order processes, i.e., fractional crystallization. Incompatible trace element compositions, however, are less affected by small extents of fractional crystallization. In addition, the higher modal abundance and different composition of garnet and clinopyroxene in pyroxenite compared to peridotite can lead to different partitioning behavior of the incompatible trace elements, which may be a useful tracer of pyroxenite versus peridotite derived melts. On the basis of recent partitioning experiments, bulk D values for pyroxenite are, on average, about factor of 3-6 higher than for garnet peridotite. The relative compatibility of the lithophile trace elements, however, is broadly similar. The main differences are an order of magnitude higher Ba/(Th, U, Nb, La), and about a factor of 2-3 lower Nb/(Th, U, La) and Sr/(Nd, Hf, Zr, Pb) bulk D ratios in pyroxenite compared to peridotite. Owing to the extremely low bulk D values of the most incompatible elements Ba, Th, U, Nb and La, however, even large differences in their bulk D ratios result in no resolvable differences in derivative melt compositions at melt fractions ≥ 5%. For the more compatible elements Sr, Nd, Hf, and Zr, partition coefficient induced differences (higher Sr/(Nd, Hf, Zr) and Nd/Hf ratios) persist up to melt fractions of 20-30%.

Whether differences in melt composition owing to the different partitioning behavior of garnet-peridotite and pyroxenite can be identified therefore depends largely on the style of melting and melt aggregation, i.e. how do melts form, what degree of melting is reached before separation from the solid (melt extraction) and how and to what extent do melts pool to form the aggregate melts erupted on the surface. Owing to its lower solidus temperature, pyroxenite starts melting deeper than peridotite. Key parameters for being able to resolve partitioning induced differences in melt compositions are therefore the extent of melting of pyroxenite before the onset of peridotite melting and the extent to which early pyroxenite melts can be extracted, if at all, without being significantly mixed with melts from the ambient peridotite. Regardless of the exact melt extraction scenario, the large extents of melting expected for pyroxenite (>20%) suggest that any partition coefficient induced differences between peridotite and pyroxenite melts are likely to be subordinate to initial compositional differences.
Mineralogical and ore-petrographic investigation of the iron ore occurrence of Ano Valsamonero, Rethymno (Crete)

A. STRATAKIS AND G. ALEVIZOS
Dept. of Mineral Resources Engineering, Technical University of Crete, Polytechnioupoli, Gr-73100 Chania, Greece (astratak@mred.tuc.gr)

Numerous iron ore occurrences appear within the Phyllite-Quartzite-Series (PQS) of Crete, some of which were occasionally mined. The PQS forms the lower part of the Phyllite nappe, which with Gypsum-Rauwacke-Formation, composes the Phyllite nappe of Crete that includes the metamorphic rocks between the Plattenkalk-Series underneath and the Tripolitza-Series above. The PQS contains mainly phyllites and quartzites, in addition to metaconglomerates, marbles, calcareous phyllites and metabasalts.

The examined occurrence is located about 15 km southwest from Rethymno next to Ano Valsamonero and occurs in the form of lenses within the phyllite and quartzite of the PQS. Sampling took place along a 10 m thick profile, in distances approximately 1 m in vertical arrangement. X-ray diffraction and ore microscopy were used for determination of the mineralogy and structure of the iron ore, while the chemical composition was determined by X-ray fluorescence.

The iron ore consists predominantly of hematite, goethite and quartz, and subordinately of chlorite and muscovite. Hematite occurs in the form of radial, or more rarely in punctate aggregates between the quartz grains of ferruginized quartzite, especially in those samples, which originate from the above layers of the profile. In the samples from the middle and lower parts of the profile, hematite and goethite form a ferruginized front, which replaced largest part of the groundmass of quartzite. The Fe-rich solutions penetrated quartzite and precipitated as goethite, which forms concentric textures. The goethite changes gradually by dehydroxylation into hematite. The replacement by the Fe-rich solutions takes place from hair-cracks of the existing quartz grains. The composition of the iron ore along the profile varies regarding the Fe2O3 and SiO2 contents within a wide range.

According to the microscopic investigation of the ore, it is concluded that the processes, which have caused the massive replacing ferrugination of the ore occurrence of Ano Valsamonero are of epigenetic origin and can be classified to the continental ones.

Multiple sulphur isotopes reflecting compositional changes in Earth’s early atmosphere

H. STRAUSS1, M. PETERS1, J. FARQUHAR2, D. JOHNSTON2, U. WIECHERT3 AND A. STÖGBAUER1

1Geologisch-Paläontologisches Institut, Westfälische Wilhelms-Universität Münster, Münster, Germany (hstrauss@uni-muenster.de)
2Department of Geology, University of Maryland, College Park, Maryland, U.S.A.
3Institut für Geowissenschaften, Freie Universität Berlin, Berlin, Germany

Pyrite extracted from more than 120 samples collected from Archean and Paleoproterozoic siliciclastic sedimentary units in southern Africa, western Australia, south-central Canada as well as in southwest Greenland and ranging in age from 3.8 to 2.1 Ga display nonzero Δ34S and Δ36S values. Based on empirical and experimental data as well as respective modeling results, non mass-dependent sulphur isotope fractionations are considered to result from photochemical reactions of different sulphur-bearing compounds in the atmosphere under low atmospheric oxygen abundances (e.g., Farquhar et al., 2000; Farquhar and Wing, 2003; Pavlov and Kasting, 2002).

The record of newly obtained non mass-dependent sulphur isotope results displays distinct temporal variations in their magnitude. High-magnitude Δ33S values for the Paleoarchean are followed by a somewhat attenuated Δ33S signal in the Mesoarchean, while the Neoarchean and early Paleoproterozoic show extremely variable Δ33S values (total range of 11.5‰). Post-2.3 Ga old sediments do not show a non mass-dependent sulphur isotope signal.

In addition to the temporal change in Δ33S, distinct temporal differences also exist considering relationships between δ34S and Δ33S as well as between Δ33S and Δ36S. This suggests variations in the respective photochemical reactions (e.g., different sulphur-bearing compounds involved) and/or reflect differences in atmospheric composition with respect to effective UV-shielding. However, we clearly rule out transient oxygen abundances as possible cause. Instead, potential alternatives include variations in the atmospheric abundance of methane and/or in the ratio of carbon dioxide to methane.

Molecular characterization of Selenium in the environment

DANIEL G. STRAWN, LIBBIE ORAM AND GREGORY MOLLER

University of Idaho, Moscow, ID 83844-2339
(dgstrawn@uidaho.edu, oram3123@uidaho.edu, gmoller@uidaho.edu)

Selenium in the environment is an important element for ecosystem nutrition, but also can be toxic when present at slightly elevated concentrations. Selenium has similar chemistry as sulfur, and thus has multiple oxidation states and molecular forms in the environment. Availability of selenium for uptake by organisms or leaching to ground and surface waters is a function of its speciation. Thus understanding Se speciation and biogeochemistry in the environment is critical for evaluating risks and developing best management practices.

In this presentation results on speciation of Se in rocks, soils, plants, and stream waters located in an active mining region in southeastern Idaho will be presented. Phosphorus-ore in the region comprises the Western Phosphate Resource Area. The affected samples have elevated concentrations of Se relative to background levels, resulting from distribution of an ore interbed-shale (middle-waste shale) throughout the surficial environment during mine-site reclamation.

Speciation of Se in the samples was investigated using microscopically focused X-ray absorption spectroscopy. This technique utilizes focused synchrotron-generated radiation to excite core electrons in Se atoms within a sample, and fluorescence or transmission can be monitored either spatially or as a function of impinging energy. It is ideally suited for speciation in natural samples because it is element specific, and has a resolution of a few microns, thus allowing for speciation in heterogeneous samples to be investigated.

In the middle-waste shale, Se existed as reduced Se(0) or Se(II-) species. Three end-members were identified in the shale: Se-substituted pyrite, an iron selenide mineral, and an organic Se phase. Within the soil, both reduced and oxidized Se phases were detected, with the oxidized phases primarily Se(IV) (selenite); very little Se(VI) (selenate) was detected. In the plant materials both reduced organic Se and Se(VI) were identified. Finally, in the stream sediments, reduced Se, and selenite and selenate were identified.

Using the speciation information together with known ecological and biogeochemical processes, we are developing a better understanding of reaction processes, sources, and sinks for Se in the Western Phosphate Resource Area. This detailed information will facilitate a better understanding of the biogeochemical cycling in the system.

Origin of sulfur rich apatite in silicic, calc-alkaline magmas

M. J. STRECK1, C. A. BRODERICK1 AND W. E. HALTER2

1Department of Geology, Portland State University, Portland USA (streckm@pdx.edu, cindyb@pdx.edu)
2Isotope Geochemistry & Mineral Resources, Department of Earth Sciences, ETH, Zürich, Switzerland (halter@erdw.ethz.ch)

We have investigated volcanic apatite from a well-known center of calc-alkaline magmatism – the Oligocene Central San Juan Caldera Complex (CSJCC), Colorado, USA – to constrain the origin of sulfur rich (> ~0.6 wt.% SO3) apatite found in dacitic to rhyolitic, calc-alkaline magmas. Allapatites are small (typically 20-100 μm) and apatite from most units investigated (Fish Canyon Tuff, tuffs and lavas of the San Luis caldera complex) yield SO3 contents ranging from ≤0.2 wt.% to values of 0.8–2.0 wt.%; the bulk of apatite, however, indicate SO3 contents of 0.3–0.5 wt.%.

We performed laser-ablation ICP-MS analyses on apatite with a range in sulfur concentrations from selected units to correlate variations observed in sulfur with variations in trace elements (e.g REE) to find evidence for melt compositional changes during crystallization of S-rich vs. S-poor apatites. Apatite among units indicates characteristic compositional changes but within single units, apatite tends to form tight compositional clusters in parameters like Eu/Eu* and Sr contents, while REE concentrations may vary by a factor of two. Exceptions are a few distinct apatites. REE concentrations are typically ≥50-60x of bulk rock and/or of interstitial glass in keeping with other natural systems (e.g. Dempster et al., 2003) and suggest partition coefficients several times the ones of experimental studies.

To constrain actual melt composition from whichapatites grew, we find the combination of REE, Sr concentrations and Eu/Eu* most useful. Based on the trend of decreasing Sr towards more silicic compositions of bulk rock & glass for the CSJCC (this study and Lipman, 2004) and a DSr ≥ 3, all apatite grew from melts more silicic than ~68 wt.% SiO2 at the exclusion of the most evolved melt composition (~6 ppm Sr, 77 wt.% SiO2) that is too depleted in Eu to yield a DSr consistent with those of neighboring REE.

Our study suggests that apatite with low to high S concentrations grew in hydodacitic/rhyolitic melt requiring either 100’s of ppm of sulfur in the melt or alternative mechanisms to explain upper end of S range in apatite. One such alternative explanation may involve some sort of interaction of S-rich fluids (which could be largely derived from an underplated, degassing mafic magma) with crystallizing apatite.

**Climate change in the southern central Andes at 8 Ma**

M.R. STRECKER1, A. MULCH2, C. UBA1, A. SCHMITT3 and P. CHAMBERLAIN4

1Institut fuer Geowissenschaften, Universitaet Potsdam, 14476 Potsdam, Germany (strecker@geo.uni-potsdam.de)
2Institut für Geologie, Leibniz Universität Hannover, 30167 Hannover, Germany (mulch@geowi.uni-hannover.de)
3Dept. of Earth and Space Sciences, UCLA, Los Angeles, CA 90095-1567, U.S.A. (axel@oro.ess.ucla.edu)
4Dept. of Geol. and Environ. Sciences, Stanford University, Stanford, CA 94301, U.S.A. (chamb@stanford.edu)

Being situated in a subtropical high-pressure region with atmospheric subsidence and cold upwelling along the western coast of the continent, the southern central Andes are extremely arid between about 15°S and 27°S. About 20mm/yr rainfall and low erosion rates characterize the Atacama Desert on the western flank of the orogen. With hyper-aridity in this region and less than 200mm/yr rainfall on the adjacent intra-Andean Puna-Altiplano plateau and in the intermontane basins E of the Puna, the southern central Andes thus comprise the most arid sector of the orogen. Despite this inherently arid character, the eastern flanks of the ranges intercept moisture-laden, easterly winds that result in up to 3000mm/yr precipitation. The cause and the timing for the establishment of this pronounced asymmetry is not known, however. Here, we report on stable C-isotope data obtained from paleosols developed in foreland-basin strata of S Bolivia that serve as proxies for paleoclimatic conditions along the eastern flanks of the Andes. Tephra in these sediments provide the chronostatigraphy for the paleoenvironmental evolution. In two sections our preliminary data show delta $\delta^{13}$C values that both decrease from -7 to -8‰ to -11 and -13‰ between about 12.5 and 8 Ma, before they become less negative with an average of -10‰ in the remainder of the profiles. The relatively rapid ~4‰ change in $\delta^{13}$C is attributed to a greater availability of moisture and increased climatic variability in this inherently dry area of the Andes. Our data suggest that the climate was characterized by a mixed C3/C4 vegetation cover since approximately 8 Ma. Moisture availability must have been similar to the present humid conditions with a dry winter season. Holocene $\delta^{13}$C values are between -9 and -10‰, thus indicating the dominance of a moisture stressed C3/C4 vegetative cover. Thus, present-day atmospheric circulation patterns and the distribution of rainfall are similar to the conditions during late Miocene time. Based on these observations we suggest that precipitation in the southern central Andes was associated with the South American Monsoon and increased at about 8 Ma. We suggest that enhanced precipitation in this region was closely linked to uplift of the Puna-Altiplano and its adjacent eastern orographic barriers that forced the southward displacement of easterly moisture-bearing winds via the Low Level Andean Jet.

**Gabbroic bodies in the Trinity Ophiolite**

K. STREMMEL AND G. SUHR

Dept. Geol. Min., Uni Köln (kolja.stremmel@uni-koeln.de)

The Trinity Ophiolite (N. California) displays discrete silurian to devonian gabbroic bodies hosted by mantle rocks. It might be a good on-land analogue to test the applicability of current accretionary models for slow spreading systems. We report here first results from a mapping campaign in a northern (China Mtn.), central (Bear Creek) and southern gabbroic body (Bonanza King). The central body contains the most regular vertical lithological sequence: mantle peridotite; a shallow dipping transition zone with thick pyroxenitic layers; foliated gabbro; varly-textured gabbro. The northern body displays a disrupted transition zone separated from varly-textured gabbro by plastically deformed amphibolitized gabbro. The strain is potentially related to extensional ridge tectonics. The southern body exhibits small exposures of wehrlitic and pyroxenic rocks overlying mantle peridotite; gabbro and gabbronorite with a mineral foliation subparallel to the local dykes; varly-textured gabbro; doleritic dikes and sills. Two kinds of lateral contacts are observed. (1) Xenolithic margins, described by Cannat et al. (1991), demonstrating brittle behavior during emplacement into a cold lithosphere. (2) Dyke-like pyroxenites intruded between mantle peridotite and gabbro. No magmatic strain is obvious. We interpret this as a reactivated contact because of the sharp, sheet-like marginal zone. An inhomogeneous succession of rare peridotite; pyroxenite; doleritic dykes and varly-textured gabbro occurs at the topographic highest parts of two bodies and might represent a roof position. The disrupted character of the transition zones in the northern and southern body suggests the presence of multiple intrusive events which probably caused displacement of existing rock units. Specifically, it is our impression that the abundance of pyroxenites and primitive gabbros is too low relative to the exposed volume of evolved gabbro if a regular, mantle-derived magma is assumed.

Helium and neon isotopes as mantle tracers

N. A. STRONCIK¹, S. NIEDERMANN¹ AND K. M. HAASE²

¹GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany (nicole@gfz-potsdam.de, nied@gfz-potsdam.de)
²Department of Earth Sciences, University of Aarhus, Høegh-Guldbergs Gade 2, DK-8000 Aarhus C, Denmark (karsten.haase@geo.au.dk)

Noble gas isotopes, especially He isotopes, are widely used tracers for the formation and evolution of the Earth’s mantle and atmosphere. Basic concepts on mantle structure and evolution are primarily based on the interpretation of mantle ³He as reflecting primordial, undegassed mantle material. In general, the relative enrichment of ³He observed in MORBs and OIBs, compared to atmospheric values, is interpreted in terms of the retention of primordial He by the mantle throughout the history of the Earth. Primordial He isotopic ratios in terrestrial matter are largely thought to be solar-like, with the deviation from those solar-like ratios increasing during Earth’s history caused by the production of radiogenic ⁴He. Thus high ³He/⁴He ratios are interpreted to represent deep mantle material, whereas ratios around 8 RA (RA stands for the atmospheric ³He/⁴He ratio of 1.39 × 10⁻⁶) are thought to be representative for the upper mantle. Based on He, Ne and Ar fusion data of fresh, submarine volcanic glasses of a number of Mid-Atlantic Ridge off-axis seamounts we show that melt formation and evolution can have a larger impact on He than on e.g. Ne resulting in a decoupled behavior of He from other elements, such as e.g. Ne or Pb. All obtained He data are indistinguishable from the MORB range. In contrast, Ne isotopic compositions are much more primitive than MORB. Combined He, Ne and Ar systematics show that the source region of these seamounts experienced a preferential loss of He compared to Ne and Ar. This He loss, combined with subsequent ⁴He production, resulted in the decoupling of the He isotope systematics from Ne and Pb. Thus, among He and Ne only Ne has preserved the evidence that a primitive mantle component contributed to the formation of the investigated seamounts. As these seamounts are not fed from a mantle plume being derived from the deep mantle, the primitive Ne component resides within the upper mantle, implying that primitive noble gases are not necessarily indicative for deep mantle material. Our studies point out the necessity of obtaining Ne data in addition to He for the modeling of mantle formation and evolution and correct source characterization.

He-Ne-Ar isotope constraints on the nature and origin of high ³He/⁴He mantle

F.M. STUART AND S. BASU

Isotope Geosciences Unit, SUERC, East Kilbride G75 0QF, UK (f.stuart@suerc.gla.ac.uk)

Olivine phenocrysts from early Tertiary picrites from Baffin Island (BI) and West Greenland have ³He/⁴He = 38-50 Ra (n=24). The high ³He/⁴He are consistent with derivation from a mantle reservoir that is relatively undegassed compared to the depleted upper (MORB-source) mantle. Although Ne and Ar concentrations are typically 2 orders of magnitude lower than in basaltic glasses a low blank crusher is allowing Ne and Ar isotope determinations of high-³He/⁴He olivines. On a conventional 3-isotope plot, the BI picrites are indistinguishable from the Iceland and solar trends; the highest ²⁰Ne/²²Ne is 11.3. ⁴⁰Ar/³⁶Ar are typically less than 1,000. ³⁸Ar/³⁶Ar are indistinguishable from air values providing no evidence for solar Ar in the high-³He/⁴He mantle. Most samples define a trend in ²⁰Ne/²²Ne-⁴⁰Ar/³⁶Ar space that is consistent with mantle end-member with ⁴⁰Ar/³⁶Ar of 6,000-8,000. ⁴He*/²¹Ne* and air-corrected ³He/²²Ne imply the magmatic noble gases have suffered intense fractionation. This is supported by co-variation of ⁴He*/⁴⁰Ar* and ³He/³⁶Ar. The elemental fractionation is consistent with recent magmatic degassing and provides no evidence for an ancient degassing event necessary if the high-³He/⁴He mantle was a residue of early Earth depletion. The BI picrites plot on a trend in ⁴He*/²¹Ne*-³He/²²Ne space defined by basaltic glasses from Iceland. This is distinct from samples of Kola intrusives and we tentatively propose different degassing/depletion histories for the high-³He/⁴He mantle domains.
Structural incorporation of Eu(III) into calcite: Process understanding on a molecular level

T. STUMPF1, M. MARQUES-FERNANDES2, C. WALTHER1, M. SCHMIDT1, K. DARDENNE1, D. BOSBACH1 AND TH. FANGHÄNEL3

1Institut für Nukleare Entsorgung, Forschungszentrum Karlsruhe, P.O. Box 3640, 76021 Karlsruhe, Germany (Thorsten.Stumpf@ine.fzk.de)
2Laboratory for waste management, Paul-Scherrer Institute, 5232 Villigen PSI, Switzerland
3European Commission, Joint Research Center, Institute for Transuranium Elements, P.O. Box 2340, 76125 Karlsruhe, Germany

Demonstrating the geochemical aspects of the long term safety of a nuclear waste repository can significantly be improved by a molecular level understanding of the actinides behavior in the geosphere. In particular the interaction of radionuclides with minerals (adsorption, structural incorporation) strongly affects their mobility and retardation. In this presentation we will focus on the interaction of trivalent actinides and lanthanides with calcite, with special focus on the structural incorporation.

Calcite (CaCO3) is an omnipresent mineral in many rocks which are discussed as potential host for a nuclear waste repository. Furthermore, many waste repository designs include cement based components. Calcite is one of the major secondary alteration products formed during the degradation of cement over geological timescales. Actinide and lanthanide partition data derived from co-precipitation experiments indicate a high sorption affinity of these elements to calcite but a comprehensive understanding of actinide and REE uptake by calcite is not yet available. From a geochemical perspective the molecular level substitution mechanism is of key interest. Trivalent actinides and lanthanides have a similar ionic radius compared to Ca, the charge compensation mechanism upon substitution is unclear despite various recent studies. We have studied synthetically doped calcite crystals with Time Resolved Laser Fluorescence Spectroscopy and Extended X-Ray Absorption Fine Structure Spectroscopy. The focus has primarily been on Eu(III), due to its fluorescence properties. The structural parameters of Am(III) doped calcites obtained by EXAFS confirm the substitution of Ca2+ within the calcite structure. Site-selective TRLFS measurements at temperatures < 20 K show the presence of various incorporated molecular species. The incorporation into calcite involves several structurally distinguishable “sites”. These sites may be due to local lattice distortions/relaxations around the metal ion in the calcite structure. These investigations give a mechanistic understanding of the incorporation process and show that the incorporation of trivalent metal ions is not a simple coupled substitution mechanism but involves complex substitution mechanisms.

Bugs in stress: Microbial control of surface reactivity in a stress field

C.A. STURM1, M.S. WATER2, R.S. ARVIDSON1, M. EL-NAGGAR3, S.D. GOODMAN2, K.H. NEALSON3, A. LÜTTE1 AND F.E. UDWADIA4

1Dept. of Earth Science, Rice Univ., Houston TX 77005 USA (sturm@rice.edu, aluttge@rice.edu)
2Div. of Diag. Sci., USC, Los Angeles, CA 90089 USA
3Dept. of Earth Sciences, USC, Los Angeles, CA 90089 USA
4Dept. of Aerospace and Mechanical Engineering, USC, Los Angeles, CA 90089 USA

The reactivity of a solid surface is strongly affected by the imposition of non-hydrostatic stress: the resulting strain rate is a driving force for mass transfer during pressure solution. Previous work [1,2] has shown that bacteria (e.g., *Shewanella oneidensis* MR-1) recognize and modify crystal surfaces through apparent recognition of surface energy, and are thus potentially sensitive to the distribution of surface stress as well. Here we present the results of a novel integration of vertical scanning interferometry (VSI) with the means to control and measure stress distribution on a solid surface, through controlled deflection of a cantilever beam. These deflection data, measured with VSI at (sub-)nanometer vertical and sub-micron lateral resolution, yield a high resolution map of surface deformation. These data can be compared with Euler-Bernoulli beam bending theory and elastic constants to yield a quantitative prediction of material response. This controlled system can be immersed in a fluid cell inoculated with MR-1 (or other microorganisms) and thus permits the study of bacterial interaction with a stressed surface.

This new technique can be used for abiotic systems as well and has a large potential for applications in earth, environmental, and material sciences.

The eclogite type locality is located in the Kor- and Saualpe region of the Eastern European Alps. The region also hosts one of the largest shear zones of the orogen: The Plattengneiss shear zone. Peak metamorphism occurred around 15 kbar and 700°C and the duration of its metamorphic cycle is loosely constrained by peak ages around 80 Ma and fission track ages around 50 Ma.

Despite the high temperatures of peak metamorphism, equilibration of both, major elements and radiogenic isotopes is extremely heterogeneous so that metamorphic conditions and the absolute timing thereof are not very well constrained. The lack of pervasive equilibration suggests that the highest grade metamorphic conditions were only achieved for a very short time and/or at very dry conditions.

In a series of projects over the last 10 years we have attempted to constrain both, the water content of the rocks and the time scales of metamorphism using petrological rather than geochronological methods. Although we generally obtain very short time scales and dry conditions, our studies are plagued by the inherent problems of petrological methods.

Nevertheless, on the largest scale, we have determined a metamorphic field gradient from north to south across the Koralpe range that shows that metamorphic conditions increase by less than 20°C per kilobar. We suggest that this shallow field gradient may be interpreted in terms of a non-lithostatic pressure gradient. This in turn implies that these conditions prevailed only very briefly.

Fractional crystallization of monosulfide solid solution from sulfide liquids lead to the PGE enrichment in the Jinchuan Ni-Cu sulfide deposit, western China

SHANGGUO SU1,2, CHUISI LI1,2,3, MEIFU ZHOU4, EDWARD M. RIPLEY 3 AND LIANG QI4

4Department of Geological Sciences, University of Hong Kong, Hong Kong, China

Discordant lenses of Pt-Pd enriched zones (ores bearing up to 1.0 ppm of Pt or Pd) have recently been identified in the sulfide-bearing peridotite of the Jinchuan Cu-Ni-PGE (Platinum group element) sulfide deposit, China. Chalcopyrite, pyrrhotite, and pentlandite occur in both Pt-Pd enriched zones and normal ores, but Cu-bearing minerals such as cubanite and Bi-, Te-, and As-bearing minerals are more abundant in the Pt-Pd enriched zones. Sperrylite is the major Pt-host minerals in the Pt-Pd enriched zones interstitially and occurs mainly as euhedral grains within base-metal sulfides which occur among the cumulates of olivine. PGE-enrichment is found only in sulfide-bearing samples. In orebody 1 and orebody 24, Rh, Ru, and Ir are positively correlated, but a negative Ir-Pd and Ir-Pt correlation. However in orebody 2 Rh, Ru, Pt, Pd and Ir are positively correlated.

Taken together, the elemental correlations and mineralogical data support a model for the origin of Pt-Pd rich ores in Orebody 1 and Orebody 24 of the Jinchuan deposit are consistent with fractional crystallization of monosulfide solid solution from sulfide liquids on cooling; The origin of Orebody 2 involves variable magma/sulfide liquid mass ratios (R-factors).
New $^{40}\text{Ar}/^{39}\text{Ar}$ and K-Ar ages from Macolod Corridor, SW Luzon, Philippines: Implication for its volcanic history

M. Sudo$^1$, E.L. Listanco$^2$, N. Ishikawa$^3$, T. Tagami$^4$, H. Kamata$^3$ and Y. Tatsumi$^5$

1 University of Potsdam, Institute of Geosciences, Germany (msudo@geo.uni-potsdam.de)
2 University of Philippines, NIGS, Philippines (eddie.listanco@up.edu.ph)
3 Kyoto University, HES, Japan (ishikawa@gaia.kyoto-u.ac.jp, kamata@gaia.kyoto-u.ac.jp)
4 Kyoto University, Graduate school of science, Japan (tagami@kueps.kyoto-u.ac.jp)
5 JAMSTEC IFREE, Japan (tatsumi@jamstec.go.jp)

Macolod Corridor, southwestern Luzon, Philippines, is an extensive Quaternary volcanic field including Taal caldera and many monogenetic/polygenetic volcanoes. Recently reported K-Ar or $^{14}\text{C}$ ages (Listanco, 1994; Sudo et al., 2000) suggest that several volcanoes have younger ages than e.g., 0.14 Ma. However, the history of the possible caldera, located at the central lobe of the lake Laguna de Bay, at the north of Macolod Corridor has not been well understood. Radiometric dates remain few other than the K-Ar age, 1.84±0.07 Ma (error: 1σ), from an essential scoria (sample name 013006; Sudo et al., 2000) with a size of ~30 cm in the pyroclastic (scoria) flow at the northeastern rim, or the $^{14}\text{C}$ ages of 5000 to 47000 yBP, from pyroclastic materials between Laguna de Bay and Metropolitan Manila.

In this study, the essential scoria (sample name P4-2), smaller than 10 cm, included in the pyroclastic (scoria) flow near Teresa city located at the north of Laguna de Bay, and the scoria, 013006, have been dated at the new $^{40}\text{Ar}/^{39}\text{Ar}$ chronology laboratory in the University of Potsdam. The system used consists of a continuous CO$_2$ laser, Micromass 5400 noble gas mass spectrometer and the ultra-high vacuum tubes adopting SAES getters and a cold trap. The prepared samples were irradiated for 96 hours at the reactor in the Geesthacht Neutron Facility (fast neutron flux: $1\times10^{12}$ n/cm$^2$/s) together with the Fish Canyon Tuff sanidine and crystals of CaF$_2$ and K$_2$SO$_4$.

The obtained $^{40}\text{Ar}/^{39}\text{Ar}$ plateau ages are 1.85±0.01 Ma and 1.83±0.02 Ma from P4-2, while 1.92±0.03 Ma from 013006. With the K-Ar age, 1.82±0.05 Ma (unpublished), obtained from the scoria in the same outcrop for 013006, all the ages show agreement within 2 sigma error. These ages would be the constraints for solving the history of the caldera at Laguna de Bay.

Gabbros drilled by IODP Leg 305, 30°N, Mid-Atlantic Ridge

G. Suhr$^1$, E. Hellebrand$^2$, K.P Jochum$^3$ and Legs 304/305 Scientific Parties

1 Geol.-Mineral. Inst., Uni-Koeln, (guenter.suhr@uni-koeln.de)
2 Dept. Geol. Geophy., Univ. Hawaii, (ericwgh@hawaii.edu)
3 Max Planck Inst. Mainz, (kpj@mpch-mainz.mpg.de)

IODP Hole 1309D (Legs 304/305) penetrated 1415 m into the core-complex of the Atlantis Massif at 30°N, Mid-Atlantic Ridge. Of the 75% recovered rock, 96% is gabbroic. Possibly, a larger-scale magmatic cycle is preserved between 600 und 1240 mbsf, as marked by olivine-rich troctolites at the base and more common gabbro-norites near the top. In detail, however, internal magmatic contacts are numerous with more evolved rocks intruding into less evolved ones. Here we present an overview of the 800-1200 mbsf interval and a detailed study of the transition from evolved rocks below 1235 mbsf to overlying primitive gabbros.

Geochemically, there is a good correlation between the REE in cpx, the Mg#$^+$ in cpx, and lithological evolution. The data can be modeled as increments of batch fractionation ranging from 5 to >80% from a primitive N-MORB. There is no immediate need for magma replenishment. The rims of nearly all clinopyroxenes were overprinted by an evolved melt. A three stage model is required to explain the data set: (1) a cumulus phase; (2) displacement of residual melt and formation of new cumulate bodies from it. These two processes can explain the presence of well-equilibrated, but differently evolved cores of clinopyroxene. (3) Compaction of residual melt and differentiation of it as it migrates through the cumulus pile. This stage explains the late overprint of the clinopyroxene rims.
‘Green’ geosequestration: Secure carbon sequestration via plant silica biomineralisation

L.A. SULLIVAN\(^1,2\) AND J.F. PARR\(^1,2\)

\(^1\)Southern Cross University, PO Box 157, Lismore, NSW 2480, Australia (leigh.sullivan@scu.edu.au)
\(^2\)Plantstone Pty Ltd, 90 Zouch Road, Stoney Chute, 2480, NSW, Australia

Phytoliths form via biomineralization processes as microscopic grains of silica in plants, especially grasses. During plant growth a proportion of the organic carbon produced by plants is encapsulated by silica within the microscopic phytoliths. This phytolith occluded carbon (PhytOC) usually comprises much less than 1% of the dry weight of plants, and less than 10% of the total carbon pool in grassland topsoils (with ages of < 200 years). However, data from soil chronosequences shows that the high resistance of the PhytOC fraction (relative to the other soil carbon fractions) against decomposition processes results in PhytOC comprising ~70% of the total carbon pool in grassland topsoils that have been isolated for >3,000 years from fresh plant material addition by burial. Therefore, unlike most plant matter, which readily decomposes returning CO\(_2\) to the atmosphere, the organic carbon occluded in phytoliths effectively sequestrates carbon in soils and sediments in a very secure manner. This ‘green’ geosequestration process (i.e. occlusion of carbon in phytoliths) is currently responsible for the secure sequestering within soil of ~300 million tonnes of CO\(_2\) equivalent per year globally.

More over different plant types biomineralise silica and yield PhytOC at greatly different rates. Some major crops produce over 100 times more PhytOC than other major crop types. Furthermore, varieties within a single major crop type, such as sugar-cane and sorghum, have been found to produce widely differing quantities of PhytOC. This suggests that crop/cultivar choice decisions by farmers and foresters etc have a considerable impact on the amount of soil carbon sequestered and are a significant contributing factor affecting the global carbon cycle. It follows that the management of PhytOC in crops, pastures, forests etc has the potential to greatly enhance the current rates of secure terrestrial carbon sequestration. 

Subducted noble gas and halogen preserved in wedge mantle peridotite from the Sanbagawa belt, SW Japan

\(^1\)Laboratory for Earthquake Chemistry, Graduate School of Science, University of Tokyo, Tokyo, Japan (sumino@eqchem.s.u-tokyo.ac.jp)
\(^2\)SEAES, The University of Manchester, Manchester, UK
\(^3\)Department of Earth and Planetary Sciences, Graduate School of Environmental Studies, Nagoya University, Nagoya, Japan

Water-rich fluids released from subducting slabs play an important role in arc volcanism. Indeed, subduction volcanism is thought to efficiently return volatiles contained in subducting material back to the Earth’s surface. Less than 100% removal of the volatile component may result in volatile recycling into the deep mantle [1]. The volatile composition of subducting fluids is however, not well characterised. The Higashi-akaishi peridotite body in the Sanbagawa metamorphic belt, southwest Japan, is possibly a unique example of a km-scale sliver of a former mantle wedge exhumed from depths of at least 100 km. Serpentine dominated micro-inclusions in olivine grains in the peridotite are regarded as relics of former water-rich inclusions developed in the wedge mantle above a subducting slab. Thus, it is expected that these micro-inclusions should preserve characteristics of slab-derived fluids. Determination of their compositions could provide important geochemical constraints on subduction zone processes.

Noble gas and halogen determination of the micro-inclusions has been carried out using noble gas isotope analysis of both neutron-irradiated and unirradiated samples. The following isotopic characteristics have been determined: (1) \(^3\)He/\(^4\)He ratios of 1.4-1.8 Ra represent a mixture of mantle and radiogenic He; (2) \(^40\)Ar/\(^36\)Ar ratios up to 470 are close to the atmospheric ratio with a small contribution of mantle and/or radiogenic Ar; (3) Seawater-like noble gas elemental ratios enriched in heavy noble gases; and (4) halogen (Cl, Br, and I) composition is similar to marine pore fluids and brines. These characteristics imply that noble gases and halogens with compositions little different to marine pore fluids are injected into the mantle wedge just above the subducting slab.

The subducted halogen and noble gas elemental ratios are clearly distinct from those of arc volcanic gases. This implies that the Higashi-akaishi peridotite body has frozen in and preserved an inferred but previously unseen part of the volatile recycling process. Return of these volatiles to the atmosphere via arc volcanism requires the addition of a mantle component and fractionation during degassing. A small proportion preserved in the downgoing slab can explain the heavy noble gases observed in the convecting mantle.

Using reflectance spectroscopy for the reconstruction of penguin palaeoecological process in Antarctic ornithogenic sediments

JING SUN\(^1\), XIAODONG LIU\(^1\), LIGUANG SUN\(^1\) and WENQI LIU\(^2\)

\(^1\)Institute of Polar Environment, University of Science and Technology of China, Hefei, Anhui 230026, P. R. China (ycx@ustc.edu.cn; slg@ustc.edu.cn)
\(^2\)Structure Research Laboratory, University of Science and Technology of China, Hefei, Anhui 230026, P. R. China

The present study explored the application of the rapid, cost-effective, non-destructive and simultaneous technique of reflectance spectroscopy within visible-near-infrared region to infer penguin palaeoecological records in the maritime Antarctic. A total of 106 samples taken from four sediment cores (Y2, Y2-4, Y4, AD3) on the Ardley Island were measured by both chemical and spectral methods. These cores were previously reported to be influenced by penguin guano, and nine elements including sulfur (S), phosphorus (as P\(_2\)O\(_5\)), calcium (as CaO), copper (Cu), zinc (Zn), selenium (Se), strontium (Sr), barium (Ba), and fluorine (F) were identified as bio-elements; their concentrations could be used as inorganic geochemical indicators for tracking historical penguin population change. The reflectance (r) and its derived indexes were employed to develop calibrations for predicting nine bio-element concentrations, using stepwise multiple linear regression (s-MLR) and principal component regression (PCR) approaches. R between optimal spectra-predicted and chemically analyzed concentrations were Ba: 0.894, all the other eight elements >0.954 for s-MLR; Ba: 0.926, all the other eight elements >0.963 for PCR.

Furthermore, principal component analysis (PCA) was performed on all the reflectance spectra data and the results showed that the first two factors were able to account for 98.9% of the variance of the data. The first PCA factor(PC1), accounting for 95.8% of the total variance, could be explained to bear the information of the content of penguin guano, and thus the PC1 score against depth of the samples (curve A) indicated the fluctuation of historical penguin population. In addition, by using spectra of pure guano and pure soil, these absorbance spectra data (log1/r) of ornithogenic sediments were linearly separated to guano part and soil part. The penguin population change inferred from the separated guano proportion (curve B) was consistent with curve A, and both curves showed similar historical change trends as inferences from inorganic elements and isotopes. Overall, this study demonstrated that using reflectance spectroscopy to infer palaeoecological information recorded in Antarctic ornithogenic sediments is feasible.

The coupling between plate subduction and intraplate evolution in eastern China

W.D. SUN\(^{1,2}\), X. DING\(^1\), Y.H. Hu\(^1\) AND X.H. Li\(^1\)

\(^1\)Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Wushan, Guangzhou 510640, P. R. China. (weidongsun@gig.ac.cn)
\(^2\)School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026

Plate interactions along subduction zones usually cause deformations ofoverlaying crusts as shown in the Andes. Numerical modelling shows that plate interaction during plate subduction is of critical importance for intraplate tectonic evolutions of the American continent [1].

Eastern China was an active continental margin related to the subduction of the paleo-Pacific plate under Eurasia from Jurassic to Cretaceous. This continent is well known for the removal of subcontinental lithosphere mantle with complicated geological evolutions, which leads to different models, ranging from extension to subduction-related compression and crust delamination etc. We find that the Cretaceous tectonic evolution in eastern China matches remarkably well with the drifting history of the paleo-Pacific plate. The most pronounced phenomenon is that the eastern China large-scale orogenic lode gold mineralisation occurred at about 125 Ma [2], concurrent with the major shift in the drifting direction of the subducting paleo-Pacific Plate [3] and the formation of the Ontong Java Plateau. Given lode gold deposits usually formed onset of compressional or transpressional deformations, the lode gold deposits dated the major tectonic change from extension to transpression in eastern China [4], consistent with the subduction regime and other geological records in the region. The Early Cretaceous drifting history of the paleo-Pacific also matches with other tectonic and magmatic evolutions in eastern China, suggesting that the major geological events in eastern China in the Early Cretaceous have been mainly controlled by the subduction of the paleo-Pacific plate, and that plate interactions are important driving forces for intraplate tectonic evolution in general. This provides a new angle of view to understand the tectonic evolution of the eastern Eurasian continents, e.g., the mechanism behind lithosphere thinning in eastern China as well as the evolution of the Tan-Lu Fault.

40Ar/39Ar dating of muscovite from the Maofeng Granite, N-Guangdong Province, China

Z.X. SUN, W. ZHANG, B. GAO
East China Institute of Technology, Fuzhou, Jiangxi 344000, China (zhxsun@ecit.edu.cn)

The Maofeng Granite, located in the Guidong granite composite, N-Guangdong Province, China, has been paid much attention to by geoscientists because of its hosting several big uranium deposits. Two muscovite concentrates have been prepared from representative samples collected from the outcrop of the granite body. They were analysed using incremental-release 40Ar/39Ar method. The 40Ar/39Ar apparent ages of the two samples are shown in Fig. 1.

The plateau ages ranging from 131.2±0.5 to 136±0.9 Ma are much different from the single grain zircon U-Pb ages varying from 207.6±3.2 to 219.6±0.9 Ma of the Maofeng Granite reported by previous researchers. The plateau ages of the U ore-forming hydrothermal activity.

This work is funded by China National Foundation of Natural Sciences under the Project No. 40472147.

Oxygen isotopic zonality at the Iultin Sn-W Deposit (Chukotka, North-East of Russia)

T. SUSHCHEVSKAYA 1, M. SPASENNYKH 1, A. IGNATIEV 2, AND T. VELIVETSKAYA 2

1Vernadsky Institute of Geochemistry and Analytical Chemistry RAS, Moscow, Russia (ryzhenko@geokhi.ru)
2Far East Geological Institute RAS, Vladivostok, Russia, (ignatiev@fegi.ru)

The oxygen isotope composition of host rocks and main vein minerals was studied at the large well known Sn-W Iultin deposit with application to the role of mixing fluids of different origins in the deposition of Sn-W ores in granite-related hydrothermal systems.

The deposit is located in the exo- and endocontact of leucogranite stock (K2) and is formed by the seria of the proximate quartz veins in hornfelsized sandstone-schist rocks (T1-2). The veins and greisens are largely composed of the productive mineral assemblage (quartz, muscovite, cassiterite, wolframite, arsenopyrite, subordinate beryl, scheelite), formed from sodium chloride boiling solutions enriched in CO2 and CH4 at T 270-350°C, P 0.5-1.0 kbar as it followed from fluid inclusion data. The postore sulfide and fluorite-carbonate assemblages are poorly developed.

The oxygen isotope composition of the rocks was examined in: a) metamorphosed sedimentary rocks of outer part of hydrothermal system, b) the contact part of the leucogranite cupola, c) the altered wall rocks in the central part of the deposit across the large ore body (62/50) and d) the wall rocks of the veins (7,10), poor in Sn-W ores. It was found that large (hundred meters) low-18O zones have been formed in the central part of the Iultin hydrothermal system. The δ18O values decreased monotonously from the initial 12‰ (1km from the contact) to 3-5‰ at the contact with granite. Substantial 18O decrease in the contact zone, formed by greisenized granites, is the result of active movement of hydrothermal solutions and is explained by higher permeability in comparison with metamorphosed sedimentary rocks (Spasennykh et al., 2002). During the development of vein ore bodies the wall rocks were altered insignificantly in oxygen isotope composition. The high δ18O values of minerals of productive association bore witness to magmatogenic source of the fluids. The notable depletion of the wall rocks in 18O took place during the final stage, when meteoric waters dominated in the hydrothermal system. That time no significant ascending fluid flows were focused within the veins. The initial picture of oxygen isotope zonality, connected with ore deposition, had been wiped away by active interaction of exogenic waters with host rocks.

This study was supported by the Russian Foundation for Basic Research (project nos. 03-05-65036, 07-05-00432)
Synchrotron-based studies of fluids, mineral-water interfaces and glasses

S. R. Sutton1,2, M. Newville3, P. Eng2, M. L. Rivers1,2, and S. K. Ghose2

1Department of Geophysical Sciences
2CARS, University of Chicago, Chicago, IL
(sutton@cars.uchicago.edu)

Synchrotron-based analytical methods have proved to be valuable in a wide variety of studies of fluids, glasses and mineral-water interfaces. This presentation is an overview of experiments of this nature being conducted at the GSECARS facility at the Advanced Photon Source (USA).

X-ray absorption fine structure (XAFS) spectroscopy is one of the principal methods used in these studies. One such microbeam application involves the determination of valence states for multivalent elements in igneous glasses, which in turn are used as proxies for oxygen fugacity inferences for both terrestrial and extraterrestrial magmas (e.g., Sutton et al. 2005). MicroXAFS is also used in ore-relevant studies to establish the speciation of metals in hydrothermal fluids. These applications involve measurements on fluid inclusions (both natural and synthetic) where the samples are analyzed in situ above their homogenization temperature using a heating stage (e.g., Berry et al. 2006).

Mineral-water interface studies aim to establish the atomic-scale structures of mineral surfaces, the structural and reactivity changes that occur during hydration and the resultant metal sorption properties of these surfaces. These in situ experiments typically involve combinations of x-ray reflectivity, crystal truncation rod, x-ray standing waves and grazing-incidence XAFS methods. A focus of this work is the determination of structural and reactivity changes of hydrated metal oxide surfaces (e.g., Eng et al. 2000).

Fluids can be imaged within objects using x-ray computed microtomography (CMT). One aspect involves the determination of the distribution and flow properties of multi-phase fluids in soil columns (e.g., Culligan et al. 2006). CMT methods can also reveal transport paths of metals in plants (e.g., McNear et al. 2005).

Raman spectroscopy of organics in Antarctic micrometeorites

A. Suzuki1, Y. Yamano1, S. Nakashima1, T. Nakamura2 and E. Katafuchi2

1Department of Earth and Space Science, Osaka University, 1-1 Machikaneyama-cho, Toyonaka-shi, Osaka 560-0043, Japan (akiko.s@ess.sci.osaka-u.ac.jp)
2Department of Earth and Planetary Sciences, Kyushu University, Hakozaki, Fukuoka 812-8581, Japan

Introduction
Micrometeorites are expected to be the major source of the C flux from extraterrestrial materials delivered to the earth and might represent a major contribution to the pre-biotic organic matter on the early earth (Maurette 2006). On the other hand, organics from carbobaceous chondrites have been characterized non-destructively by means of Raman microspectroscopies (Raynal, 2003; Matrajt et al., 2004).

Methods
Raman spectra have been measured on 73 points of 11 unmelted Antarctic micrometeorite (AMM) grains pressed on aluminum foils under a Raman microscope. Peak positions, full widths at half maximum (FWHM), band intensity ratios (I(D)/I(G) and band area ratios (A(D)/A(D+G)(%)) for D (defect: ~1360 cm⁻¹) and G (graphite: ~1600 cm⁻¹) bands were determined for the AMMs and compared with the literature data on carbonaceous chondrites and other cosmic materials.

Results and Discussion
The peak position and FWHM of G band of the AMMs are ranging from 1581 to 1593 cm⁻¹, and from 87 to 133 cm⁻¹, respectively. These value ranges are almost the same as those for CM2 carbonaceous chondrites. The peak position and FWHM of D band for the AMMs are from 1357 to 1379 cm⁻¹, and from 66 to 271 cm⁻¹, respectively. This region for the AMMs mostly overlaps with the region for C11s. The D peak position range of the AMMs is similar to those for CM2 and CR2 chondrites. The I(D)/I(G) and A(D)/A(D+G)(%) are ranging from 1.1 to 1.7 and from 65 to 78, respectively. These distributions of the AMMs are close to Orgueil carbonaceous chondrite (CI1). A(D)/A(D+G) band area ratios (%) of the AMMs are in the similar range to those for CR2 and Tagish Lake carbonaceous chondrites.

These Raman features of macromolecular carbonaceous materials in the AMMs are similar to those in C1 and C2 chondrites. The AMMs studied here might have the aqueous alteration level higher than 2 and have possibly delivered useful organic components to the early earth.

Osmium behavior in a subduction zone setting elucidated from Cr-spinel sands of boninites and tholeiite in Bonin islands

K. SUZUKI, R. SENDA AND K.SHIMIZU
Institute for Research on Earth Evolution (IFREE), Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan (katz@jamstec.go.jp)

Osmium (Os) isotope is a sensitive tracer of crust and sediment as its eroding form, because of significant contrast between a high Os isotope ratio of crust and sediments ($^{187}\text{Os}/^{188}\text{Os}>0.5$) and a low ratio of mantle ($^{187}\text{Os}/^{188}\text{Os}<0.13$). Therefore, Os isotope provides information on slab components contribution to the mantle source of island arc lavas (Brandon et al., 1999; Borg et al., 2000; Alves et al., 2002). Radiogenic Os isotopic compositions are commonly found in volcanic lavas and peridotite xenoliths in a subduction zone setting. Though most of the authors had attributed these high $^{187}\text{Os}/^{188}\text{Os}$ to the input of the slab component to the mantle source, some pointed out that assimilation of crustal materials during magma ascent possibly reproduce the elevated Os isotope ratios of the arc lavas (Lassiter and Luhr, 2001; Woodhead and Brauns, 2004). Since then, whether the high Os isotope ratios of arc lavas are caused by contribution of slab component or by assimilation of the overlying crust has long been highly debated.

Here we report the unradiogenic Os isotopic ratios of Cr-spinel sands from Chichi-Jima and Yome-Shima boninites and the significantly high $^{187}\text{Os}/^{188}\text{Os}$ of Cr-spinels of the Mukoo-jima tholeiite, Izu-Bonin arc. As Cr-spinel is resistant to later alteration and weathering and, more importantly, is the early stage crystal in the fractional crystallization, it preserves the chemical and isotopic compositions of very primitive magma in its melt inclusion and spinel itself without any later stage crustal contamination. Therefore, extremely high $^{187}\text{Os}/^{188}\text{Os}$ of 0.1429 of Mukoo-jima tholeiite is most likely caused by inputs from slab component, not by assimilation of the overlying crust. As a result, we demonstrate that Cr-spinel is the most useful mineral to decode the Os isotopic compositions of primitive arc magmas.

Reduction of U(VI) by Shewanella putrefaciens in the presence of organic acids

Y. SUZUKI, T. NANKAWA, T. OZAKI, T. OHNUKI AND A.J. FRANCIS

1Research Group for Hevey Element Biogeochemistry, Japan Atomic Energy Agency, 2-4, Shirakata shirane, Tokai, Ibaraki 319-1194, Japan (suzuki.yoshinori@jaea.go.jp)
2Brookhaven National Laboratory, Upton, New York 11973, USA (ajfrancis@bnl.gov)

Introduction
The oxidation state of uranium is one of the important factors that affect its migration in the environment. Although microbial reduction of U(VI) has been extensively investigated, limited information is available of the effects of organic acids. We examined the reduction behavior of U(VI) by Shewanella putrefaciens in the organic acid solutions.

Experimental
Shewanella putrefaciens was incubated in anaerobic medium at pH 7 that contained 1mM UO$_2^{2+}$, 50 mM lactic acid and 100 mM organic acids (acetic, oxalic, malonic, succinic, adipic, malic, tartaric, citric acid or EDTA). Aliquots of medium were periodically withdrawn, and filtered. Dissolved uranium concentrations and UV-vis spectra of the aliquots were measured. Precipitates generated were analyzed by XANES and SEM. The medium without organic acid (except for lactic acid) was examined as a control.

Results and Discussion
In the control medium and the media containing acetic or adipic acid, dissolved uranium decreased with time, and precipitates were observed. The XANES spectra of the precipitates showed that the precipitates contained U(IV). The SEM analysis showed that the precipitates was uraninite (UO$_2$). In the other media, dissolved uranium was almost constant. The UV-vis spectra showed that dissolved U(VI) was reduced to U(IV), and it was present as U(IV) organic complex in the medium containing oxalic, tartaric, citric acid or EDTA. No evidence of U(VI) reduction was observed in the media with succinic or malic acid. These results suggest that the reduction behaviors of U(VI) by S. putrefaciens are categorized into three cases depending on organic acid.

James Ross Basin contains one of the thickest and most complete Jurassic-Paleogene age sedimentary successions anywhere in the Southern Hemisphere. The basin is filled by a sequence of arc-derived clastic and volcaniclastic marine sediments through the Late Jurassic to Late Eocene. In order to reconstruct thermal history for basin low-temperature evolution of potential sedimentary resources and post-sedimentations succession, we dated detrital zircons andapatites from the sequence of sandstones collected from the James Ross and Seymour Island using fission-track (FT) thermochronology. All zircon FT ages are older than apatite FT ages provided in the identical individual rocks. Provenance of individual FT zircons and apatites ages varies in wide spread of Carboniferous to Early Paleogene ages between ~60 to ~350 Ma. Jurassic-Cretaceous ages of northwest James Ross Island are probably compatible with derivation of sediment from western lying Mt. Reece and Mt. Bradley region, where the rocks of the Antarctic Peninsula batholith appears.

Sediments from Seymour Island are probably originating from Trinity Peninsula Group and Antarctic Peninsula Volcanic Group. Shortening of tracks was due to subsequent volcanic/magmatic activity before transport of rocks and deposition into the James Ross Basin or alternatively, due to volcanic reheating after deposition.

Time-temperature modelling of the apatite fission-track samples from Seymour Island (Marambio and Seymour Island Groups) shows a similar thermal history style, involving a period of total thermal annealing and subsequent cooling (erosion/denudation). The samples were above 120°C until about the Upper Triassic (220 – 210 Ma) age and then followed by the period of relatively quick Neogene and Quaternary exhumation (since ~30 – 40 Ma) to the present erosion surface.

**Isotopic and trace element evidence for groundwater discharge in the coastal zone**

P.K. SWART¹, J STALKER² AND R.M. PRICE³

¹MGG/RSMAS, University of Miami, Fl 33149 (pswart@rsmas.miami.edu)
²Department of Earth Sciences, Florida International University, Fl 33199 (jstalker@fiu.edu)
³Department of Earth Sciences and SERC, Florida International University, Fl 33199 (pricer@fiu.edu)

Determination of the relative importance of freshwater discharge from surface and groundwater sources into coastal estuaries and lagoons is important in making assessments regarding water control policies. In this study, variations in δD, δ18O, δ13C, and concentrations of Sr, Ba, and Mg relative to Ca have been used to distinguish the input of fresh groundwater from rainwater and surface discharge into coastal ecosystems of South Florida (Biscayne Bay and Florida Bay). These tracers are able to distinguish between these various sources, because rainwater has relatively negative δ18O and δD values and low concentrations of cations. Groundwater also has depleted δ18O and δD, but low Sr/Ca, Mg/Ca, and Ba/Ca ratios. In contrast, surface waters have relatively positive δ18O and δD values, intermediate concentrations of Ca, high concentrations of Ba, and negative δ13C values (Swart and Price, 2002). The differences in the geochemical parameters arise because (i) surface waters in South Florida are highly evaporated thereby enriching δD and δ18O values, (ii) surface waters are highly influenced by surface organic activity which produces waters depleted in δ13C and elevated in Ba, (iii) groundwaters dissolve the local carbonate rocks which contain high concentration of Ca, but relatively low concentrations of Ba, Sr, and Mg; these waters also contain relatively positive δ13C values. Our results indicate that within Florida Bay, the input of fresh groundwater contributes an insignificant amount to the hydrological balance. Instead the salinity is controlled by runoff and precipitation. In contrast in Biscayne Bay, groundwater, surface water, and direct precipitation all contribute equally to the salinity balance.

In situ U/Pb geochronology of baddeleyite by LA-ICPMS

P.J. SYLVESTER, M.N. TUBRETT AND A.K. SOUDERS

MicroAnalysis Facility, INCO Innovation Centre and
Department of Earth Sciences, Memorial University, St.
John’s, NL A1B 3X5, Canada (pauls@esd.mun.ca)

Baddeleyite (ZrO$_2$) is a useful U-Pb chronometer for determining magmatic crystallization ages of silica-poor rocks that failed to form zircon. In situ baddeleyite dating has been plagued by analytical problems, however, limiting its application. Crystal orientation effects produce unacceptably large variations in $^{206}$Pb/$^{238}$U ratios measured by ion microprobe so that ages must be determined from $^{206}$Pb/$^{206}$Pb ratios alone. Laser ablation-inductively coupled plasma mass spectrometry (LA-ICPMS) analyses have produced $^{206}$Pb/$^{238}$U and $^{207}$Pb/$^{206}$U ratios that plot in arrays extending far above concordia, suggesting severe laser-induced Pb/U fractionation. Correction procedures for instrumental mass bias, in particular the extent of matrix effects between baddeleyite and common zircon standard reference materials (SRMs) used for calibration of measured isotope ratios, are poorly defined. We have dated two baddeleyites of known (TIMS) age using a Finnigan ELEMENT-XR magnetic sector ICPMS coupled to a GeoLas 193 nm ArF excimer laser ablation system. The baddeleyites are from carbonatite in the Phalaborwa Complex in South Africa (PHB; 2059.8± 0.8 Ma) and gabbroic anorthosite of the Duluth gabbro complex at Forest Center, Minnesota (FC-1; 1099.0± 0.6 Ma). Two methods commonly used for LA-ICPMS U-Pb dating were tested. The first involved spot analysis (40 micron beam, 5 Hz, 5 J/cm$^2$) and calibration of isotopic ratios by standard-sample-standard bracketing with zircon 91500 as the calibrant. The second employed raster analysis (10 micron beam, 10 Hz, 5 J/cm$^2$), making a 40 by 40 micron box pattern and Pb/U determinations by the “intercept” method. Mass bias corrections are made by reference to a tracer solution of Tl-Bi-$^{231}$U-$^{237}$Np (with a composition defined by reference to zircon SRMs) aspirated into the argon plasma at the same time as sample ablation. Both spot and raster analyses exhibited laser-induced U/Pb fractionation during analysis, but the degree of fractionation was much more severe for the spot analyses. PHB baddeleyite exhibited much more fractionation than FC-1 baddeleyite. The reason is unclear but may be related to polysynthetic twinning on {100} being less well-developed in FC-1. Pb and U are heterogeneously distributed in the PHB baddeleyite: there is much less scatter on Pb/U ratios when it is drilled perpendicular to the {100} planes than when drilled parallel to them, suggesting that Pb/U ratios are more homogeneous at the scale of laser sampling in this orientation. Both zircon SRM and tracer solution calibration methods produced inadequate mass bias corrections for measured Pb/U and $^{206}$Pb/$^{206}$Pb ratios and erroneous ages for analysed baddeleyites. LA-ICPMS U-Pb ages with accuracies comparable to those determined for zircon can be attained using raster analyses, intercept corrections, and a tracer solution calibrated for baddeleyite.

Efficiency of Cl recycling during subduction of oceanic crust: Constraints from melt inclusions in HIMU lavas

LINDSAY ANN SZRAMEK AND JOHN C. LASZITTER

The University of Texas at Austin, Geol Science Dept, 1 University Station C1100, Austin TX, 78712-0254, (szramek@mail.utexas.edu; laszitter1@mail.utexas.edu)

The amount of chlorine that is recycled into the deep mantle through subduction processes is poorly constrained. Estimates of the chlorine content in recycled, dehydrated oceanic crust range from <50 ppm [1] up to ~200 ppm [2,3].

In order to better constrain the Cl content in subducted crust, we have examined Cl concentrations as well as Cl/K$_2$O and Cl/Nb ratios in olivine-hosted melt inclusions in HIMU lavas from the island of Raivavae, Austral Islands. Raivavae lavas span a wide range of lead isotopic values, with $^{206}$Pb/$^{206}$Pb ranging from ~19.3 to 21.3. Previous isotopic and trace element studies suggest that Raivavae lavas derive from a mantle source containing ancient dehydrated oceanic crust.

Chlorine and K$_2$O concentrations range from 40-1070 ppm and 0.22-3.5 wt.% respectively. The majority of Cl/K$_2$O ratios range from 0.01-0.12 and Cl/Nb ratios range from 5-25. Cl/K$_2$O and Cl/Nb ratios are positively correlated with $^{206}$Pb/$^{206}$Pb and negatively correlated with $^{207}$Pb/$^{206}$Pb. In addition, a positive correlation exists between Cl/K$_2$O and Nb/Zr. No correlation exists between host olivine forsterite content and Cl concentration or Cl/K$_2$O ratios.

The lack of correlation between host forsterite content and inclusion Cl/K$_2$O and the correlation between Cl/K$_2$O and Pb-isotopes suggest that Cl contents and Cl/K$_2$O ratios in HIMU lavas are not controlled by shallow assimilation processes. This contradicts the previous suggestion of [1], who argued that elevated Cl/K$_2$O ratios in some Raivavae lavas resulted from assimilation of Cl-rich brine. Instead, the high Cl/Nb and Cl/K$_2$O ratios observed in the HIMU samples suggest that the HIMU source is preferentially enriched in Cl.

Because Nb should be largely retained in subducted oceanic crust during slab dehydration, we can use the average Cl/Nb ratio observed in inclusions from HIMU lavas (~18) to estimate a Cl concentration in recycled oceanic crust. For an average N-MORB Nb content of 5.6 ppm, we estimate ~100 ppm Cl in subducted oceanic crust after slab dehydration, intermediate between previous estimates of [1] and [3].

Given an estimated Cl content in altered oceanic crust of ~157-322 ppm [2], we estimate ~30-65% of the Cl in altered crust is retained in the slab after subduction-induced dehydration and eventually returned to the deep mantle.

The occurrences of turquoise in advanced argillic alteration of Darreh-Zerresk and Ali-Abad porphyry copper deposits, Taft-Yazd Province, Central Iran

B. TAGHIPOUR AND I. NOORBEHESHT
Department of geology, Isfahan University, Isfahan, Iran (goharr@yahoo.com)

The studied area is located in Cenozoic Magmatic Belt of Central Iran. In ali- abad area granitoid rocks which belong to tertiary age are caused the phyllic, argillic and advanced argillic alterations.

In addition to intrusives the red arkosic sandstones and microconglomerates (host rocks) have been subjected to processes of hydrothermal activity too. The following mineral assemblages are distinguished in altered rocks.

Sericite, quartz, kaolinite, epidote, garnet, pyrite, alunite, jarosite, turquoise and iron oxides.

Alunite- jarosite and turquoise occurred as veinlets, encrustations and disseminated nodules mainly in sericitized host rocks. Turquoise genesis are related to oxidation of sulfides and development of advanced argillic alteration in a supergene environment, according to following reactions:

\[\text{alunite} + \text{H}_3\text{PO}_4 + \text{CuSO}_4 + \text{K} = \text{turquoise} + \text{K}_2\text{SO}_4 + \text{H} \]
\[\text{Al(OH)}_3 + \text{H}_3\text{PO}_4 + \text{CuSO}_4 = \text{turquoise} + \text{H}_2\text{SO}_4 + \text{H}_2\text{O} \]

\textsuperscript{2}Department of Geology, Isfahan University
\textsuperscript{3}Department of Geology, Isfahan University, Shahid Beheshty University

Northern parts of Isfahan province are included into well known Cenozoic Magmatic Belt of Central Iran. There is extensive Eocene volcanic events. Field observation indicated that, the late intrusion bodies which are belonged to Oligo – Miocene are caused some dispersed hydrothermal alteration in area. On the base of XRD, XRF and SEM data mineralogy and chemical composition of fresh and altered volcanics are determined. Volcanic rocks with chemical composition andesite to trachy- andesite have more extensive in this area. Kaolinite, alunite and jarosite are major minerals in altered pyroclastic rocks. Mineral assemblages of these alterations are characteristic of acid – sulfate or advanced argillic type alterations. With attention to the geochemistry of major and trace element the kaolinite - alunite association are likely from hypogene source in Kesheh area.

Chondrite volatility trends revisited

R. TAGLE1 AND J. BERLIN2

1Dept. of Geology, Vrije Universiteit Brussel, B 1050 Brussels, Belgium (roald.tagle@vub.ac.be)
2Dept. of Earth & Planetary Sciences, UNM, Albuquerque, NM 87131, USA (jberlin@unm.edu)

At the Lunar and Planetary Science Conference, we showed that there is complementarity between EH and CK chondrites for certain elements in bulk meteorite patterns [1,2]. In search for more elements showing similar behaviour, we plotted bulk chondrite data (Fig. 1) from [3]. Data are normalized to “volatile-free” CI abundances considering 20% H2O and 3.5% C [4,1].

Fig. 1: Volatility trend for EH and CV/CK chondrites.

A general complementary “mirror-like” trend is observed for elements condensing above 1060 K (Au). CV and CK chondrites are enriched in refractory elements, whereas EH (and EL chondrites, not shown) are depleted. Between 1400 and 1300 K the patterns cross over with EH chondrites becoming enriched over CV/CK. This relative enrichment of EH continues with decreasing condensation temperature.

The temperature interval at which the element patterns cross over corresponds to the transition between refractory inclusion and chondrule formation. EH and EL contain <<1 vol.% refractory inclusions. Removal of a refractory component from the enstatite chondrite forming region has been suggested previously [e.g. 5]. Our observations indicate that this refractory component could have been transported into the CV/CK chondrite forming region before chondrite parent bodies accreted.

Spatial and temporal (30 yr.) variations of lead geochemical signature in a macrotidal highly polluted estuary

A. TAILLEZ1, A. JACQMOT1, J. PETIT1, C. MAERSCHALK1, D. LEMADEC1, N. FAGEL2, S. VERHEYDEN1, L. CHOU1 AND N. MATTIELLI1

1DSTE - Université Libre de Bruxelles (ULB) – CP 160/02, Av F.D. Roosevelt, 50, 1050 Brussels, Belgium (ataillez@ulb.ac.be)
2UR. Clay and Paleoclimate and Mare, University of Liège, B-4000 Liege, Belgium

Two dated sediment cores (210Pb) were sampled in 2005 on tidal flats of the Scheldt estuary at the vicinity of the heavily industrialized harbour city of Antwerp. Coring was close to the estuarine turbidity maximum and in the reactive 0-10 psu zone. The cores were compared with suspended particulate matter (SPM) and surface sediments (SS), sampled between 2002 and 2006 from the Scheldt river to the southern bay of the North Sea. Pb isotopic compositions measured by MC-ICP-MS were compiled regarding to grain-sized distributions as well as sedimentological, mineralogical and geochemical data. The present study aims at characterizing the sources and the evolution of Pb inputs during last 30 yr. in that complex environment.

As a whole, Pb isotopic data for SPM, SS and cores from the Antwerp area show a narrow range of variations. 206Pb/207Pb data vary of 1.9 ‰ (RSD) from the mean value of 1.1629 (with 1.1630 for SS and SPM, and 1.1628 for cores) suggesting that ~70% of particulate Pb has an anthropogenic origin. A close look at the Pb isotopic ratios highlights systematic variations reflecting different controlling mechanisms. In the SPM and SS samples, the larger Pb isotopic variations (from 1.1582 ± 0.000010 -2sd- to 1.1697 ± 0.000017) are related to daily tidal cycles, where the relative contribution of fluvial and marine waters controls the isotopic signature. In the cores, the relative lower variation range (from 1.1608 ± 0.000011 to 1.1646 ± 0.000007) may result from a larger time-series integration and homogenization of the surface layers by bioturbation. Pb isotopic variations are correlated with grain-sized distributions, that are controlled by changes in deposition modes, mainly related to neap tide/spring tide cycles. In contrast, the decrease in Pb concentration, recorded from the 75-80’s period to 2005, does not imply any significant isotopic answer. Therefore, Pb sources in the Scheldt estuary may remain unchanged, in component and relative contribution, over 30 yr. The water quality improvement, in terms of Pb contents, is not related to the removal of the leaded gasoline, but only to industrial emission control policies and establishment of water treatment plants.
Adsorption of oxyanions on schwertmannite and its post-adsorption behavior

M. Takada¹, K. Fukushi², T. Sato¹ and T. Yoneda¹

¹Hokkaido University, Sapporo, Hokkaido, Japan (t-morio@eng.hokudai.ac.jp)
²Kanazawa University, Kanazawa, Ishikawa, Japan (fukushi@kenroku.kanazawa-u.ac.jp)

Understanding of toxic trace metal behavior in the natural environment is important in predicting the long-term effects of human activities. Particularly, the behavior of toxic oxyanions is complex for the prediction. Iron hydroxides have been considered to play an important role for the behavior in nature. In this context, adsorption of toxic oxyanion on schwertmannite (major natural iron hydroxide in acidic condition) and its post-adsorption behavior were extensively investigated.

Synthesized schwertmannite was used in the adsorption experiments for Se, Cr, As, P at room temperature and pH 3.9. The concentration of the reactive fluid for the experiments ranged from 0.0mM-2.0mM. Aging experiments at 50°C were conducted for the schwertmannite exchanged original sulfates with the above oxyanions. The zeta-potential of schwertmannites with various oxyanions were also measured.

From the results of adsorption experiments, As and P selectivity on schwertmannite was higher than Cr and Se and much amount of As and P adsorbed on schwertmannite (Fig.1). XRD patterns of the samples with various oxyanions after aging experiments showed the schwertmannite with oxyanions with higher selectivity such as As and P was more stable than that with other oxyanions. The schwertmannite with lower selectivity was easily tranformed to goethite. The result of zeta-potential measurements suggested that inner-sphere complex would be formed for As and P and outer-sphere complex for Cr and Se with schwertmannite surface. Consequently, inner-sphere complexation with oxyanions would retard the transformation of schwertmannite (metastable phase) to goethite (stable phase).

Effect of volatiles in the partial melting in Earth’s asthenosphere

E. Takahashi, P. Bhalla, N. Takehara and K. Sato
Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan (bhalla@geo.titech.ac.jp)

Introduction and experimental procedure

Existence of partial melting in the asthenosphere is currently a matter of debate (i.e., Faul and Jackson, 2005). A recent study by Hirano et al. (2006) showed a natural evidence for an asthenosphere-derived magnatism on 140Ma old Pacific plate. The newly found alkalic basalts are less than 1Ma old and show remarkable vesicularity even erupted at 5500 m water depth which indicates high concentration of CO₂ present in the magma. In order to understand the nature of melts present in the asthenosphere, we performed a series of melting experiments on a parental alkalic picritic magma found on the Pacific plate near the Japan Trench (JPT-1 (18.4 wt% of MgO and 2.3 wt% of K₂O) and JPT-1* (~1 wt% each of CO₂ and H₂O were added to the JPT-1)). Experiments were also carried out using a mixture of a natural undepleted peridotite (KLB-1) and a wet alkalic picrite JPT-1* (97:3 in weight ratio). Two types of double capsules (Pt/graphite and Pt/Re) were used and the experiments were conducted at 1300–1500°C and 2.7–3.3 GPa for 40–120 hours using piston-cylinder apparatuses. Experiments are also in progress at pressures >5.0 GPa using multi-anvil apparatuses.

Results and discussion

At 3.0 GPa, dry alkalic picrite (JPT-1) has the liquidus T of 1450°C, whereas, at same pressure, the liquidus of the wet JPT-1* lies at ~1400°C and is multiply saturated with an assemblage of olivine+cpx+garnet. Although the dry solidus of the peridotite (KLB-1) is >1500°C at 3.0 GPa, K₂O-rich partial melts were observed in the run products between 1350 and 1500°C. In experiments using starting material (KLB-1+JPT-1*), cpx is the only phase (as quenched crystals) which represents the location of the partial melt. At ≤1350°C, K resides in isolated granules (most probably phlogopite), whereas at >1450°C, K is more widely distributed in interstitial quenched melt, between the cpx dendrites.

Our experimental results and the findings of Hirano et al. (2006) reinforce the partial melting model for the asthenosphere (Wyllie, 1988). Considering a short horizontal thermal gradient within the asthenosphere (Priestley and McKenzie, 2006) and small amounts of K₂O, H₂O and CO₂ are present, partial melt must be present ubiquitously under the oceanic plate.

Distribution of helium-3 plumes and deep-sea circulation in the central Pacific Ocean

N. TAKAHATA¹, K. KIYOTA¹, K. SHIRAI¹, M. NISHIZAWA¹,², Y. SANO³ and T. GAMO³

¹Ocean Research Institute, University of Tokyo, Japan
²Present address: Department of Earth and Planetary Science, Tokyo Institute of Technology, Japan

Introduction
Helium isotope data have been used to study the circulation of various water masses using the mantle derived helium [1]. In order to clarify the origin of helium and deep-sea circulation in the central Pacific basin, we have collected about 200 seawater samples at 20 stations along about 170°W from 45°N to 70°S at various depths (200m ~ 5500m) on the KH-03-1 and KH-04-5 cruises of the Research Vessel, Hakuho Maru. Observed ³He/⁴He data are compared with those in the eastern Pacific [1] and over the East Pacific Rise at 25°S [2].

Analysis
The ³He/⁴He ratios were measured on a conventional noble gas mass spectrometer after extraction, purification and separation using Ti getters and cryogenic charcoal traps. The observed ³He/⁴He ratios were calibrated against atmospheric helium. The ⁴He/²⁰Ne ratios were measured by on-line quadrupole mass spectrometer before cryogenic separation of He from Ne.

Results and Discussion
Homogeneous excess ³He of ~10% is observed below 1000-m depth over the Antarctic Ridge in the Southern Ocean. The excess is significantly smaller than those observed over the East Pacific Rise at 25°S of ~50% [2]. This may be due to the lower supply of mantle helium from the ridge and dilution by well-mixing of deep seawater by fast current around the Antarctic.

In meridional helium transect along 170°W line in the South Pacific, circulation pattern inferred from salinity and dissolved oxygen distributions is confirmed by ³He/⁴He ratio. Moreover a pattern of two helium-3 maxima at 10°N and 15°S with a minimum on the equator at 2500-m depth is observed, which is similar to those observed along WOCE P16 (152°W) and P17 (135°W) sections [1]. Observed pair of helium plumes may be originated from the EPR based on the lateral distribution of excess ³He at 2500-m depth, which suggests westward flows at 10°N and 15°S in the central Pacific Ocean.

Determination of lead isotopic ratios in ferromanganese crust by using MC-ICP-MS and NanoSIMS

Y. TAKATA1, M. TANIMIZU2, N. TAKAHATA1, H. AMAKAWA1 AND Y. SANO3

1Ocean Research Institute, the University of Tokyo (takata@ori.u-toyko.ac.jp)
2Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology

The isotopic compositions of such trace elements as Pb and Nd, which have short residence times in the ocean, are considered to be influenced by fluctuation of deep ocean circulation. Therefore, the isotopic compositions of those elements in seawater could be a sensitive tracer for investigation of deep ocean circulation.

Ferromanganese crusts are regarded as a natural archive of past deep ocean circulation. Because of quite low growth rates of crusts, a long range record of the fluctuation of deep ocean circulation is expected to be preserved in them. By using Pb, Nd and Hf isotopic compositions of crusts, intensive studies have been undertaken to reconstruct the past deep ocean circulation pattern [e.g., 1]. However, in those earlier studies, spatial resolution of determination spots for the isotopic ratios was ~1mm and it is equal to ~1Ma. Therefore, in order to improve the spatial resolution, we applied SIMS (NanoSIMS) analysis for determination of Pb isotopic ratios of crust. For evaluation of the data of NanoSIMS, the Pb isotope ratios were also determined by MC-ICP-MS method described in Tanimizu and Ishikawa [2].

We analyzed a ferromanganese crust collected at 19°N, 138°E in the Northwest Pacific Ocean. By using microdrilling technique (the spatial interval is ca. 1mm), we prepared the samples for MC-ICP-MS. The data obtained by MC-ICP-MS show a good agreement with in surface layer of other crusts collected in the Pacific (206Pb/204Pb ; 18.67 for this study, 18.7 ± 0.1 by Klemm et al. [3]). However, in the bottom of the crust, our data are less radiogenic than those obtained by NanoSIMS, the Pb isotope ratios were also determined by MC-ICP-MS method described in Tanimizu and Ishikawa [2].

NanoSIMS analysis of Pb isotopic ratios of the crust sample was performed by a spatial resolution of 20µm. The data of NanoSIMS are lower than those obtained by MC-ICP-MS for the same layer. A possible cause of the difference between the data of NanoSIMS and those of MC-ICP-MS is the interference of 204Hg on mass number 204 in NanoSIMS analysis. However, Hg concentration of the crusts is much lower than Pb concentration and cannot be a main reason for the discrepancy. Thus, there might be other unknown isobaric interferences or problems about sample preparations or analytical technique.

Exsolution texture of alkali feldspar in a granite porphyry

M. TAKAYA, N. SHIMOBAYASHI, A. MIYAKE AND M. KITAMURA

Department of Geology and Mineralogy, Kyoto University, Kyoto, 606-8502, Japan (m-takaya@kueps.kyoto-u.ac.jp)

Microtextures of alkali feldspar are useful tool for petrologists to deduce the thermal history of felsic rocks. Exsolution texture is, for example, closely related to the cooling rate. In slowly cooled rocks the thickness of the exsolution is coarser than in rapidly cooled rocks. The relationship between the cooling rates and the wavelength of exsolution lamellae in alkali feldspars has for a long time been examined by many previous researchers, e.g., for rhyolitic lava flow [1] and for syenitic rock [2]. However, there are few studies on exsolution texture of alkali feldspar in porphyry with an intermediate cooling rate between volcanic and plutonic rocks. To examine the microtexture of alkali feldspar in felsic rock with the intermediate cooling rate, granite porphyry from the Kose granitic body was used in the present study.

The Kose granitic body is composed of cordierite-biotite granite and biotite granite porphyry [3] and located in the northern Omine acid rocks which are one of Middle Miocene granites in the outer zone of Southwest Japan. In the granite porphyry, some phenocrysts of alkali feldspar can be clearly divided into textually-distinct two regions; in a presence and absence of the well-developed lamellar intergrowth in a microscopic scale. The latter regions look like ‘homogeneous’ by a petrographic microscope and SEM, but TEM observation proves a presence of the fine lamellae in a submicroscopic scale (hereafter, the lamellae observed in the former regions with a microscopic scale are denoted as the coarse lamellae). The chemical compositions of the latter regions without the coarse lamellae (Or54-63) are slightly lower Or contents than those of the former regions with the coarse lamellar intergrowth (Or60-64). Coarse lamellar intergrowth (1 µm in average) has an irregular periodicity and its interfaces between adjacent lamellae are straight and sharp, strongly indicating a formation due to the nucleation and growth mechanism. The wavelength of the fine lamellar intergrowth (40 nm in average), in contrast, is one order or more smaller than that of the coarse lamellar intergrowth. The fine lamellar texture has a regular periodicity and the interfaces are slightly waved and branched, indicating a formation due to the spinodal decomposition mechanism. The fact that these distinct types of exsolution lamellae each of which was formed by the different mechanism coexist in the same phenocryst can be explained by taking a kinetic effect into consideration even through the simple cooling process.

EA-IRMS: Analysis of graphite and diamond  
A.G. TALIBOVA, V.A. PONOMARCHUK AND D.V. SEMENOVA  
Institute Geology and Mineralogy, Novosibirsk, Russia (ponomar@uiggm.nsc.ru)

The continuous-flow mass-spectrometry with EA + ConFloIII is widely used for the isotop analysis of organic carbon, oil fractions, coals, kerogens and doesn’t use for measurement of carbon isotope ratios in graphites and diamonds.

The theoretical precondition of complexity of the isotopic analysis of graphite is connected with the increase of order strength in graphite structure from amorphous to hexagonal form and, accordingly, with growth of activation energy for the reaction of carbons nanocluster oxidation using molecular oxygen. It is interesting, that in contrast to the oxidation of amorphous and linear particles of carbon at which formed only CO₂ molecules, in grafen clusters oxidation CO₂ as well as CO may be formed. All these factors finally lead to incomplete combustion of graphite using standard EA-IRMS technique.

Moreover, there is a problem of isotopic zonality of carbon and heterogeneity in diamond crystal. Our experiments have shown, that the 13C/12C ratio of various domains of a diamond crystal can vary within the limits of 0.5-3 ‰. The typical picture of a diamond crystal burning is presented in the table.

The technique used for analysis of 13C/12C in graphites and diamond is an adaption of continuous-flow mass-spectrometry with EA + ConFloIII methods that used for the 13C/12C ratio determination in organic compounds.

In our experiments we used submission of several oxygen portions. The temperature of an oxidizing reactor in EA was 1020°C. Molybdenum and tungsten oxides are added do the investigated sample in order do achieve complete combustion.

Experimental study on the mechanism of metasomatism in the system between scheelite and huebnerite  
I. TAMURA¹, M. NAKATA², N. SHIKAZONO¹ AND K. FUJIMOTO²  
¹Department of Applied Chemistry, Faculty of Science and Technology, Keio University, 3-14-1 Hiyosi, Kohoku-ku, Yokohama 223-8522, Japan (itoe@z5.keio.jp, shikazono@appc.keio.ac.jp)  
²Department of Astronomy and Earth Science, Tokyo Gakugei University, 4-1-1 Nukui-kitamachi, Koganei, Tokyo, 184-0015, Japan (nakata@u-gakugei.ac.jp; koichiro@u-gakugei.ac.jp)

Experiments on metasomatism were carried out in the tungstates (scheelite and huebnerite) - aqueous solutions (MnCl₂ and CaCl₂) system. We changed duration (1.5 to 1440 hours), concentration of aqueous solution (0.01, 0.1, 1.0 mol/l) and temperature (100 to 170°C) systematically. Reaction mechanism was considered based on the observation of the mineral texture and chemical analysis of experimental solutions.

In the scheelite - MnCl₂ system, huebnerite crystals grow toward the inside of host scheelite accompanying a lot of void space. The texture is categorized into pseudomorphic replacement texture. However, in the huebnerite - CaCl₂ system, small amount of scheelite was precipitated on the surface of host huebnerite. The texture is categorized into rim replacement texture. Since molar volume of huebnerite (41.88 cm³) is smaller than that of scheelite (47.05 cm³), the reaction solution can easily penetrate through the reaction layer to reach the unreacted scheelite in the former system. The progress of the replacement inside the host mineral is dependent on the ratios of the molecular volumes of the minerals. This is why the replacement textures are different in two systems. In the former system, dissolution of the starting material was a rate limiting process. And, in the latter system, precipitation of the product was probably a rate limiting process.

Dissolution rates of scheelite and huebnerite were obtained from the changes in concentration of the solution which was obtained from the dissolution of the product. Activation energies in the three different concentrations (0.01, 0.1, 1.0) were calculated. Activation energies of scheelite dissolution were estimated to be 16.6×10⁻³, 18.5×10⁻³ and 16.9×10⁻³ kJ/mol for 0.01, 0.1 and 1.0 mol/l aqueous MnCl₂ solution respectively. Activation energies of scheelite dissolution were estimated to be 1.5×10⁻⁴, 18.0×10⁻⁴ and 18.5×10⁻⁴ kJ/mol for 0.01, 0.1 and 1.0 mol/l aqueous CaCl₂ solution respectively. The former values were about one order of magnitude larger than the latter.
Silicic magmas in the Izu-Bonin oceanic arc and implications for crustal evolution

7IFREE, JAMSTEC (tatsumi@jamstec.go.jp)

Crustal structure and chemistry of volcanoes

Rhyolite magmas occur to a greater or lesser degree in most volcanoes along the Izu-Bonin volcanic front from Hakone to Torishima, a distance of 550 km. Their origin, together with that of dactitic magmas, in oceanic arcs is a matter of considerable interest and debate (e.g. Tamura and Wysozanski, 2006). Recent studies of along-arc crustal structures show a clear correlation between the average crustal velocity and thickness of middle crust and the average seismic velocity of the underlying arc crust chemistry (basaltic vs rhyolitic) of the Quaternary volcanoes of the Izu-Bonin arc. We will show the complex history of the 50 Ma crust. We will show the relationship between the chemical compositions of rhyolites and the average crustal velocity and thickness of middle crust beneath the volcanoes, and discuss the origin of rhyolites along the Izu-Bonin volcanic front by examining their chemical variations.

Conclusions

A number of conclusions are reached. 1) Remelting of middle crust and the formation of rhyolite magmas may have occurred both in the basaltic and rhyolitic volcanoes. 2) Basalt volcanoes consume newly produced middle crust at higher temperatures to produce rhyolite magmas. 3) Rhyolite volcanoes may have no mantle roots. The melts that feed these volcanoes originate, instead, in the middle crust. Lateral intrusions of basaltic dikes cause low temperature melting in the old (Oligocene?) middle crust, generating the rhyolitic magmas.

Elemental and isotopic fractionation in some organs of bamboo

T. TANAKA¹, S. WAKAKI¹, M. TANIMIZU² AND Y. ASAHARA¹

¹Dept. Earth Environmental Sci., Nagoya Univ., Nagoya 464-8601 Japan (tanaka@eps.nagoya-u.ac.jp)
²Kochi Inst. for Core Sample Res., JAMSTEC, Nankoku 783-8502 Japan

Chemical and isotopic compositions are useful tracers to assess the growing environment for plant life. Bamboo is one of the plants providing chemical and isotopic fractionation due to its long fibriform organs. Fu et al. (2001) and Ding et al. (2003) reported difference in REE and Si isotope compositions among organs of bamboo.

A bamboo (Phyllostachys nigra Munro var. henonis Stapf) with 7m high was collected in campus of Nagoya Univ. It is cut into lower trunk, middle trunk, upper trunk, lower branch, upper branch, lower spray, upper spray, lower leaf and upper leaf. After the reducing in ashes, elemental abundances and isotopic compositions are measured by INAA, XRF and surface ionization mass-spectrometry with double spikes (Wakaki et al., this vol.).

Samples are reduced to ashes about 0.5wt% (trunk) to 4wt% (leaf) from raw bamboo. The most abundant element in trunk ash is potassium. Potassium abundance is richer in trunk (60wt%) and lower to leaf (17%). The contrasting is silica. Silica is richer in leaf (68wt%) and lower to trunk (16%). No other elements than these two are enriched in bamboo more than 10wt%. Zn and Rb show similarity in trend to K₂O. Iron, Ca, Sc, Cr, Co and Ba abundances are decreasing from leaf to trunk like that of SiO₂. No clear trend is found in REE and Cs abundances. These features are summarized in the figure. The grouping of the elements seems independent on ionic radius, ionic charge or solubility in water. Isotopic compositions of heavy elements will be discussed.

Co-precipitation of Sr²⁺ with calcite from 5 to 40°C

J. TANG, M. DIETZEL, AND S. KÖHLER
Institute of Applied Geosciences, Graz, Austria (martin.dietzel@tugraz.at)

Trace elements may fractionate during CaCO₃ crystallization. Degree of fractionation can be used as a proxy to reconstruct e.g. precipitation environments. CO₂ Diffusion Technique is used to crystallize calcite. The aim is to decipher temperature, precipitation rate (R), and solution chemistry effects on Sr²⁺ incorporation.

Sr incorporation into calcite was studied at various R values and T = 5, 25, and 40°C. Results show that (1) at constant T elevated R results in less Sr discrimination in calcite, (2) at constant R lower T yields less Sr fractionation, (3) R effect is enlarged at lower T, (4) an upper limit for Sr incorporation exists at 40°C, and (5) besides T and R effect Sr co-precipitation is influenced by solution chemistry (i.e. pH).

Complex Sr incorporation behaviour can be reasonably explained by the surface enrichment model (e.g. Watson, 2004). According to this model, Sr is significantly enriched in a surface layer of the growing calcite. Sr incorporation into the final calcite crystal lattice depends on crystal growth kinetics, value of Sr enrichment factor, and ion diffusion within the proposed surface layer.

Finding of negative $\delta^{18}O$ zircon from metagranite in eastern Sulu, China: Implications for local paleoclimate

J. TANG, Y.-F. ZHENG AND Y.-B. WU

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China
(juntang@ustc.edu.cn)

Since finding of extremely low $\delta^{18}O$ eclogite at Qinglongshan in the western end of the Sulu orogen (Yui et al., 1995; Zheng et al., 1996), much efforts have been devoted to unraveling of not only more lithologies of this $\delta^{18}O$ anomaly surrounding the Qinglongshan outcrop, but also more localities of low $\delta^{18}O$ metamorphic rocks along the Dabie-Sulu orogenic belt (Zheng et al., 2003, and references therein). This study reports our new finding of unusually $18O$-depleted zircons in granitic gneiss in the eastern end of the Sulu orogen. Low $\delta^{18}O$ values as negative as $−7.8$ to $−3.1\%$ occur along a profile of 60 m length at Zuobuzhen. They are close to extremely low $\delta^{18}O$ values of $−9.0$ to $−5.9\%$ for metagranite at Qinglongshan and adjacent areas. CL imaging shows that the low $\delta^{18}O$ zircons at Zuobuzhen are primarily of igneous origin, but underwent different degrees of metamorphic modification by recrystallization and overgrowth. SHIRMP U-Pb dating yield mid-Neoproterozoic ages of 751±27 Ma for the igneous zircons and Triassic ages of 232±4 Ma for the metamorphic zircons. They are respectively interpreted to represent timing of protolith emplacement and ultrahigh-pressure metamorphism.

The variably negative $\delta^{18}O$ values for the zircons indicate considerable $O$ isotope heterogeneity in its granitic protolith. The low $\delta^{18}O$ zircons are interpreted as crystallizing from low $\delta^{18}O$ magma due to melting of meteoric-hydrothermally altered low $\delta^{18}O$ rocks in an active rift setting at the mid-Neoproterozoic. The metagranites at Zuobuzhen and Qinglongshan, about 450 km apart, are two known localities of low $\delta^{18}O$ metamorphic rocks along the Dabie-Sulu orogenic belt (Zheng Y.-F., Fu B., Gong B., Li S.G. (1996) Eur. J. Mineral. 8, 317-323. Zheng Y.-F., Fu B., Gong B., Li L. (2003) Earth Sci. Rev. 62, 105-161).

Re-evaluation of the equilibrium Fe isotope fractionation between $Fe^{3+}(H_2O)_6$ and $Fe^{2+}(H_2O)_6$ in aqueous solution

MAO TANG AND YUN LIU

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, 46 Guanshui Road, Guiyang, Guizhou 550002, P. R. China

We have used high level ab initio quantum chemistry methods to re-evaluate the equilibrium Fe isotope fractionation between $Fe^{3+}(H_2O)_6$ and $Fe^{2+}(H_2O)_6$ in water. The calculated equilibrium fractionation $\Delta_{Fe^{3+}-Fe^{2+}}$ is $3.7\pm0.4$ at $22^\circ C$, which is quite different from previous theoretical or experimental results.

Because it is an important and basic fractionation to govern the Fe isotopic fractionation extent between different redox states, many researchers have previously studied this. Schauble et al. (2001) first used a semi-empirical method (MUBFF) to calculate this fractionation as about $5.5\%$. The experimental result suggested by Johnson et al. (2002) and Welch et al. (2003) is a much smaller fractionation ($\sim$2.9\%). Meanwhile, the DFT & PCM calculation result suggested by Anbar et al. (2005) and Jarzecki et al. (2004) is even smaller (i.e. $\sim$2.5\%). Since there are several possible error sources in the experimental process (e.g. possible Fe-Cl or Fe-OH complexation, etc...) and the DFT & PCM calculation also has a weak point (e.g. PCM methods can poorly handle the salvation effects with strong H-bonding situations), we re-evaluate this fractionation by using a larger basis set and a better way to handle the solvation effects other than the PCM method. Our method is using up to 40 water molecules to form various supermolecules or so-called “water-droplets” surrounding the $Fe^{2+}$ or $Fe^{3+}$ ion, then do the geometry optimization and frequency calculations at B3LYP/6-311G* level. This method can treat the interactions between solute and solvent molecules explicitly and hence provides more accurate results when there is strong H-bonding existing. We also check the possible contributions from the complexation of $Fe^{2+}$, $Cl^-$ and $OH^-$ in the solution. It turns out to form the Fe-Cl or Fe-OH species will let the experimental fractionation value become smaller. We conclude that the fractionation between $Fe^{3+}(H_2O)_6$ and $Fe^{2+}(H_2O)_6$ will be larger than 2.9\% and our calculated fractionation ($3.7\% \pm 0.4$) is very reasonable if those previously ignored errors have been included in.
Use of carbon and hydrogen stable isotopic composition to quantitatively assess natural gas generation

YONGCHUN TANG1, GEOFFREY S. ELLIS2, AND QISHENG MA1

1Power, Environmental, and Energy Research Center; California Institute of Technology, Pasadena, California U.S.A (tang@peer.caltech.edu; qim2@peer.caltech.edu)
2U.S. Geological Survey, Denver Colorado U.S.A. (gsellis@usgs.gov)

The mechanisms of natural gas generation and migration are distinctly different from those that control oil accumulation, and consequently new tools and strategies must be developed in order to create effective gas exploration programs. Over the past few decades, carbon isotopic composition has been widely integrated with other geochemical tools in order to determine thermal maturity of gas, gas to gas, and gas to source correlation, as well as oil to oil and oil to source correlation. In recent years, interest has increased in the application of hydrogen isotopic composition of hydrocarbons to these essential questions of petroleum geochemistry. In this presentation, we will review the fundamental chemistry of kinetic and thermodynamic fractionations of both carbon and hydrogen stable isotopes in petroleum hydrocarbons affected by thermal alteration processes.

We have conducted an extensive number of pyrolysis experiments on a wide variety of different source rocks and whole oils in order to determine kinetic isotope fractionation constants for different hydrocarbon gas sources. However, without theoretical constraints on these fractionation constants, it is difficult to derive unique kinetic parameters based only on the laboratory simulation results. Consequently, we have performed a substantial number of ab initio quantum chemical calculations of kinetic isotope fractionations (both entropy and enthalpy terms) in order to developed a model for both carbon and hydrogen isotopes that, when coupled with compositional kinetics, allows for the prediction of the stable isotopic response to thermal stress, the gas quality (e.g., wetness), the thermal maturity of the gas source rock, and the gas to oil ratio (GOR).

We have also quantified the thermodynamic equilibrium fractionation constants for both carbon and hydrogen isotopes of methane based on ab initio quantum chemical calculations. Moreover, we have used a similar approach to determine the theoretical abundance of methane molecules containing both a heavy carbon atom (\(^{13}\)C) and a deuterium atom. We will demonstrate that using the abundance of this doubly, isotopically substituted methane (\(^{13}\text{CDH}_3\)), one might be able to predict the paleotemperature of methane generation. In order to measure the abundance of \(^{13}\text{CDH}_3\), we have developed a new, laser-based, analytical technique and have obtained a detailed spectrum of synthetic \(^{13}\text{CDH}_3\). When combined with traditional stable isotope modeling, this new approach will provide an additional dimension for understanding natural gas geochemistry.

Enhanced Uranium Sorption on Alumina through Surface Modification

YUANZHI TANG AND RICHARD J. REEDER

Department of Geosciences and Center for Environmental Molecular Science, State University of New York at Stony Brook, NY 11794-2100, USA; (yuatang@ic.sunysb.edu; rjreeder@notes.cc.sunysb.edu)

Sorption onto mineral surfaces is one of the principal mechanisms that governs the mobility and bioavailability of U(VI) in subsurface environments and in permeable reactive barriers. Although strongly dependent on pH and solution chemistry, U(VI) sorption is rather limited on some mineral and oxide surfaces. Consequently, sorption may not be effective in restricting its mobility. Considering that uranyl phosphates are highly insoluble and stable in geological settings, we explored mechanisms for increasing U(VI) sorption by pre-treating gamma-alumina surfaces with arsenate, which has a high affinity for binding with uranyl ions and is an analog for environmentally abundant phosphate.

Batch uptake experiments were conducted by treating gamma-alumina surface by pre-equilibration with arsenate, followed by addition of uranyl to the suspension at pH ~4. Parallel experiments were carried out with different U concentrations (from moderate to high) and corresponding particle loading and pretreated As concentrations. Results show a positive correlation between U(VI) uptake and [As]soln/[U]ini (defined as the ratio between As solution concentration after pre-equilibration with alumina and the initial U concentration). Compared to ~20% U uptake on untreated gamma-alumina, U uptake by the pretreated gamma-alumina sharply increases to ~70% at [As]soln/[U]ini ~0.1 and ~100% at [As]soln/[U]ini >0.4, indicating the formation of ternary surface complex(es) and/or precipitates. X-ray absorption fine structure spectroscopy (XAFS) was applied at both the U LIII-edge and the As K-edge on selected sorption samples to characterize the local coordination environments of both elements and to identify the sorption products. XAFS fit results show U-As correlation at ~3.7 Å, suggesting the formation of U-As precipitates with a structure similar to UO\(_2\)HAsO\(_4\)-H\(_2\)O. U-U distances at ~3.9 Å and/or ~4.2 Å, likely corespond to formation of dimeric U species and/or schoepite-like uranyl oxy-hydroxide. The ratios between U-As precipitate and these uranyl dimeroxy-hydroxides are dependent on the [As]soln/[U]ini ratio and the absolute U initial concentration.

Results from this work can provide fundamental information for surface chemical processes in well-defined model systems as well as predictive information of U(VI) mobility in complex natural systems. Knowledge gained may also have applications for the selection and design of permeable reactive barriers, which can be used in removing dissolved uranyl from contaminated sites.
Does Tanzawa plutonic complex represent the IBM middle crust? New age constraint from SHRIMP zircon U-Pb geochronology

KENICHIRO TANI1, DANIEL J. DUNKLEY2, RICHARD WYSOCZANSKI3 AND YOSHIYUKI TATSUMI1

1Institute for Research on Earth Evolution (IFREE), JAMSTEC (kentani@jamstec.go.jp)
2National Institute of Polar Research (NIPR), Japan
3School of Geography, Environment and Earth Sciences, Victoria University of Wellington, New Zealand

The Tanzawa plutonic complex (TPC) is located in the Izu-Tanzawa collision zone, where the northern extent of the Izu-Bonin-Mariana (IBM) arc is colliding with the Honshu arc. The TPC ranges from tonalite to gabbro, and has been regarded as an exposed mid-crustal section of the IBM arc. Such exposures are extremely scarce in active intra-oceanic arcs.

Despite this importance, emplacement and crystallization ages are not well constrained for the TPC. K-Ar hb/bt ages vary widely (11 - 4 Ma, e.g. Saito et al. 1991), and have led to the suggestion that the formation of the TPC predates the collision of the Tanzawa block with the Honshu arc at ~6 Ma. However, more recent Ar-Ar age study suggests that older K-Ar ages are due to excess argon.

SHRIMP zircon U-Pb ages are newly obtained for tonalite and gabbro samples from the six major plutonic bodies of the TPC. Zircon crystallization ages of 4-5 Ma show that the main pulse of TPC emplacement post-dates the collision of the Tanzawa block.

TPC lithologies are characterized by strong depletion of incompatible elements such as K2O, LILEs, and REEs (Kawate and Arima, 1998), which has been considered to be the general characteristic of IBM arc crust. However, in light of the new post-collisional ages, the association of TPC geochemistry with juvenile IBM crust needs to be carefully assessed, through a comprehensive study of the geochemistry and geochronology of silicic plutonic rocks previously collected in the IBM arc. SHRIMP zircon crystallization ages range from 49 Ma to <1 Ma, representing almost the entire magmatic history of the IBM arc, and compositionally range from tonalite to granite. Most do not show strong depletion of incompatible elements as observed in the TPC. Moreover, the rocks of the TPC have significantly higher Th/Nb (<8) than other silicic plutonic rocks of the IBM arc (~2). Elevated Th/Nb ratios are a good indicator of sediment input from mature crust, and in the TPC may represent incorporation of sediments from the Honshu arc during the collision.

New zircon crystallization ages and geochemical data suggest that the TPC may not be the geochemical representative of the IBM middle crust.

Determination of magnesium isotopic variation and fractionation in carbonate minerals

MASAHARU TANIMIZU

Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, Monobe-B 200, Nankoku, Kochi 783-8502, Japan (tanimizum@jamstec.go.jp)

Calcium carbonate is one of the most important biominerals in aqueous environments. Ca, Mg, and other elements are incorporated through various mechanisms into the lattice. Although extensive studies of C and O isotopes and elemental abundances in these CaCO3 minerals are carried out to understand the mechanisms, little attention has been paid to isotope ratios of heavy elements.

In recent years, inductively coupled plasma mass spectrometry (ICP-MS) with multiple collectors (MC) has been introduced for the precise isotope analysis of heavy elements. The time-independent characteristic of the mass spectrometry against the mass discrimination allowed the precise analysis of Mg isotope ratios. Here, Mg isotope analysis technique was independently developed. The technique was applied to seawater and Mg rich CaCO3, and Mg isotope ratios were determined with the reproducibility of 0.02 % for 25Mg/24Mg and 0.05 % for 26Mg/24Mg ratios. The reason of the isotopic variation and degree of fractionation from seawater will be discussed.

The overall natural Mg isotopic variation and related change in Mg atomic weight are compiled to estimate the uncertainty of Mg atomic weight. Present availability of Mg isotopic reference material is also reported.
Intra-reservoir geochemical heterogeneity in the Shixi oilfield of the central Junggar Basin, China

G.L. TAO, W.X. HU, J. CAO AND X.K. GAO
Department of Earth Sciences, Nanjing University, Nanjing 210093, China (taonju@yahoo.com.cn)

The Shixi oilfield is located in the central Junggar Basin, northwestern China. Previous geologic and geochemical studies have suggested that the West Pen 1 Well sag to the southwest was the hydrocarbon kitchen, in which there existed mainly two sets of Permian source sequences (the Lower Permian Fengcheng and Middle Permian Lower Wuerhe Formations). Petroleum exploration results show that hydrocarbons have been produced mainly from two sets of reservoirs, i.e. the deeper Carboniferous volcani-clastic and upper Jurassic clastic ones. In this study, we aim to unravel intra-reservoir geochemical heterogeneity within these two sets of reservoirs and tentatively discuss its controlling factor.

According to geochemical analyses, carbon isotopes and maturity of oils from the Carboniferous reservoir are greater than those from the Jurassic one, while density of the oils is lower in the Carboniferous reservoir. This likely implies that the oils in these two reservoirs have undergone different petroleum migration and accumulation process.

To approve this, we carried out artificial oil mixing experiments. After detailed geochemical analysis, we find that the distribution pattern of C20-C21-C23 tricyclic terpanes varies along with oil-mixing ratio accordingly. Based on this, we studied the characteristics of oils in the two reservoirs. It is indicated that in the Carboniferous reservoir, petroleum sourced from Lower Wuerhe Formation have a higher proportion than from Fengcheng Formation, however, this trend is to the contrary in the Jurassic reservoir.

Also, we studied the history of petroleum accumulation. The results show that the petroleum sourced from Fengcheng Formation migrated into the Carboniferous reservoir in Triassic, and then, adjusted into the Jurassic reservoir in Late Jurassic. The petroleum sourced from Lower Wuerhe Formation inptured into the two reservoirs in Late Cretaceous.

According to our research, the key event caused the heterogeneity is the adjuster of the petroleum sourced from Fengcheng Formation in Late Jurassic. Because of this event, the proportions of petroleum sourced from Fengcheng and Lower Wuerhe Formation in two reservoirs are not consistent. As a result, the carbon isotopes, maturity and density of the oils in these two reservoirs are different.

Interactions between carbonate magmas and MARID metasomes: The case of diamondiferous aillikites from the Torngat Mountains, Canada

S. TAPPE1, S.F. FOLEY2, L.M. HEAMAN1, R.L. ROMER3, A. STRACKE4, B.A. KJARSGAARD5 AND G.A. JENNER6
1Earth Sciences, University of Alberta, Edmonton, Canada
2Geosciences, Universität Mainz, Germany
3Geoforschungszentrum Potsdam, Germany
4Isotopengeologie, ETH-Zürich, Switzerland
5Geological Survey of Canada, Ottawa, Canada
6Earth Sciences, Memorial University, St. John’s, Canada

Aillikite magmas (a carbonate-rich ultramafic lamprophyre; UML) erupted through the Archean crust of the Torngat Mountains in northern Labrador between 610 and 550 Ma. These dykes are characterized by long-term isotopic depletion (\( ^{87}\text{Sr} / ^{86}\text{Sr} = 0.70323-0.70377 \); \( \varepsilon\text{Nd} = +1.2 \) to \( +1.8 \); \( \varepsilon\text{Hf} = +1.4 \) to \( +3.5 \); \( 206\text{Pb} / 204\text{Pb} = 18.2-18.5 \)), but grade into carbonate-poorer mela-aillikites which show isotopic enrichment (\( ^{87}\text{Sr} / ^{86}\text{Sr} = 0.70388-0.70523 \); \( \varepsilon\text{Nd} = -0.5 \) to \( -3.9 \); \( \varepsilon\text{Hf} = -0.6 \) to \( -6.0 \); \( 206\text{Pb} / 204\text{Pb} = 17.8-18.2 \)). This long-term enriched signature is coupled to distinctively higher Rb/Cs and Zr-Hf-Ti. Increased partial melting involving old phlogopite- and rutile-bearing source material reminiscent of MARID probably imparted this signature to carbonate-rich aillikite magmas, thereby shifting compositions towards mela-aillikites. Channelling of CO2-rich melts into pre-existing MARID vein networks in the lower reaches of the cratonic lithosphere and their varying interactions best explains the aillikite/mela-aillikite continuum. As there is no evidence for independent melting of the low-T fusible MARID veins, temperatures during aillikite magma generation may never exceed 1200°C. Thus, decompression and volatile-fluxing are the principal causes of UML/carbonatite magma generation within rifting cratonic mantle. Strong interactions between CO2-rich melts and lithosphere are unavoidable, explaining the rarity of direct eruptions of primary carbonatite magmas. The degree of interaction controls whether CO2 (i) remains dissolved in UML magmas, enabling separation of carbonatite intrusions at crustal levels, or (ii) largely reacts out at mantle depths resulting in carbonate-poor UML magmas, as in the Torngat examples.
Geochemical variability within the lithospheric mantle beneath the Adelaide Fold Belt, South Australia

R. TAPPERT\textsuperscript{1}, J. FODEN\textsuperscript{1}, K. WILLS\textsuperscript{2} AND M.C. GORYNIUK\textsuperscript{2}

\textsuperscript{1}University of Adelaide, Adelaide, South Australia
  (ralf.tappert@adelaide.edu.au, john.foden@adelaide.edu.au)
\textsuperscript{2}Flinders Diamonds Ltd., Adelaide, South Australia
  (kwills@flindersdiamonds.com, mgoryniuk@flindersdiamonds.com)

Kimberlites in South Australia

The Adelaide Fold Belt hosts one of the largest kimberlite provinces in Australia. More than one hundred diamondiferous and non-diamondiferous kimberlites have been discovered in the Southern Flinders Ranges region, ~200 km north of Adelaide. The kimberlites, which commonly occur as northwest-trending dykes, sills, or pipe-like structures, contain abundant mantle-derived xenocrysts, including garnets, clinopyroxenes, orthopyroxenes, Cr-spinels, and ilmenites. The major- and trace-element compositions of these minerals have been used to reconstruct spatial variations in the structure and geochemical history of the mantle lithosphere beneath kimberlites in the Eurelia/Orroroo, Franklyn, and Monk Hills areas.

Results

The xenocryst populations from all kimberlites are dominated by peridotitic parageneses; eclogitic minerals are rare or absent. Although compositional ranges of the xenocryst populations are rather similar within each area, variations on a regional scale do exist. Garnets from the Franklyn area, for example, are characterized by more Ti-rich compositions, when compared to the other areas, and a lack of garnets with sinusoidal REE patterns. Regional differences also exist in the compositional ranges of spinel xenocrysts and the absence and presence of ilmenites.

Geothermobarometry based on single clinopyroxenes indicates a regional gethermal gradient of \(-45\) mW/m\(^2\), which is in stark contrast to previous estimates for the lower crust in this region.

Conclusions

The geochemical variations in the lithospheric mantle are likely caused by variable degrees of metasomatism and/or different styles of metasomatism. Regional changes in the thickness of the lithosphere may also exist, and these factors together may explain the diamond potential of the kimberlites.

Variations of the Eocene climate reflected in the isotopic composition of fossil resins from the Northwest Territories, Canada

R. TAPPERT, A. WOLFE AND K. MUEHLENBACHS

University of Alberta, Edmonton, Canada
  (rtappert@ualberta.net, awolfe@ualberta.ca, karlis.muehlenbachs@ualberta.ca)

Middle Eocene conifer resins have been analyzed for their C and H isotopic compositions, as well as spectral characteristics using FTIR. The resins were recovered from an un lithified peat sequence that forms part of the infill of the Giraffe kimberlite crater in the Lac de Gras field, Northwest Territories, Canada. Based on the presence of well-preserved macrofossils and FTIR spectra of fossil and modern resins, it is believed that the fossil resins were produced by \textit{Metasequoia glyptostroboides}.

Results

The FTIR spectra indicate that all resins are chemically identical with only minor variations in redox history that is unlikely to influence isotopic composition. Throughout the sequence, resins are extremely variable with respect to \(\delta D\) and \(\delta^{13}C\), ranging from -374 to -286‰ (\(\delta D\) vs SMOW) and -27 to -20‰ (\(\delta^{13}C\) vs PDB), respectively. Variability is broadly mimicked by both isotopic systems, implying pervasive biogeochemical changes in the ecosystem. Based on a constant fractionation factor for hydrogen between resin and water (~200 ‰, Nissenbaum & Yakir, 1995), very light H-isotopic compositions are inferred for the Eocene waters accessed by these trees (-174 to -86‰).

Conclusions

Extreme co-isotopic variability of Eocene conifer resins, coupled to highly-depleted \(\delta D\) values, are indicative of short-lived climatic/hydrological variability in the Canadian low Arctic, in keeping with recent results from biomarkers in cores from the Arctic Ocean (Pagani et al., 2005). This challenges the notion of stable Middle Eocene climates at northern latitudes.

Globally, total nitrogen (TN) loadings to estuaries are increasing due to changes in urbanisation etc. Organic N (ON) constitutes >50% of the TN input to estuaries, but its speciation, reactivity and fluxes are poorly quantified.

Water Samples were collected from the Tamar Estuary (SW England). Suspended particulate Material (SPM) was fractionated and the water and particles characterised. Incubations using ¹⁴C-labelled amino acids (AA) as ON proxies examined SPM-water partitioning.

The particle concentrations used for incubation experiments were those measured in the estuary. The results under the two conditions employed (‘live’ and ‘dead’ particles) were considerably different. Under dead conditions there was only negligible binding of the AA to the particles and most remained in the water. The results were similar regardless of the AA chemical structure. Under live conditions, uptake of the AAs onto particles was rapid, with 80-90 % removed from solution over 24 hours. This indicates that the AA uptake onto particles was controlled by bacteria, which used the AAs for cell growth. The results were unexpected as the research literature suggests that the compound chemistry controls its attachment to particles and we used a range of compounds to test this. The broad conclusion to be drawn was that bacterial uptake of AAs is much more rapid and quantitatively important than any other type of physico-chemical binding. Our findings contradict the idea that particle-associated ON is protected from bacterial degradation, and it appears that assumptions on the behaviour of ON in aquatic systems will need to be revised.

Volatile budget of the Kamchatka arc

Y.A. TARAN

Institute of Geophysics, UNAM, Mexico (taran@geofisica.unam.mx)

In this study I estimate the volatile output (C, N, He, Cl) from the Kamchatka volcanic arc using: (1) direct measurements of flow rates and chemical compositions of thermal waters and vapors from more than 100 groups of thermal springs and hydrothermal systems; (2) direct measurements and indirect estimations of the gas fluxes from Kamchatkan volcanoes and (3) volcano-plutonic Holocene productivity of magmas and the corresponding volatile flux. Plank and Langmiure (1998), Hilton et al (2002), Sadofsky and Bebout (2004) Jarrard (2002) are main sources for the accepted here input data for H₂O, CO₂, N₂, S, Cl and He. The main results (fluxes in mole/year) are shown in the table below:

Kamchatkan fluxes relative to global fluxes are roughly proportional to the length of the Kamchatkan segment relative the global arc length (700 km vs ~40,000 km). “Arc-Magmatic” ratios N₂/³He, C/³He and Cl/³He for Kamchatka in log-units are 8.7 ± 0.5, 9.8 ± 0.7 and 9.7 ± 0.6 respectively. It looks like the Cl/³He ratio is a stable indicator of the arc magmatism. Its uniform value among different manifestations including volcanic gases suggests an essentially magmatic source of Cl in thermal springs.

Experimental re-equilibration of quartz-hosted H2O-CO2-NaCl inclusions under differential stress using a Griggs apparatus

A. TARANTOLA1, L. W. DIAMOND1 and H. STÜNITZ2

1Institute of Geological Sciences, University of Bern, Switzerland (alexandre.tarantola@geo.unibe.ch, diamond@geo.unibe.ch)
2Institute of Geology and Paleontology, University of Basel, Switzerland (holger.stuenitz@unibas.ch)

Little is known about the effects of plastic deformation on the properties of fluid inclusions within deforming host-crystals. Geochemical and petrologic investigations based on fluid inclusion analysis must therefore be confined to samples in which the host minerals are unstrained or at least contain strain-free domains. For want of a clear interpretative framework, the potentially useful information in inclusions within sheared hydrothermal veins and metamorphic rocks remains inaccessible.

To elucidate the basic behaviour of fluid inclusions during plastic deformation of their host crystals we are undertaking experiments using a Griggs-type piston-cylinder apparatus with weak salt as the solid confining medium. In addition to offering higher experimental pressures than conventional hydrothermal autoclaves pressurized by gas, the Griggs device permits experiments under deviatoric stress. A first series of experiments under hydrostatic conditions have been carried out on natural H2O-CO2-NaCl inclusions in large undeformed quartz crystals, obtained from orogenic gold-quartz veins at Brusson, NW Italy. Disks were cut from the samples at 45° to the crystallographic c-axis and polished such that their upper and lower faces were perfectly parallel.

Prior to the experiments numerous inclusions were mapped, photographed and analysed by microthermometry and Raman spectroscopy to determine their initial molar volumes and compositions. The corresponding fans of isochores were calculated to span a range of pressures at 700 °C, the mean internal pressure being approximately 600 MPa. The samples were therefore placed at 700 °C and 500, 600 and 800 MPa (all within the alpha-quartz field) for 16 hours, in order to induce re-equilibration of the inclusions under conditions of internal underpressure and internal overpressure. Following the experiments the inclusions were relocated and reanalysed. In each case, irreversible changes in the shape and composition of the inclusions were observed. Moreover, the initial variation in bulk molar volumes reduced considerably during the experiments, converging on the values expected for the externally imposed P–T conditions. The successful instrumental control attained in these hydrostatic re-equilibration runs is a necessary prerequisite for our on-going experiments involving deviatoric stress.

Feldspars of composition K[(Al,Fe)Si3O8]: Their growth and ordering behaviour

V. TAROEV1, J. GÖTTLICHER2, H. KROLL3, A. KASHAEV4, L. SUYOROVA1, H. PENTINGHAUS5, H. BERNOTAT-WULF2, U. BREIT3, V. TAUSON1, AND V. LASHKEVICH4

1Vinogradov Institute for Geochemistry, RAS, Irkutsk, Russia (taroev@igc.irk.ru)
2Forschungszentrum Karlsruhe GmbH, Karlsruhe, Germany (joerg.goettlicher@iss.fzk.de)
3Institut für Mineralogie der Universität, Münster, Germany (kroll@nwz.uni-muenster.de)
4Earth Crust Institute, RAS, Irkutsk, Russia (taroev@igc.irk.ru)

K-feldspars in the system K[AlSi3O8] - K[FeSi3O8] have been synthesized hydrothermally from oxide mixes together with KOH solution at P H2O = 1 kbar and T = 400 °C, 500 °C, and 600 °C to investigate their ordering behaviour, the extent of Al,Fe substitution, and the influence of oxygen fugacities on the run products.

In the Ni-NiO buffered runs Fe3+ was partly reduced to Fe2+. Abundant growth of Fe-containing mica left the K-feldspar strongly depleted in Fe3+ relative to the starting material. In the Cu-Cu2O runs with their larger oxygen fugacities, growth of delafossite (Cu1+Fe3+O2) took up various amounts of Fe3+ resulting in Fe2+ contents of the K-feldspars ranging from 20 mol% to 100 mol%.

Considering the discontinuous character of the sanidine-microcline transition in both K-feldspar endmembers, a phase diagram has been calculated from known transition temperatures (480 °C and 704 °C, respectively) and known (7300 J/mol; Hovis, 1988) or derived transition enthalpies (11500 J/mol) yielding a narrow two-phase field separating (Al,Fe)-sanidine from (Al,Fe)-microcline. In the Al-rich part of the diagram, metastable monoclinic K-feldspar persisted in the stability field of microcline, whereas Fe-rich compositions attained the triclinic ordered state. No indication of a miscibility gap was detected.

Pure KAl-feldspars, even after long annealing, kept a high degree of disorder in agreement with predictions from the Mueller rate equation, when using an updated calibration of ln(Kd) vs. 1/T: -RTln(Kd) = 4047(668) - 1.80(47)*T + 10955(929)*Q.

Structural incorporation of Fe3+ leads to increasing order, the more so the lower the temperature of annealing. Following the ideas of Graham & Elphick (1991), this is interpreted as a consequence (i) of the proton concentration in the structure having a larger effect on Fe, Si than Al, Si interchanges and (ii) of solution-reprecipitation processes, dominating over solid state diffusion at increasing Fe contents. Solution-reprecipitation becomes the more effective the more the metastable monoclinic K(Al,Fe)-feldspars deviate from their field of stability.

Aqueous processes have left indelible marks on the morphology of the Martian surface. The geochemical effects are visible in Martian meteorites, at the landing sites of robotic missions, and from orbit (Thermal Emission Spectrometer on Mars Global Surveyor; Gamma-Ray Spectrometer on Mars Odyssey, OMEGA on Mars Express). The nakhlite meteorites show clear evidence for aqueous alteration: alteration veins with elevated S concentrations, dissolution of phosphates (producing relatively high abundances of REE in alteration veins), dissolution of residual glass (marked by high abundances of Cs and Rb in alteration phases), and incipient alteration in olivine. These observations are consistent with short-duration alteration by acidic fluids. Landing site data show that the secondary mineralogy is dominated by Mg- (with minor Fe- and Ca-) sulfates and iron oxides, not the clay minerals and Al-hydroxides common in terrestrial weathering. Typical terrestrial alteration follows paths like the arrows on diagram. In contrast, on Mars the alteration process is dominated by olivine dissolution and formation of iron oxides, probably in an environment rich in sulfuric acid at low water/rock ratio. Such conditions allow for rapid dissolution of phosphates and olivine, but, if time is short and water/rock is low, inhibits dissolution of pyroxene and plagioclase, not dissimilar to the record in the nakhlites. The global data from TES and GRS show that this process is not unique to the few landing sites: it appears to be a Mars-wide weathering style. The uniformity of K/Th measured by GRS is consistent with little dissolution of plagioclase or formation of aluminous alteration products.

This record reflects conditions from the mid-Noachian. Models of regolith evolution that include impact, volcanism, and aqueous alteration suggest that most alteration material was produced by 4 Gy. The lack of evidence in the highlands for alteration under neutral-pH and high water/rock (GRS and TES global data) suggests that such conditions were rare, even early in Martian history, although the identification of phyllosilicates (e.g., nontronite or chamosite) by OMEGA suggests that more Earth-like conditions prevailed sometimes.

Temporal increase in iron oxide inputs into a shallow marine carbonate sediment system: A sediment, porewater and geomicrobiological study

KEVIN G. TAYLOR¹, CHRIS T. PERRY¹, PHILLIP MACHENT¹ AND ANTHONY GREENAWAY²

¹Department of Environmental & Geographical Sciences, Manchester Metropolitan University, Manchester M15GD. U.K. (k.g.taylor@mmu.ac.uk)
²Department of Chemistry, University of the West Indies, Jamaica

Discovery Bay, a carbonate-dominated embayment in north Jamaica, has been subject to inputs for 40 years of iron-rich bauxite sediment associated with the local mining and transport of processed bauxite. As such, this site is an ideal natural laboratory to study the records and impacts of iron oxide inputs upon geochemical, diagenetic, and microbial processes in tropical carbonate sediments.

The iron contents in these sediments vary from 1500 µg/g in shallow (5m) sites to over 6000 µg/g in deeper water (20m) sites as a result of the preferential deposition of fine-grained iron oxide-rich bauxite material in deeper water. Down-core increases in Fe record the increased inputs into the bay. The presence of iron oxides markedly alters the chemical processes taking place within Discovery Bay, with a shift from dominance of bacterial sulphate reduction at non-impacted (Fe-poor) sites, to a dominance of bacterial Fe(III) reduction in Fe-rich bauxite-impacted sediments. These different carbon oxidation pathways results in contrasting styles of CaCO₃ grain dissolution and preservation.

Iron oxides within all impacted sediments display a high potential reducibility, from 40% to 80% dithionite-extractable Fe(III). Experimental analysis of the potential susceptibility to, and rates of, bacterial Fe(III) reduction, utilising Discovery Bay sediment and Shewanella putrefaciens CN32 (a known Fe(III)-reducer) have confirmed the high bacterial reducibility of iron oxides within the sediment. Up to 70% of initial Fe(III) in the sediments was reduced over 15 days. Current research, using molecular 16s rRNA techniques, will determine the shifts in bacterial communities in the sediment as a result of these iron oxide inputs.
Experimental determination of trace element partition coefficients between zircon, garnet and melt

R.J.M. TAYLOR, S.L. HARLEY, R.W. HINTON AND S. ELPHICK
School of Geosciences, University of Edinburgh, UK.
(rich.taylor@ed.ac.uk)

The problem of relating ages, as calculated by zircon U-Pb geochronology, to processes and hence geological events is central to understanding mountain building and crustal evolution. Accurate P-T-t paths can only be produced if zircon growth can be linked to specific rock and mineral processes used to establish pressure and temperature values for metamorphic episodes.

As a major metamorphic mineral in crustal events, garnet is widely used as a thermobarometric tool, and linking garnet growth to zircon formation could be used to refine the interpretation of U-Pb ages.

Attempts to resolve this issue have focussed on REE partitioning between zircon and garnet, both of which strongly incorporate the HREE into their structure, and so it is possible there is a distinct REE partitioning signature which will highlight whether the two minerals have grown at the same time. There are two complementary methods to obtaining this information, empirical and experimental.

Empirical methods of determining this signature using carefully selected rocks have proved troublesome, with a wide range of partitioning signatures found.

This project has used experimental techniques to produce zircon-melt, garnet-melt and zircon-garnet-melt partition coefficients at a range of P-T conditions in melt compositions relevant to natural rocks. Zircon and garnet are grown in trace element equilibrium with a water-undersaturated granitic melt, which represents partial melts formed in the lower crust during anatexis. Temperature ranges from 850°C to 1050°C at a pressure of 5Kbar were produced using internally heated gas apparatus. Trace element concentrations were measured using SIMS analysis at the Ion Microprobe Facility at the University of Edinburgh.

The experimental data produced will be applied to interpret chemical signatures of zircon in garnet-bearing metamorphic rocks, and will provide an objective basis for interpretation of the timing of growth or recrystallisation of zircon in many high-grade terrains.

New insights into peralkaline magma chamber processes in the Naivasha area, Kenya Dome

A. TCHALIKIAN1, O. NEBEL2, M.A. ELBURG3, P.A.M. ANDRIESSEN1 AND G.R. DAVIES2
1Department of Isotope Geochemistry, Faculty of Earth and Life Sciences, Vrije Universiteit, De Boelelaan, 1085,1081HV, Amsterdam, The Netherlands (arnaud.tchalikian@falw.vu.nl)
2Department of Petrology, Vrije Universiteit, De Boelelaan, 1085,1081HV, Amsterdam, The Netherlands
3Department of Geology and Soil Sciences, Krijgslaan 281 S8, Ghent University, 9000 Ghent, Belgium

The Naivasha area, located in the central Kenya rift, comprises three quaternary-recent peralkaline salic volcanic complexes: the caldera Longonot volcano, the Great Olkaria Volcanic Complex, and the Eburru Volcanic Complex (EVC) [1].

In order to further constrain the genesis of peralkaline magmas in this area, the most recent EVC peralkaline trachytes and rhyolites have been the subject of an integrated multi-isotope approach (Sr, Nd, Hf, Pb, U/Th, Rb/Sr, Ar/Ar) coupled with major and trace elements. A model is presented in which an OIB-like parental magma undergoes extensive Assimilation-Fractionation-Crystallisation (AFC) in the upper crust. Subsequent feldspar-dominated fractionation in an upper crustal reservoir increases the peralkaline character of the evolved magma, resulting in isotopic disequilibrium between amphibole, clinopyroxene, feldspars and glass. Pb and Sr isotopes show that the feldspar is the first major phase to crystallise, prior to amphibole and/or clinopyroxene. The oldest rhyolites (<400ka) are succeeded by trachytes (150-95ka) and rhyolites (65-7ka). This temporal evolution is associated with decreasing Sr isotopes ratios (0.7089-0.7047), suggesting the establishment of a mature magmatic plumbing system, preventing extensive crustal contamination. In addition, timescales of magma production and residence in the crust will be discussed using combined Rb/Sr, U-series and Ar/Ar data.

Beyond the Moho: Plans for a complete penetration of in situ ocean crust into the upper mantle

DAMON A.H. TEAGLE1 ON BEHALF OF THE MISSION
MOHOROCIC PROPOSERS2 AND THE ODP LEG 2063 AND IODP
EXPEDITION 309/312 SCIENCE PARTIES4

1National Oceanography Centre, Univ. Southampton, SO14 3ZH, UK (dat@noc.soton.ac.uk)
2http://www.iodp.org/ocean-lithosphere/#7
3http://www-odp.tamu.edu/publications/206_IR/front.htm
4http://iodp.tamu.edu/publications/exp309_312/30912title.htm

Sampling the upper mantle was the original inspiration for scientific ocean drilling and remains an unfulfilled ambition of Earth scientists. Fundamental questions about the composition, structure, and evolution of the ocean lithosphere, and the magnitude of chemical exchanges between the mantle, crust and oceans remain unresolved due to the absence of in situ samples and measurements. The geological nature of the Mohorovicic Discontinuity itself remains poorly understood.

“Mission Moho” is a proposal with the ultimate goal to drill completely through intact oceanic crust formed at a fast spreading rate, across the Moho and into the uppermost mantle. The “MoHole” will be the final stage of a multi-cruise campaign requiring non-riser and riser drilling, detailed geophysical survey and technological development, including the construction of a +4000 m riser. The initial cruises will harness existing ocean drilling capabilities to sample shallow and deep targets in increasingly hostile conditions in ocean crust formed at both fast and slow spreading rates.

A major step on the “Road to the MoHole” was made with the drilling of Hole 1256D into intact crust formed during a period superfast spreading (>200 mm/yr) on the East Pacific Rise 15-million years ago. This is the first complete penetration of upper oceanic basement through lavas, dikes and into the uppermost gabbros [1, 2]. The first gabbroic rocks were encountered at 1407 m below seafloor. Below this lies a ~100 m complex zone of fractionated gabbros intruded into contact metamorphosed dikes. The first gabbros were recovered from within the depth range predicted by extrapolating the inverse relationship between spreading rate and the depth to low velocity zones, thought to be axial melt lenses, at modern ocean ridge crests (e.g., [3]). Hole 1256D is open to its full depth and future deepening in the next phase of IODP should recover cumulate gabbros that will settle long-standing debates on the mechanisms of accretion of the lower oceanic crust.

Reconstructing the Mg/Ca and Sr/Ca history of seawater from ocean ridge-flank hydrothermal carbonate veins

DAMON A.H. TEAGLE1, ROSALIND M. COGGON2, CHRIS SMITH-DUQUE1, JEFFREY ALT2 AND MATTHEW COOPER1

1National Oceanography Centre, Univ. Southampton, SO14-3ZH, UK (dat@noc.soton.ac.uk, csd2@noc.soton.ac.uk, mjco@noc.soton.ac.uk)
2Geological Sciences, University of Michigan, Ann Arbor, MI48109, USA (coggon@umich.edu, jalt@umich.edu)

Calcium carbonate veins formed from low temperature (~100 °C) ridge flank hydrothermal fluids are common in the upper oceanic crust. Carbonate veins from the Juan de Fuca Ridge (<3.6 Ma) record the compositional evolution of seawater-derived hydrothermal fluids as they are heated and react with the basaltic basement. δ18O-calculated fluid temperatures correlate with the proportion of basalt-derived 87Sr. The Sr/Ca and Mg/Ca of the basement fluids, calculated from carbonate trace element analyses combined with suitable partition coefficients, are also temperature dependent [1].

The precipitation of carbonate veins from fluids with a basaltic Sr component precludes the use of the seawater Sr-isotope curve to date individual carbonate veins. However, the Sr-isotopic compositions of suites of carbonate veins in older sections of ocean crust also correlate with temperature and record the chemical evolution of basement fluids from seawater. The age of a suite of carbonate veins can therefore be estimated from the seawater 87Sr/86Sr curve, by determining the 87Sr/86Sr of contemporaneous seawater from the vein δ18O-calculated fluid temperature. Similar to modern carbonate veins, suites of ancient carbonate veins record decreasing basement fluid Mg/Ca and Sr/Ca with increasing temperature, due to fluid-rock interaction. Extrapolation of these trends back to seawater temperatures allows the determination of past ocean Mg/Ca and Sr/Ca.

The fidelity of a particular suite of ocean basement carbonate veins for determining past ocean chemistry depends on the thermal and hydrological history of the site, the duration of fluid circulation and carbonate precipitation, and the variation of ocean chemistry during this period. Analyses of veins from ODP Sites 801 (170 Ma), 1179 (129 Ma), 417 (110 Ma), and 1224 (46 Ma) indicate that ocean Sr/Ca and Mg/Ca were significantly lower than present from the Middle Jurassic to Late Eocene. This approach provides independent corroboration of past seawater chemistry estimates based on foraminifera and sedimentary calcite chemistry.

The Iberian Massif is a large segment of the European Variscan Belt formed during the polycyclic collision between Laurentia-Baltica and Gondwana in the Devonian/Carboniferous. The Central Iberian Zone forms the inner domain of the Iberian Massif and consists mainly of autochthonous Early Paleozoic metasediments, a few pre-Variscan granites and numerous Variscan granitoids, which were emplaced between 340 and 290 Ma, during and after the Variscan continental collision (at ~360 - 350 Ma). Only few granitoids formed during the early stages of the Variscan cycle (D₁ and D₂ deformation phases) with closure of the intervening ocean, crustal thickening and nappe emplacement. By contrast, extensive granitoid activity accompanied the post-thickening and post-collisional extension (D₃ deformation phase). Based on the emplacement ages the granitoid magmatism of Central Iberian Zone has been classified as: 1) pre-D3; 2) syn- to late-D₃; 3) post-D₃. Most syn-D₃ granitoids are aligned along NW-SE vertical folds and subvertical ductile shear zones.

Peraluminous two-mica granites at Carrazeda de Ansiães, northern Portugal, represent successive intrusive events during the D₃ Variscan deformation phase. Based on tectono-magmatic relationships and petrographic criteria, three groups can be distinguished, from older to younger: I (G1, G2, G3, G4, G5 and G6), II (G7, G8 and G9) and III (G10). The granites from Group I show evidence of high-temperature solid-state deformation, such as microfracturing of feldspar, kinks in biotite, flexural bends in plagioclase and S-C structures. Group II granites show a magmatic syntectonic NW-SE foliation, defined by euhedral phenocrysts of microcline, micas and also surmicaceous enclaves, that is continuous with the regionally developed foliation in the wall rocks. The emplacement of granite G10, belonging to Group III, was controlled by late-Variscan NNE-SSW fractures, which explains its brittle deformation. Representative granites from each group (G5, G7 and G10) were selected for a U-Pb (ID-TIMS) zircon and monazite study. The zircon systematics are generally complex because of Pb loss and inheritance, the latter also affecting some of the monazites. Nevertheless, the data combine to yield consistent ages of 320.5 ± 0.5 Ma for G5, 317.8 ± 0.5 Ma for G7 and 316.2 ± 0.7 Ma for G10, and thus tightly constrain the timing of the main D₃ event.

Time series diffusion experiments with natural alkaline melts

F. TEIXIDÓ¹,², C. DE CAMPOS², J. MARTÍ¹AND D. DINGWELL²

¹CSIC, Instituto de Ciencias de La Tierra Jaume Almera. C/Luis Solé i Sabarís s/n 08028 Barcelona, Spain (fteixido@ija.csic.es, joan.marti@ija.csic.es)
²Ludwig Maximilians Universität. Department für Geo- und Umweltwissenschaften. Theresienstrasse 41/III, D-80333 Munich, Germany (campos@min.uni-muenchen.de, Dingwell@lmu.de)

We performed in this work time series diffusion experiments with contrasting alkaline melts obtained from natural volcanic products. The starting materials are the two end-member compositions and rheologies in the volcanic Province of Tenerife (Canary Islands, Spain). They correspond to an alkali basalt (43% SiO₂; υ= 4,412 Pa·s) and a phonolite (59% SiO₂; υ=10³ Pa·s).

The samples were loaded in a platinum capsule and arranged in a buoyantly stable geometry, where the denser material is placed at the bottom (alkali basalt, ρ=2,73 gr/cm³) and the lighter material at the top (phonolite, ρ=2,36 gr/cm³). We run experiments during 4, 25, 49 and 125 hours and we performed three different sets of experiments (with the same time duration) at 1350°C, 1300°C and 1250°C under atmospheric conditions. For every set the temperature has been kept constant during the whole experimental run and with an irrelevant thermal gradient (< 2°C). These temperatures, well above the liquidus for the system, avoid crystallization. No forced convection was applied, so that the diffusion process takes over and the compositional gradient becomes the only parameter enhancing the mixing process.

Microprobe and laser ablation analyses were performed to track major, minor and trace elements. The evolution of the diffusion profiles along a longitudinal section of the resulting products showed that mixing was possible. Diffusivity coefficients of the main elements at every temperature will be calculated in the near future.
Lower crustal material in the source of the Ontong Java Plateau?

M.L.G. TEJADA1, K. SUZUKI2, T. HANYU3, J. MAHONEY3, Y. TATSUMI4 AND S. NAKAI4

1NIGS, Univ. of the Philippines, Quezon City, Philippines (ma_luisa.tejada@up.edu.ph)
2IFREE, Japan Agency for Marine-Earth Sci. & Tech., Japan
3SOEST, University of Hawaii, Honolulu, HI, USA
4ERI, Univ. of Tokyo, Tokyo, Japan

Was an oceanic plateau as large as Ontong Java Plateau (OJP) a product of voluminous melting by a mantle plume or just a consequence of unusual plate tectonic processes during the Aptian time (120 My ago)? Our Os-Hf results on the plateau lavas put further constraints on the origin of the OJP, suggesting that the plateau is a product of a two-component mantle source possessing distinct Os isotope signatures that are both suprachondritic (0.12-0.17 for Kwaimbaita-type lavas and 0.24-0.60 for Singgalo-type lavas) and different from MORB (with an average composition of 0.125, [1]). In contrast, Hf isotope results for the same Central Malaitan and ODP Sites 807, 1185, and 1187 samples show a slight difference between the Singgalo- and Kwaimbaita-type lavas in 176Hf/177Hf, consistent with previous results for the ODP Leg 192 lavas [2]. Both isotopic groups of lavas have Hf isotope compositions that lie on the terrestrial array defined by MORB and OIB data in HF-Nd diagram but have a gentler slope, reminiscent of the Hawaiian data trend. Both the involvement of pelagic sediments and altered, recycled normal oceanic crust do not have the required Pb and Hf isotopic compositions that can explain the Os-Pb and Os-Hf trends of the OJP data. Instead, the Os and Hf isotopic compositions of the OJP lavas both indicate an origin distinct from the shallow mantle tapped by MORB lavas. Our modeling results indicate that the Os isotopic composition of the Singgalo-type lavas may be explained by incorporation of up to 40% lower continental crust material into the Kwaimbaita-type source of the OJP lavas. This is broadly consistent with suggestions by [3] and [4] but differs from previous interpretation in inferring that the entrained recycled crust is lower continental crust. The present interpretation allows for widespread contamination of the OJP mantle source with delaminated lower crust, possibly during continental break-up, that paved the way for the birth of the Pacific ocean in the past.

Although a huge number of studies have been devoted to metal-organic ligand interactions in natural aquatic systems, the effect of dissolved organic matter on the behavior of toxic metalloids like Sb, Se or As is still very poorly known. This is because metalloids are subjected to strong hydrolysis in aqueous solution, by forming neutral and negatively charged hydroxide species. This strong affinity to hydroxide ligands was believed to limit their complexing with organic ligands in comparison to most metals which exist as simple cations in solution. In this study, we combined systematic solubility and potentiometry measurements with in situ XAFS spectroscopy and dialysis experiments to assess structures and stabilities of antimony aqueous complexes formed with organic ligands having functional groups typical of natural organic matter.

Results show that both trivalent (SbIII) and pentavalent (SbV) antimony form surprisingly stable complexes with hydroxy-carboxylic and hydroxy-phenolic functional groups of organic ligands (lactic, oxalic and citric acids, and catechol), with Sb/ligand stoichiometries from 1:1 to 1:3, over a wide pH range (2<pH<9). The key condition for the formation of such complexes is the establishment of a five-membered chelate cycle via Sb-O-C bonds with two adjacent functional groups of the organic ligand. In these species, SbIII and SbV are respectively four- and six-coordinated, as demonstrated by XAFS spectroscopy.

The stability constants determined for SbIII organic-complexes have been used to approximate Sb complexing with natural humic acids which possess the same functional groups as those investigated in this study. Results show in unpolluted organic-rich natural waters up to 60% of total Sb may be complexed with humic and fulvic acids via carboxylic and hydroxy-carboxylic groups, which is also in agreement with dialysis experiments on a commercial humic acid. Thus, organic matter plays an important role in Sb transfer in natural waters than believed. Our findings indicate that because of the high selectivity of Sb to bidendate linkages with two adjacent functional groups of organic ligands, antimony may serve as a proxy for such moieties in aqueous humic and fulvic acids.

Our results imply that natural organic matter may also exert an important effect, largely neglected before, on the transport of analogous metalloids like As and Se in aquatic systems.
Geochemical properties of Miocene basaltic rocks from Yavuzeli-Araban-Narlı region, Southeast Anatolia, Turkey

S. TELSIZ1, A. TEMEL1, A. GOURGAUD2 AND M. ALPASLAN3

1Hacettepe University, Dept. of Geol. Engineering, 06800, Beytepe-Ankara, Turkey (stelsiz@hacettepe.edu.tr; atemel@hacettepe.edu.tr)
2Université Blaise Pascal, OPGC, Laboratoire CNRS "Magmas et Volcans" 5 rue Kessler-63038, Clermont-Ferrand Cedex, France (gourgaud@opgc.univbpclermont.fr)
3Mersin University, Department of Geology, 33343, Çiftlikköy-Mersin, Turkey (malpaslan@mersin.edu.tr; malikurt@mersin.edu.tr)

Miocene basaltic rocks from northern part of the Arabian plate (Southeast Anatolia, TURKEY) exposed as lava flow and blocky lava flow from the base to the top. The volcanic rocks are basalt-basaltic andesite in composition, and all of them have tholeiitic characteristics. Based on mineralogical and petrographical studies, it is observed that volcanic rocks are composed of mainly pyroxene and olivine phenocrysts. In the Wo-En-Fs classification diagram of Moritomo (1988), pyroxene compositions plot in the augite (Wo 31-41) field. Composition of olivine phenocrysts range from Fo 77 to Fo 84. Plagioclase minerals are generally found as a microlites in the matrix and labradorite-andesine (An43 to An60) in composition. Clinopyroxene and olivine are normally zoned, and MgO composition of the core and rim are virtually similar. Oxide minerals are ilmenite.

Major and trace element versus MgO diagrams indicate that fractional crystallization process is effective on the evolution of these basalts. Basaltic rocks are characterized by slightly LREE enrichment and high 87Sr/86Sr and low 143Nd/144Nd ratios ranging from 0.704574 to 0.705054 and 0.512652 to 0.512720, respectively. Slightly depletion of Nb-Ta on primitive mantle normalized multi-element diagrams, with high 87Sr/86Sr and low 143Nd/144Nd ratios, and Th/Yb-Ta/Yb diagram reveal that crustal contamination could be effective in their generation. La/Nb (≈0.7) ratios are similar to athenospheric mantle source. The trace elements and isotopic values indicate an athenospheric mantle source. Whereas, these rocks were not derived from a single mantle source according to partial melting modeling. The melts are produced probably by mixing of athenospheric and garnet or spinel peridotitic mantle sources.

Petrogenesis of Delihalil Quaternary basaltic volcanism, South Anatolia, Turkey

A. TEMEL1, R. FREI2, M. ALPASLAN3 AND M. A. KURT3

1Department of Geological Engineering, Hacettepe University, Beytepe Campus, 06800 Ankara, Turkey (atemel@hacettepe.edu.tr)
2Geological Institute University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen, Denmark (robertf@geol.ku.dk)
3Department of Geological Engineering, Mersin University, Çiftlikköy Campus, 33342, Mersin, Turkey (malpaslan@mersin.edu.tr; malikurt@mersin.edu.tr)

In this study, Delihalil Quaternary basaltic volcanic rocks situated in the southwest of Osmaniye (south Anatolia, Turkey) were studied. Volcanic units are composed of scoria cones and lava flows exhibiting alkaline characteristic. They are basanite (early eruption phase) and basalt (late eruption phase) in composition. Volcanic rocks consist of olivine and clinopyroxene phenocrysts with plagioclase and clinopyroxene microphenocrysts and microlites. Such features as resorbed surface, skeletal textures, glass and opaque mineral inclusions in the olivine phenocrysts of the early eruption phase indicate magma mixing process in the evolution of these volcanic rocks.

Variation diagrams of MgO with major and trace elements are consistent with fractional crystallization process for basanites. However, this process did not play an important role in the formation of the alkaline olivine basalts which are the late eruption phase. Primitive mantle normalized trace- and RE-element spider diagrams exhibit that the early eruption phase (basanites) is more enriched than the late eruption phase. However, because of similar trace element patterns seen in spider diagrams, it can be concluded that they are derived from the same mantle source with different degrees of partial melting. Delihalil volcanism has low Sr and high Nd isotopic compositions. Their Sr and Nd isotopic compositions range between 0.703012-0.703617 and 0.512848-0.512947, respectively. In the Sr-Nd isotopic variation diagram, the early eruption phase samples are located into the HIMU-OIB area, whereas the late eruption phase sample is located into the EM-I field.
Post-collisional Tertiary volcanism in the Ulubey region at the western edge of the eastern Pontides paleo-arc started with sediments in a shallow marine environment in the Paleocene-Eocene time and then continued extensively with sub-aerial andesitic and rare basaltic volcanism during Eocene and Miocene time. The volcanic rocks studied are mainly andesite/trachyandesite and rarely basalt/trachybasalt and pyroclastics, and show porphyric, hyalo-microlitic porphyric and rarely glomeroporphyric, interstitial, intergranular, fluidal and sieve textures.

The volcanic rocks indicate a magma evolution from tholeiitic-alkaline transitional to calc-alkaline, and have medium to high-K in character. Petrochemical data of the rocks suggest a dominant fractional crystallization and less crustal contamination processes in their evolution. Most samples have also low Mg#, Cr, and Ni, which indicates that they have undergone significant fractional crystallization from mantle-derived melts. Generally, major and trace element geochemical variations in the rocks can be explained by fractionation of common mineral phases. E-MORB normalized trace element patterns show that Ulubey volcanic rocks have geochemical patterns with enrichment in LILE and to a lesser extent in LREE, but depletion in HFSE. The rocks have geochemical patterns with enrichment in LILE and normalized trace element patterns show that Ulubey volcanic rocks developed hornblende + plagioclase + clinopyroxene ± titanomagnetite controlled fractionation whereas andesitic rocks developed hornblende + plagioclase + clinopyroxene ± titanomagnetite controlled fractionation and, rare crustal contamination in shallow level magma chamber(s).

The 40Ar/39Ar dating of the basaltic rocks 15.1±0.6 Ma and the andesitic rocks are between 44.6±0.1 and 49.4±0.1 Ma. The rocks evolved from a parental magma derived from a parental magma derived from an enriched source formed by subduction induced metasomatism of basaltic rocks formed clinopyroxene ± titanomagnetite controlled fractionation whereas andesitic rocks developed hornblende + plagioclase + clinopyroxene ± titanomagnetite controlled fractionation and, rare crustal contamination in shallow level magma chamber(s).
The absence of magnesium isotope fractionation during basalt differentiation

FANG-ZHEN TENG1, MEENAKSHI WADHWA2, ROSALIND T. HELZ3 AND FRANK M. RICHTER1

1Department of the Geophysical Sciences, The University of Chicago, Chicago, IL 60637 (teng@geosci.uchicago.edu)

3U. S. Geological Survey, Reston, Virginia 20192

In order to understand Mg isotope geochemistry during basalt differentiation and characterize the Mg isotopic composition of the mantle, we present high-precision Mg isotopic data measured by MC-ICP-MS for a set of well-characterized samples from Kiluaea Iki lava lake, Hawaii, U.S.A. Samples from the Kiluaea Iki lava lake, produced by closed-system crystal-melt fractionation, range from olivine-rich cumulates to highly differentiated basalts with MgO content ranging from 2.37 to 26.87 wt.%. Our results demonstrate that although these basalts have diverse chemical compositions, mineralogies, crystallization temperatures and degrees of differentiation, their Mg isotopic compositions display no measurable variation within the limits of our external precision (average δ26Mg = -0.36 ± 0.10 and δ25Mg = -0.20 ± 0.07; uncertainties are 2SD). This indicates a lack of Mg isotopic fractionation during crystal-melt fractionation at temperatures of ≥ 1055 °C. Calculations based on these observations suggest that at near-magmatic temperatures the maximum fractionation in the 26Mg/24Mg ratio between olivine and melt is 0.07‰. These results are in contrast to those for lunar basalts, which exhibit significant Mg isotopic variation that has been attributed to fractionation during magmatic differentiation in the lunar magma ocean (Wiechert and Halliday 2007).

Continental basalts (BCR-1 and BCR-2), two mid-oceanic ridge basalts and two chondrites (Allende and Murchison) analyzed in this study have Mg isotopic compositions similar to the Kiluaea Iki lava lake samples. These compositions are additionally similar to those reported recently for several ordinary and carbonaceous (including Allende and Murchison) chondrites (Wiechert and Halliday 2007). This indicates that the terrestrial mantle may have a chondritic Mg isotopic composition. This obviates the need for a model such as that of Wiechert and Halliday (2007), which would be required to explain a non-chondritic Mg isotopic composition for the Earth.

Two views of initial Pb of early Earth

F. TERA

DTM- Carnegie Institution of Washington, 5241 Broad Branch Road, NW, Washington, DC 20015, (tera@dtm.ciw.edu)

A Mixi-chron (Fig. 1), is a line by isochronous samples having a singular K = Th/U and a range in μ = U/Pb. The correlation allows calculation of initial 208Pb. The twin-mixichrons of Barberton intersect the Y-axis in 2 places whose ratio yields the age, t. From t ± intercepts, K of crystallization is calculated (see values in Fig. 1). Assuming a 4.56 Ga source, one obtains from a Pb/Pb isochron (not shown), initial 206/204 = 12.05, and 207/204 = 13.88. The resulting 207/206 = 1.152 is used to define 206/208 and 207/208 endpoints in Fig. 1 (filled circles). These yield initial 208/204 = 31.75. From the isotopic ratios one calculates μ = 8.30 and K = 4.0, for the first stage. Applying this method to three other terrains resulted in μ ranging from 7.8 to 8.9, and K ranging from 4.0 to 4.65. These results appear in general accord with the prevailing view of a Silicate Earth having μ ~ 9 and K ~ 4.

A counter view is that a two-stage model for Earth is a gross approximation that results in a false image, with invalid parameters (1). Also, all models of bulk isotopic composition of silicate Earth, plot to the right of a 4.56 Ga geochron, in the conventional Pb/Pb diagram, thus indicating enrichment in 206Pb. That this is erroneous (1), is further indicated in Fig. 2, where the plotted data are for nine, widely separated terrains [sources of data are in (1)]. Primordial Pb was subtracted. The results indicate excess radiogenic *(207Pb), even for data plotting below the geochron (all are < 4.0 Ga old). Conclusions: The prevailing view of 206Pb-enriched ‘Bulk Earth’ is invalid. The methodology of Pb-isotope planetary evolution is inadequate.

Modeling of Zn sorption onto clayey sediments using a multi-site and multi-component ion-exchange model

E. TERTRE, N. COREAU, A. JUERY AND C. BEAUCAIRE
Commissariat à l’Energie Atomique, DEN/DPC/SECRL3MR; Centre de Saclay, 91120 Gif-sur-Yvette, France

In literature, many sorption models have been proposed to interpret experimental sorption data onto complex mineralogical assemblages, such as sediments and soils. Nevertheless, these models are often empirical and cannot interpret data obtained in a wide range of physico-chemical conditions (pH, ionic strength, initial trace element concentration, solid/solution ratio…).

The aim of this study is (1) to elaborate a model of multi-site and multi-component cation exchange capable to describe the retention of transition metal on pure clay-minerals (2) to test the ability of this approach to reproduce the retention of these elements on natural material (soils/sediments) in various chemical conditions.

This study is focused on the behaviour of Zn in presence of clayey sediments. Considering that clay-minerals behave as a multi-site cation exchanger, it is possible to describe the retention of metals as well as the competitor cations, including the protons, by ion-exchange equilibria with the surface minerals. This approach was applied with success to interpret the experimental data obtained by Bradbury and Baeyens (1997) in the Zn-Na-montmorillonite system. Behaviour of Na, K, Ca and Mg versus pH was already studied in previous studies on pure montmorillonite (Gorgeon, 1994; Nolin, 1997) and permitted us to elaborate a thermodynamic data base including the exchange site concentrations associated to the montmorillonite and the selectivity coefficients of Na⁺, K⁺, Ca²⁺, Mg²⁺, and Zn²⁺ versus H⁺.

Sorption isotherms of Zn were carried out onto two different sediments in batch reactors at different pH and ionic strengths, and using NaCl and CaSO₄ as electrolytes. CEC measurements of both sediments were performed by cation displacement using CsCl solution.

Modelling of Zn retention onto sediments was carried out for the different experimental conditions, using the data base obtained previously upon montmorillonite. Assuming that clay minerals are the main ion-exchanging phases, site concentrations can be expressed in function of fractional weight content of the clayey minerals constituting of the sediments. Whatever the physico-chemical conditions tested, we observe a relatively good agreement between experimental and simulated Kd’s.

Isotopic record of Hadean crust in Western Australia

S. G. TESSALINA¹, P. PHILIPPO¹, M. VAN KRANENDONK², B. BOURDON³ AND J. L. BIRCK¹
¹Institut de Physique du Globe de Paris; Paris, France (svetes@ipgp.jussieu.fr)

³Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, Switzerland (bourdon@erdw.ethz.ch)

Application of the ¹⁴⁷Sm-¹⁴³Nd and ¹⁴⁶Sm-¹⁴²Nd chronometers suggests that mantle depletion and related crust extraction had started during the first hundred million years of Earth history (Caro et al., 2006), but there is limited evidence for the presence of an enriched silicate reservoir before 4.0 Ga (Harrison et al., 2006). Here, we report new ¹⁴⁷Sm-¹⁴³Nd data from low-grade metamorphosed Paleoarchean volcanic and sedimentary rocks of the Warrawoona Group, Pilbara Craton, Western Australia. A Sm-Nd isochron age of 3.48 ± 0.09 Ga is in agreement with the U-Pb zircon age from intercalated volcanoclastic rocks and indicates the preservation of their Sm-Nd isotope signature since the Archean. The initial εNd value of -3.3 ± 0.5 is out of the range (+1< εNd < +3) established for the Archean cratons based on whole-rock Sm-Nd isochrons with ages agreeing with independent chronological constraints. This data is best explained by the assimilation of older continental crust, as shown by significant Ta-Nb depletion associated with LILE, Th, U and LREE enrichment (Green et al., 2000). Geochemical modeling suggests the assimilation of 10% to 20% of crustal material that may be either Archean granites, shales, or average upper continental crust (Condie, 1993). Assimilation of this crustal material with εNd values of −6 (granite), −8 (shales) and/or −10 (upper CC) by a mantle-derived melt accounts for the observed Nd isotope composition of basalts. This crustal component, with ¹⁴⁷Sm/¹⁴⁴Nd ratios of 0.99–0.12, would have been isolated from the depleted mantle at 4.0–4.4 Ga, which is consistent with the Nd model ages derived from the studied rocks. Our observations, albeit indirect, clearly show the existence of a an Hadean crustal reservoir. Its presence is confirmed by negative εNd of Archean seawater, inferred from carbonate rocks with seawater-like REE patterns. The presence of a crustal basement involved in plume magmatism indicates eruption of flood basalts onto a submerged continental platform, analogous with the Phanerozoic Kerguelen plateau (Van Kranendonk and Pirajno, 2004). This could have been an important mode of crustal production in the Archean.

Spatial and temporal variations in exhumation across the NW-Himalaya

R.C. THIEDE1,2, T.A. EHLERS2 and M.R. STRECKER1

1Institut für Geowissenschaften, Universität Potsdam, Potsdam, Germany (thiede@geo.uni-potsdam.de), (streecker@geo.uni-potsdam.de)
2University of Michigan, Ann Arbor, Mi, USA, (tehlers@umich.edu)

Erosional exhumation and topography in Mountain belts are temporally and spatially variable over million year time scales due to changes in both the location of deformation and climate. However, many studies are limited in the extent to which spatial variations in exhumation can be quantified due to the limited geographic extent over which samples are collected. We investigate spatial and temporal variations in exhumation and deformation across a 150x200 km region of the NW Himalaya, India. 25 new and 168 previously published apatite and zircon fission track and muscovite 40Ar/39Ar ages are integrated with a 1D model to quantify rates and timing of deformation and exhumation along strike of several major structures in the Lesser and Greater Himalaya. The model solves the advection-diffusion equation and predicts thermochronometer ages for variations in exhumation rates, thermophysical properties, and basal temperature.

The new and previously published AFT ages range from 10 to 0.6 Ma. The sample area is characterized by 0.7-5 km-high-topography, high relief (~4 km), and large (~1 to 4 m/yr) precipitation gradients. All the thermochronometer data indicate large temporal and spatial variations in exhumation. AFT ages are inversely correlated with local relief, but not with modern precipitation gradients. Results from thermokinematic modeling of all thermochronometer systems indicate: (1) Greater Himalaya exhumation rates were ~0.5-0.8 mm/yr before ~12 Ma and increased to ~2-3 mm/yr after ~10 Ma. (2) In the Lesser Himalaya exhumation rates are ~1-2 mm/yr over the last 10 Ma. The previous temporal variations in erosion in the Greater Himalaya are spatially consistent along 200 km of strike, regardless of structural variations. This implies that erosion, rather than tectons, has controlled the topographic evolution of this region over the last ~15 Ma.

Ca-Sr fractionation between margarite, anorthite, calcite, and fluid at 400-500 °C and 3.5-5 kbar

M. THIELE1, G. DOERSAM1, G. FRANZ1, A. LIEBSCHER1 AND M. GOTTSCHALK2

1Technische Universität Berlin (konzentrat@gmx.de, guidedoersam@web.de, gerhard.franz@tu-berlin.de, axel.liebscher@tu-berlin.de)
2GeoForschungsZentrum Potsdam (gottschalk@gfz-potsdam.de)

We determined experimentally the Ca-Sr distribution between an 1 molar aqueous (Ca,Sr)Cl2-solution and (Ca,Sr) solid solutions of margarite, anorthite, calcite ± slawsonite and clinozoisite at 400-500 °C and 3.5-5 kbar using conventional cold-seal hydrothermal experiments. Solid oxide-hydroxide starting mixtures were prepared from SiO2, Al2O3, Ca(OH)2, and Sr(OH)2·8H2O (containing small amounts of carbonate impurities) weighted in stoichiometric amounts of the desired margarite composition plus ~ 3 wt% SiO2 excess to compensate for Si solubility in the fluid at run conditions. Strontium bulk compositions X Sr bulk [Sr/(Sr + Ca)] ranged from 0.07 to 0.40 with initial X Sr solid = X Sr fluid. The initial solid/fluid weight ratios were ~ 1:1. Solid run products were analyzed by REM, electron microprobe, and XRD; fluids were analyzed by inductively coupled plasma emission spectrometry.

Syntheses products are margarite, anorthite, and calcite in all runs ± clinozoisite and slawsonite in one run each at X Sr ≥ 0.15. Margarite forms idiomorphic hexagonal plates of generally less than 5 μm diameter. Anorthite and also clinozoisite are likewise idiomorphic but form significantly larger crystals with up to 100 and 150 μm lengths, respectively.

In all runs, X Sr of margarite, anorthite, and calcite is less than the corresponding X Sr bulk and X Sr fluid and ranges up to X Sr = 0.166 in margarite, 0.137 in anorthite, and 0.031 in calcite. Within these compositional ranges, electron microprobe analyses indicate continuous Ca-Sr solid solution series for all three minerals. X Sr of clinozoisite is slightly higher than X Sr of coexisting margarite, anorthite, and calcite but still less than the corresponding X Sr fluid. Contrary, slawsonite has notably higher X Sr than X Sr bulk and X Sr of coexisting fluid and other solid phases. We used our data to calculate exchange coefficients K D for the generalized reaction Ca Phase 1 + Sr Phase 2 = Sr Phase 1 + Ca Phase 2 (where K D Phase 1 - Phase 2 = (Sr/Ca) Phase 1/ (Sr/Ca) Phase 2): K D marginite-fluid ranges from 0.49 to 0.67, K D anorthite-fluid from 0.47 to 0.59, and K D calcite-fluid from 0.08 to 0.11; K D clinozoisite-fluid is 0.72 and K D slawsonite-fluid is 7.75. The data clearly show a preference of Sr over Ca for the fluid when compared to margarite, anorthite, calcite, and clinozoisite, but a preference of Ca over Sr for the fluid when compared to slawsonite. Calculated K D anorthite-calcite and K D anorthite-calcite range from 5.14 to 8.60 and 4.91 to 7.55, respectively, and indicate notably Ca-Sr fractionation. On the other hand, K D marginite-anorthite ranges from 1.01 to 1.26 and suggests only weak Ca-Sr fractionation between margarite and anorthite.
Not much gabbro in the Icelandic mantle!

Matthew Thirlwall¹ and Mary Gee²

¹Geology, Royal Holloway University of London, Egham TW20 0EX, UK. (m.thirlwall@gl.rhul.ac.uk)
²Earth and Geographical Sciences, Univ. Western Australia, Crawley WA 6009. (mgee@cyllene.uwa.edu.au)

Picritic lavas from Iceland have unusual trace element signatures, including strong incompatible element depletion, that have been used to infer derivation from a source dominated by oceanic gabbros, either through deep ancient recycling [e.g. 1] or shallow recent recycling [2]. We report results of a multi-element MC-ICP-MS isotope dilution study of lavas from the Reykjanes Peninsula that include depleted lavas (‘picrites’ ± l) from 14 separate localities, with the aims of testing the recycled gabbro hypothesis and constraining the timing of incompatible element depletion.

The key features that have been attributed to a gabbroic source are positive anomalies for Sr, Ba and Eu, relatively low Ce/Pb, and negative anomalies for Zr and Hf. We would also expect Dy/YbN>1 due to melting clinopyroxene that had crystallized from liquids with flat HREE patterns. Sr/Nd, Sm/Zr and Pb/Ce increase systematically with increasing LREE depletion, consistent with reported anomalies in depleted lavas. However, Sr/Sm is essentially constant across the full spectrum of LREE enrichment, while Nd/Zr and Pb/Nd decrease systematically with LREE depletion. This suggests that the reported anomalies are substantially due to incorrect assumptions about the REE K D analogues for Sr, Zr and Pb. Eu/Eu* increases from about 1.03±0.02 in LREE-enriched lavas to ~1.08 in the most LREE-depleted lavas, an increase at least in part due to the strong concave-down curvature in depleted lava REE patterns. Most depleted lavas show Dy/YbN<1, inconsistent with large-degree melting of gabbro-dominated sources, and suggesting that their sources are simply produced by extensive melt extraction from normal Icelandic mantle sources in the garnet facies. Their more depleted isotopic compositions may largely reflect the time elapsed since this melt extraction, at most 270 Ma. Tight coupling between Lu/Hf and Sm/Nd, but not between these and Hf or Nd isotope ratios, also requires a dominant control by melt extraction on the incompatible element depletion.

Depleted lavas from the BIR1 locality, and maybe one other, show strongly elevated Sr/Sm, Nd/Zr, Ba/La and Ba/Rb; Eu/Eu*>1.1 and Dy/Yb>1 despite similar LREE depletion to many other Reykjanes lavas. So the famed Icelandic recycled gabbro signature is only clear in one ~200m location, made famous because of an international reference sample! [1] Chauvel and Hemond (2000). G¹. 1, 1525-2027

Mineralogical investigation of fly ashes of the electricity power stations of the Ptolemais - Amynteon district (Greece)

S. Thomaidis, G. Kostakis and A. Stratakis

Technical Univ. of Crete, Dept. of Mineral Resources Engineering, Gr-73100 Chania, Greece (kostakis@mred.tuc.gr)

Fly ashes were examined, those in one period of approx. 3 months of altogether six boilers from four electricity power stations (Agios Dimitrios, Kardia, Ptolemais and Amynteon, Greece), which are fired with lignite of the Ptolemais-Amynteon-basin. From each fly ash the size fractions of > 71 µm, 71 µm to 20 µm, 20 µm to 2 µm and < 2 µm are mineralogically by Roentgen-diffraclometry (RIETVELD method), as well as chemically by Roentgen fluorescence were analyzed.

It is shown that the examined fly ashes of the power stations of Agios Dimitrios, Kardia, and Ptolemais, have, essentially, the same qualitative mineralogical composition (anhydrite, lime, periclase, gehlenite, brownmillerite, Ca₃SiO₄, calcite, quartz, feldspar, muscovite/illite, hematite, amorphous phase and ± merwinite, and/or mayenite). Also their quantitative mineralogical composition is similar. Compared the ashes of the above three power stations with the fly ashes of the power station of Amynteon show only a relative little difference of the qualitative composition (anhydrite, lime, periclase, gehlenite, brownmillerite, Ca₃SiO₄, calcite, quartz, feldspar, muscovite/illite, hematite, pyroxene, hercynite and amorphous phase) but different quantitative phase composition, owing mainly to a differentiated relationship between the SiO₂ and CaO content.

The main part of the mass of the fly ashes constituted the grain size fractions > 71 µm, 71 µm to 20 µm and 20 µm to 2 µm, since the grain size fractions < 2 µm in all samples constitute less than 0.2%.

In all fly ashes by decreasing grain size was determined, on the one hand an increasing of the CaSO₄ content and on the other hand, excepting a few cases, a decreasing of content of the amorphous phase, of quartz as well as feldspar and/or the pyroxene. Beyond by the grain size fractions < 71 µm an increasing of the contents of gehlenite, brownmillerite, Ca₃SiO₄ and, in the most cases, calcite were observed.

It was shown that the contents of the amorphous phase (glass phases, unburned lignite), as well as of the not reacted silicates by burning of the lignite, decrease by the smaller grain sizes, while the crystalline, mainly calcium-rich, phases which are formed when burning, in the grain size fraction < 71 µm of the fly ashes are enriched.

The biogeochemistry of anaerobic porewaters is marked by obligate microbial syntrophy and complex ecological relationships. These in situ ecological properties are extremely difficult to probe either in vitro or in situ with specific inhibitors, since both of these treatments disrupt important microbial connections. Alternatively, stable carbon isotopic analysis of the gaseous substrates and products of methanogenesis can reveal the pathways of methane production. Carbon isotopic analyses of the methyl carbon of acetate provide us with the ability to relate laboratory derived fractionation factors between the acetate methyl and methane to natural systems in the field.

We hypothesize that isotopic estimates of methane production pathway that assume an acetate methyl isotopic composition similar to bulk organic matter can be significantly compromised during times when hydrogen concentrations are high. Such situations might occur when 1) pulses of fermentable substrates are applied or 2) methanogen activity is limited by low temperatures.

We have adapted a pyrolitic technique for the intramolecular carbon isotopic analysis of acetate in natural samples via direct injection of an aqueous solution. This method capably measures the isotopic composition of the carboxyl carbon from injections of 1 nanomole of acetate in aqueous solution. Samples with acetate concentrations less than 1mM are preconcentrated via lyophilization and reacidified to an appropriate concentration. This technique is reliable down to 30µM acetate in the original sample.

Our analyses of the carbon isotopic composition of methane, CO₂, and the intramolecular values of acetate from an acidic peatland in central Pennsylvania challenge assumptions of acetate-methyl isotopic similarity to bulk organic matter. We find the carbon isotopic composition of acetate-methyl carbon in late-winter samples are 10% depleted relative to bulk organic matter. Using a laboratory determined fractionation factor for autotrophic acetogenesis, we find that a significant percentage of the acetate in acidic peatland porewaters may derive from CO₂.
Progress in the establishment of a new Infrared calibration for the SiO2-system

S.-M. THOMAS1, M. KOCH-MÜLLER1, P. REICHART2, R. THOMAS1 AND J. HÖVELMANN3

1GeoForschungsZentrum Potsdam, Sektion 4.1, D 351, Telegrafenberg, 14473 Potsdam, Germany
2Universität der Bundeswehr München, Dept. für Luft und Raumfahrttechnik 2, 85577 Neubiberg, Germany

Conventionally used Infrared (IR) calibrations (Paterson, 1982; Libowitzky & Rossman, 1997) for the quantification of water in solids are established on hydrous minerals and glasses with several wt% water. These calibrations are based on a negative correlation between the IR absorption coefficient for water and the mean wavenumber of the corresponding OH pattern. The correlation reflects the dependence of the OH band position on the corresponding O-H...O distances and thereby the magnitude of the dipole momentum which is proportional to the band intensity. It has been observed that these calibrations can not be applied to nominally anhydrous minerals (NAMs) (Rossman, 2006). Up to now the ultimate cause remains entirely unclear.

To learn more about absorption coefficients in NAMs and their potential dependence on structure and chemistry we synthesized SiO2 polymorphs with specific isolated hydroxyl point defects, e.g. quartz, coesite and stishovite with B3++H+=Si4+ and/or Al3++H+=Si4+ substitutions. Experiments were performed with water in excess in piston cylinder and multi-anvil presses. Single crystal IR spectra reveal the presence of hydroxyl groups in all our samples and enable us to propose new OH incorporation models. Furthermore, IR spectra demonstrate that we successfully managed to separate generally complicated OH band patterns as e.g. observed in spectra demonstrate that we successfully managed to separate generally complicated OH band patterns as e.g. observed in conventional IR spectra. The correlation reflects the dependence of the OH band position on the corresponding O-H...O distances and thereby the magnitude of the dipole momentum which is proportional to the band intensity. It has been observed that these calibrations cannot be applied to nominally anhydrous minerals (NAMs) (Rossman, 2006). Up to now the ultimate cause remains completely unclear.

We present new material-specific correlations and resultant single calibration constants for the SiO2 polymorphs. It turns out that the magnitude of absorption coefficients within one structure type is independent of the liable OH point defect and therewith the wavenumber of the observed band position but in contrast varies with the structure itself. Similar results concerning an intra-structural constancy of the integral molar absorption coefficient have been shown before for feldspars (Johnson & Rossman, 2003).

Multiple Sulfur and Carbon isotopic chemiostratigraphy of the 2.73 Ga carbonated Tumbiana formation, new insights for the Fortescue excursion

CHRISTOPHE THOMAZO1,2, M. ADER1, J. FARQUHAR3 AND P. PHILIPPOT2

1Laboratoire de géochimie des isotopes stables, Institut de Physique du Globe de Paris, France: (thomazo@ipgp.jussieu.fr)
2Laboratoire Géobiosphère actuelle et primitive, Institut de Physique du Globe de Paris, France: (philippo@ipgp.jussieu.fr)
3Department of Geology, University of Maryland, College Park, Maryland, USA: (jfarquha@essic.umd.edu)

In order to bring further insights into the environmental conditions prevailing during the δ13C negative Fortescue Excursion attributed to an increase in methanotrophic biomass, we carried out a detailed carbon (13C, 14C) and multiple sulfur (32S, 33S, 34S) isotopic study through the entire pristine core drilled from the 2.7 Ga Tumbiana Formation (Pilbara Drilling Project; Van Kranendonk et al., 2006).

Organic δ13C_CPM values vary markedly at meter scale and display a bimodal distribution with two maxima at -43 and -28‰. This isotopic record, together with palynological and other geochemical evidence, cannot be explained by secondary processes including diagenesis or metamorphism and argues for the occurrence of two distinct pools of biomass likely produced by different metabolic pathways, photosynthesis and methanotrophy. δ34S_CDT values of sedimentary pyrite vary from -5.8 to 2.7‰ (average -0.5‰). Lithologically indendent heterogeneities (at centimeter scale) in isotopic composition (>5‰), sulfur content and S/C ratio are best interpreted by coexisting microbial sulfate reduction and sulfur oxidation metabolisms. Sedimentary pyrite display Mass Independent Fractionation with ∆33S_CDT anomalies ranging between -0.24 and 1.64 ‰ (average 0.46 ‰) and correlating positively with the 12C enrichment of organic matter. This suggests that the sulfur components derived from photochemically-processed volcanic gases and delivered to the Tumbiana sediments were ultimately involved in the metabolic activity of sulfur processors.

Our results suggest that at least four different types of metabolism operating under various redox conditions were present in the Tumbiana paleo-environment and we propose that the δ13C negative Fortescue Excursion reflects methane assimilation by a consortium of organisms including Anaerobic Oxidation of Methane Archaea and Sulfate Reduction Bacteria in anoxic time of the Tumbiana basin.

**Magma chamber processes beneath Icelandic central volcanoes: Evidence from gabbros of the Austurhorn intrusive complex, SE Iceland**

S.B. THORARINSSON1 AND C. TEGNER2

1Iceland GeoSurvey, Reykjavik, Iceland
2Department of Earth Sciences, Aarhus University, Denmark

The ~6 Ma Austurhorn (15 km²) intrusive complex was emplaced at approx. 2 km depth into Neogene basalts of Southeast Iceland. The exposed gabbros, granophyres and acid-basic complexes are among the largest in Iceland and represent the exhumed roots of a late Neogene central volcano.

The 2.3 km² layered gabbro sequence at Hvalnesfjall makes up the central part of the intrusion. Our results demonstrate that the cumulate stratigraphy exceeds 800 m, making it the largest known gabbro outcrop in Iceland. The gabbro is dominated by leucocratic, plagioclase–clino-pyroxene–Fe-Ti oxide cumulates. However, seven 2-10 m thick olivine-bearing melanocratic layers define the bases of macrorhythmic units. Cumulus minerals have a limited compositional range (An85-56 in plag; Mg#84-72 in cpx) compared with closed-system layered intrusions and show no variation shows a zigzag pattern with increases in Cr₂O₃ in overall evolution from bottom to top of the sequence. Cryptic macrorhythmic units. This is interpreted to reflect crystallisation in a periodically replenished, tapped and fractionated magma chamber.

The emplacement sequence of the intrusive rocks at Austurhorn is debated. An approx. 100 m thick gabbroic body at Hvashjalli east of the Hvalnesfjall gabbro was mapped by Furman et al. (1992) as gabbro cross-cut by granophyre. Our mapping, however, demonstrates that this gabbroic body is a monster pillow that grades from lobate dolerite at the margins to gabbro at the centre. We therefore suggest that all gabbroic bodies at Austurhorn were formed by intrusion of basaltic magma into pre-existing riftotic magma chambers.

**Excess ¹⁷⁶Hf in early crystallised meteorites**

The ¹⁷⁶Lu decay decay constant (λ¹⁷⁶Lu) has been determined to be 1.87 x ¹⁰⁻¹¹ yr⁻¹ using terrestrial samples of known U-Pb ages (Scherer et al. 2001, Söderlund et al. 2004), a value recently verified by an internal isochron from phosphate minerals from a 4557 m.y. old meteorite (Amelin 2005). However, previous Lu-Hf analyses from meteorites older than 4.56 Ga have ¹⁷⁶Hf excesses that are correlated with their Lu/Hf elemental ratios (Blichert-Toft et al. 2002, Bizzarro et al. 2003). To evaluate this issue, we derived an internal Lu-Hf isochron from the basaltic angrite SAH99555 yielding a Pb-Pb age of 4564.5 Ma (Amelin et al. 2007). Similar to the earlier results on pre-4.56 Ga meteorites, our Lu-Hf results show an ¹⁷⁶Hf excess corresponding to ~6% increase in the slope of the isochron. Due to the correlation with Lu, we infer this excess be generated by an accelerated decay of Lu most likely related to the formation of the ¹⁷⁶Lu⁰ isomer with a half-life of 3.7 hours. Alberède et al. (2006) proposed that ¹⁷⁶Lu was excited due to solar and/or supernova generated gamma radiation. However, the shallow penetration of gamma radiation precludes this model explaining the ¹⁷⁶Hf excess in SAH99555. We considered supernova generated neutrinos as an alternative means to excite ¹⁷⁶Lu but this process is precluded by the very small neutrino cross section. A third energy source also related to supernova shocks is cosmic rays. Cosmic rays can excite nuclei and penetrate accreted material as deep as 100-200 meters. As such, they could account for the excess ¹⁷⁶Hf in material crystallised before the supernova explosion. This model is consistent with Fe-Ni isotope data that indicate that a supernova(e) occurred after accretion of the angrite parent body (Bizzarro et al. in press).

Geochemical characteristics of the Mashan Au-S Deposit in Tongling, Anhui Province

SHIHONG TIAN 1,2, ZENGQIAN HOU 2,3, ZHUSEN YANG 1, TIPING DING 1,2, YIFENG MENG 1, PUSHENG ZENG 4, YANBIN WANG 3 AND XUNCHENG WANG 5

5 No. 321 Team of Bureau of Geology and Mineral Resources of Anhui Province, Tongling 244033, P.R. China

The Tongguanshan copper field in Tongling, Anhui, is one of the typical skarn orefields in the middle-lower Yangtze Valley iron, copper, sulfur and gold metallogenic belt of China. The Mashan Au-S deposit located in the Tongguanshan field is related to the Tian’ebaotanshan quartz diorite. A lot of research work has been done in such aspects as mineral deposit, mineralogy, tectonics, isotope geochemistry and fluid inclusions. Based on the work done, this paper deals mainly with hydrogen, oxygen, carbon, sulfur, silicon isotopic compositions and REE geochemistry of the Mashan Au-S deposit.

The results show that chondrite-normalized REE patterns are right-inclined, and the REE distribution patterns for ores are similar to those of the Tian’ebaotanshan quartz diorite, which indicates that the hydrothermal fluids of the deposit were mainly derived from dioritic melt. The O isotopic compositions of quartzes in ore range from 6.9‰~10.7‰ with the average of 8.7‰, which are approximate to those of the pluton (9.3‰~11.1‰, with the average of 10.0‰). Together with the D isotopic compositions of quartzes in ore (-61‰~ -62‰), it shows that the metallogenic fluids were mainly derived from magmatism. The C and O isotopic compositions of calcites in ore are different from those of country rocks in the orefield. The C and O isotopic compositions range from -5.2‰~ -3.6‰ and 12.2‰~12.9‰, respectively, which are similar to the C and O isotopic compositions of magmatism. Therefore, C and O in ores might have come from magmatism. Silicon and sulfur isotopes are quite similar to those in magma or magmatic hydrothermal solutions.

The origin and evolution of dust in the interstellar medium

ALEXANDER TIELENS
Space Sciences Division, MS245-3, NASA Ames Research Center, Moffett Field, CA 94035-1000 (atielens@mail.arc.nasa.gov)

At the end of their life, stars return most of their material back to the interstellar medium. This material undergoes a complex evolution in the interstellar medium before it becomes part of the next generation of stars and planets. Small dust grains condense in the ejecta of stars as it cools because of expansion. Astronomical observations and analysis of stardust isolated from meteorites have revealed a highly diverse interstellar and circumstellar grain inventory, reflecting the varied physical and chemical conditions in their birthsites. This talk will review this dust inventory contrasting and comparing both the interstellar and circumstellar reservoirs as also the astronomical and meteoritic evidence.

Interstellar dust is highly processed during its sojourn from its birthsite (stellar outflows and explosions) to its incorporation into protoplanetary systems. Of particular importance is processing by cosmic rays in the interstellar medium and by strong shocks due to supernova explosions. The latter leads to rapid destruction due to sputtering by impacting gas ions and shattering due to grain-grain collisions. We will review theoretical calculations describing these processes and the astronomical and meteoritical evidence for their importance.
Two Late Mesozoic pulses of silicic volcanism within the North Chukotka area (NE Russia): Magma sources and geodynamic significance

P.L. Tikhomirov1,2 E.A. Kalinina1; E. Nakamura1 and K. Kobayashi1

1Institute for Study of the Earth's Interior, Misasa, Japan; (petr37@misasa.okayama-u.ac.jp; elka@pheasant.misasa.okayama-u.ac.jp; eizonak@misasa.okayama-u.ac.jp; katsura@pheasant.misasa.okayama-u.ac.jp)
2Moscow State University, Geologic Faculty

The Cretaceous Okhotsk-Chukotka volcanic belt (OCVB) is one of the largest Andean-type volcanic provinces of the Earth. Silicic magmatic rocks are the major component of the OCVB, comprising up to 90% of some segments. The lifetime of this belt is still under discussion but all existing models imply the onset of volcanism between 107 Ma and 90 Ma. However, remnants of older (Paleozoic and Mesozoic) subduction-related volcanic provinces overlap by sequences of the OCVB are known.

One such remnant has been discovered within the northern part of the volcanic belt (Tikhomirov et al., 2007). This is a 1-1.5 km thick uniform pile of welded rhyolitic tuffs intruded by related granodiorites and overlain by felsic ignimbrites of the OCVB. Zircon U-Pb ages of both tuffs and granodiorites are about 150 Ma (Late Jurassic). The continental crust is inferred to be the main magma source during both Jurassic and Cretaceous events as contemporaneous basalts are absent, and andesites take a minor part (10-15% in vol.). Sr, Nd, Pb, and Hf isotopic characteristics of the Late Jurassic assemblage are very uniform and originate from a relatively depleted source, with εHf = +4.4 to +5.0, and εNd = -0.5 to -0.1. Isotopic ratios are not correlated with rock chemistry, and therefore considerable contribution from mantle sources are considered unlikely. OCVB rhyolites display a wider range of isotopic composition (εHf = -1.6 to +3.8, and εNd = -4.1 to -2.1), and appear to result from mixing of at least 3 different endmembers within the compositional field of continental crust.

We relate the Late Jurassic magmatic assemblage to a hypothetical continental volcanic arc at the active margin of the Anyui-Angayucham oceanic basin which closed in the Early Cretaceous (Sokolov et al., 2002). Absence of apparent tectonic deformation of the volcanic sequence implies that the main Mesozoic compressional event in North Chukotka took place before the Tithonian age.

Melting processes by Rayleigh-Taylor instabilities beneath Continents: Evidence from Cenozoic intraplate volcanism on Zealandia, SW Pacific

C. Timm1, L. Rüpke2 and K. Hoernle1

1IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (ctimm@ifm-geomar.de)
2Physics of Geological Processes, University of Oslo, PO BOX 1048 Blindern, Norway

Intraplate volcanism is mainly attributed to upwelling and subsequent partial melting of hot mantle material. However, the origin of these hot mantle material is still a matter of an active debate (e.g. www.mantleplume.org). On the New Zealand micro continent Zealandia (consisting ~ 90 % of submerged continental crust) intraplate volcanism occurs widespread and nearly continuously since the initial separation activity from Gondwana about 100 Ma ago. Voluminous volcanism was associated with the Cretaceous rifting of Zealandia from Gondwana. In contrast, only scattered, low volume eruptives were produced in the Cenozoic. Two volcanic endmembers can be defined in the Cenozoic: 1) diffuse but widespread monogenetic volcanic and dike fields (e.g. Waipati Volcanic Field, Pukaki Bank, Alpine dike swarm) and 2) shield volcanoes (e.g. Banks Peninsula, Dunedin Volcano, and Chatham Islands).

The geological processes responsible for this intraplate magmatism remain enigmatic. A mantle plume origin appears unlikely as there is no age progression in the erupted lavas in direction of plate motion, although Zealandia drifted ~ 6,000 km to its present position. This combined with the absence of an anomalous hot mantle or large extensional structures requires an alternative process to trigger partial melting beneath Zealandia. It has been proposed that the gravitationally unstable lower lithosphere was subjected to multiple delamination events during the Cenozoic. Using finite element modeling, we will test two alternative mechanisms: Rayleigh-Taylor type delamination of a dense layer at the base of the lithosphere and edge driven convection. The concept of an anomalously dense lower lithosphere is supported by the geological history of Zealandia. Located at the NW margin of Gondwana it was exposed to subduction for hundreds of million of years. Influx of subducting plate derived fluids and melts may have re-fertilized and thereby densified the lower lithosphere making it gravitationally unstable with respect to the underlying asthenospheric mantle. In addition, the relatively small lateral dimensions of Zealandia might make it particularly vulnerable to erosion by edge driven convection. We will present the conditions under which these two processes are viable explanations for the intraplate volcanism in Zealandia.
The effect of water-rock interaction time on stable carbon isotope of cave drip in Qixing cave, China

LI TINGYU AND WANG SHIJIE
State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Science, Guiyang, China (tingyuli@hotmail.com and wangshijie@vip.skleg.cn)

Aim
As substitute index of environment, stable carbon isotope has been used broadly in different natural records, such as tree rings, stalagmite, and so on. The aim of this work is to better understand the mechanism of palaeoclimate and palaeoenvironment reconstruction by stable carbon isotope of speleothem.

Results
The stable carbon isotope composition was measured in Qixing cave drip water in April 2002 and 2003. The results were showed as followed:

![Graph showing δ13C value vs drip height and drip speed]

Discussion and conclusion
The effect of water-rock time on stable carbon isotope of cave drip can be discussed by drip height and drip speed. According to the aboved figure, the δ13C value(PDB) of drip water changes inversely with drip height and drip speed. The reason is that the higher and faster drip indicate the thinner rocky cover, the shorter time of water-rock interaction and the less heavy carbon isotope coming from carbonate rock in common situation. The conclusion is that the water-rock time is longer, the DIC δ13C value of drip water become heavier.

Calcium and magnesium isotope systematics in rivers. Fractionation or lithological control?

E. T. TIPPER1, A. GALY2, J. GAILLARDET1 AND M.J. BICKLE2
1Institut de Physique du Globe de Paris, 4 Place Jussieu 75252 Paris cedex 05, France (Tipper@ipgp.jussieu.fr).
2Department of Earth Sciences, University of Cambridge, Cambridge, CB2 3EQ, UK.

Ca and Mg are two of the most concentrated elements in continental fresh waters, and analysis of their isotope ratios by MC-ICP-MS or TIMS provides a powerful new tool for investigating the global cycles of Ca and Mg and the under constrained weathering reactions by which these elements are released from the continental crust [1,2].

Stable isotope ratios in rivers are controlled by mixtures of waters with distinct compositions, often inherited from source rock heterogeneity, but also from fractionation during a series of processes associated with weathering reactions including uptake by biomass. Ca and Mg isotope ratios in the dissolved ratios of rivers from diverse weathering environments reveal that their isotopic compositions are sometimes but not always controlled by lithology.

This is illustrated by the fact the rivers with the lowest δ26Mg drain limetone, the rock type with the lowest δ26Mg. However, the δ26Mg between the solid and dissolved phase are offest by up to 1‰. Similarly small rivers draining granite and gneiss have a δ26Mg which is distinct from the solid phases. Similar differences between the solid and dissolved phase exist for Ca isotope ratios. The difficulty in interpreting such variations is that they may arise as a result of mixtures between inherited lithological signatures or as a result of fractionation during weathering processes.

A multi-tracer approach, linking major dissolved ions, Sr isotope ratios, and Ca and Mg isotope ratios in small and large basins, and soil pore waters, allows the difficulty between inherited isotope signatures and process related signatures to be considered in more detail.

The implications are of significance for better constraining the oceanic cycles of Ca and Mg, as rivers deliver a significant proportion of Ca and Mg to the oceans.

Trace element sulfide geochemistry as an indicator of vent fluid pH

M.K. TIVEY AND P.R. CRADDOCK

Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543 (mktivey@whoi.edu)

Study of actively venting seafloor massive sulphide deposits allows quantitative links to be made between vent fluid and deposit compositions. Models that reproduce mineral assemblages using measured vent fluid compositions and considering transport within the deposits indicate greatest sensitivity to the large ranges in temperature, and lesser but still significant sensitivity to the ranges in pH, present within the deposits; sensitivity to variations in oxygen and sulphur fugacity, which are small except at deposit exteriors, is not as significant (Tivey, 1995). Interest in finding an indicator of past pH from seafloor vent deposits stems from the ranges in pH (~2 to ~6) exhibited in fluids venting from seafloor sulphide deposits (Von Damm, 1995), and calculated for pore fluids within vent deposit interiors (Tivey, 1995). It also stems from our understanding that the pH of the highest temperature, lowest Mg vent fluids provides information about subsurface processes (e.g., temperatures of water-rock reaction, substrate composition, interactions with organic matter and sediment, input of magmatic volatiles).

Trends observed within bulk geochemical datasets obtained from deposits within a number of different active vent fields suggest that distributions of certain trace elements can be used as indicators of pH. For example, Ag/Fe correlates well with Zn/Fe in massive sulphide deposits from vent fields where vent fluid pH is low (<3.5 at 25°C). In contrast, Ag/Fe does not correlate well with Zn/Fe in massive sulphide deposits from vent fields where vent fluid pH is considerably higher (>4 at 25°C). The latter is consistent with wurtzite or sphalerite precipitating at higher temperatures from higher pH fluids and Ag remaining in solution, partitioning at lower temperatures into other sulphide minerals (e.g., pyrite and chalcopyrite). This behaviour, reported for Main Endeavour (high pH) versus Snakepit (low pH) vent fields (Tivey et al., 1999), holds for many additional vent fields, e.g., those along the Eastern Lau Spreading Center. The consistency of these correlations to vent fluid pH suggests that detailed in situ chemical analyses may allow estimates of pH to be made within vent deposits (e.g., inside chimney walls).

How to cool a supersaturated solution and ‘watch’ in real-time the nucleation and growth of silica nanoparticles?

D. J. TOBLER1,2 L. G. BENNING1,2 AND S. SHAW1

1School of Earth and Environment, University of Leeds (tobler@earth.leeds.ac.uk)
2Earth and Biosphere Institute, University of Leeds

The mechanisms and kinetics of silica nanoparticle formation in natural environments has been the subject of extensive laboratory investigations, yet, silica polymerization was usually induced by lowering the pH to near neutral values where silica solubility is at a minimum. However, in natural systems (e.g., geothermal pools or deep-sea vents) silica polymerization and silica colloid formation is a result of rapid cooling of a supersaturated near neutral fluid. So far, experimental challenges to simulate natural geothermal processes precluded the quantification of the kinetics and mechanisms of silica nanoparticles formation from cooling hot fluids.

Here we present data from X-ray and light scattering experiments that followed the nucleation and growth of silica nanoparticles in situ and in real-time with the polymerization being induced by rapid cooling of a supersaturated silica solution. A novel flow-through geothermal simulator system that was designed to work on-line with a synchrotron-based Small Angle X-ray Scattering (SAXS) or conventional Dynamic Light Scattering (DLS) cell and detector system was used. Silica solutions ([SiO₂] = 600 or 1'500ppm, and ionic strengths of 0.02 and 0.22) were equilibrated in this flow-through set-up to 230°C (all silica monomeric) and silica polymerization was initiated by continual rapid cooling of the flowing fluid to between 90°C to 20°C. This way the polymerisation of monomeric silica from a supersaturated hot spring fluid upon discharge at the Earth’s surface was simulated. SAXS, DLS (and complementary cryo-TEM) data pertaining to changes in size and polydispersity of the nucleating and growing silica nanoparticles as a function of temperature, concentration and ionic strength will be discussed.
Methane hydrological cycle on Titan

T. TOKANO
Institut für Geophysik und Meteorologie, Universität zu Köln, Germany (tokano@geo.uni-koeln.de)

Saturn’s largest moon Titan is covered by a dense nitrogen atmosphere mixed with a few % of methane. Titan’s atmospheric condition allows the existence of methane in gaseous, liquid and solid phase analogously to water on Earth. Detection of several types of clouds in the lower atmosphere (e.g. Brown et al., 2002), dendritic features on the surface presumably carved by flowing liquid methane (Tomasko et al., 2005) and evidence of methane drizzle at the landing site of Huygens (Tokano et al., 2006) indicate that an active hydrological cycle of methane exists on present Titan. Methane in Titan’s atmosphere may play a similar role as water in Earth’s atmosphere in that it causes greenhouse effect, clouds, precipitation and geological features. However, several important differences to the terrestrial water cycle also became clear during the Cassini/Huygens mission. Titan lacks a global ocean, but the atmosphere contains a huge amount of condensable methane corresponding to a liquid layer of 5 m depth. Titan’s methane hydrological cycle is much more affected by chemistry than the terrestrial counterpart. Atmospheric methane has a net source (surface) and a net sink (photochemistry) on geologically short timescales. Models suggest that rainfall is only possible because nitrogen and ethane can be dissolved in liquid methane, suppressing the freezing point and slowing evaporation. Availability of ethane at cloud-forming altitudes relies on the ethane production by photochemistry. This paper gives a survey of Titan’s hydrological cycle, elucidating the role of chemistry and apparent analogies and differences to the terrestrial hydrological cycle.

Geochemical dynamics in an active margin of East Asia: Implications from the temporal and spatial geochemical evolution of magmatism in northern Kyushu, SW Japan

S. TOKESHI, K. KOBAYASHI, A. MAKISHIMA AND E. NAKAMURA.
The Pheasant Memorial Laboratory for Geochemistry and Cosmochemistry, Institute for Study of the Earth’s Interior, Okayama University at Misasa, Tottori, Japan (tokeshi@pheasant.misasa.okayama-u.ac.jp)

The margin of East Asia has been a locus for various tectonic events, having been affected by many arc-trench systems and back-arc basins. The upper mantle is expected to be complicated in physico-chemistry, reflecting the active tectonic environment. In order to decode the evolution of the upper mantle, clarification of the temporal and spatial geochemical variations in volcanic products is essential. Here, attention will be paid to Neogene non-subduction-related mafic volcanism in northern Kyushu, southwest Japan, ranging in age from ca 10 Ma to 0.5 Ma. The volcanism broadly has shifted eastward by ~150 km over time, and both alkali and sub-alkali lavas occur together. Their geochemical variations cannot be explained only by shallow processes such as fractional crystallization and crustal assimilation, and might reflect geochemical evolution of the upper mantle. Based on major and trace element abundances, the northern Kyushu volcanic rocks can be divided into three series: alkali basalt, sub-alkali basaltic rocks, and High Mg andesite (HMA). The alkali basalts in northern Kyushu have trace element distribution patterns similar to oceanic island basalts (OIB), suggesting asthenospheric sources within the convecting upper mantle. The sub-alkali basaltic rocks and HMA in northern Kyushu have incompatible element ratios that differ from OIB. Their compositions range from OIB-like patterns moderately depleted in HFS elements to strongly depleted patterns. These geochemical variations are best interpreted as an indication of interaction of asthenospheric-derived alkali basaltic magma with two chemically distinct lithospheric mantle sources: one is characteristically more depleted in Sr-Nd-Hf isotopic compositions and the other is isotopically enriched in these isotopic compositions. The relative contributions of these lithospheric mantle sources have changed over time and space. Contributions to the western region change from enriched to depleted character, whereas in the east, it has related its enriched character. This suggests that involvement of these lithospheric mantles in the genesis of sub-alkali basaltic rocks and HMA may be related to Tertiary lithospheric thinning caused by asthenospheric upwelling. Furthermore, isotopic compositions of alkali basalt derived from the asthenosphere change systematically over time and space, possibly associated with the opening of the Sea of Japan and rifting of the northern part of the Okinawa Trough.
Dehydration behaviour of muscovite by in situ infrared microspectroscopy

KAZUYO TOKIWAI AND SATORU NAKASHIMA
Department of Earth and Space Science, Osaka University, 1-1 Machikaneyama-cho, Toyonaka-shi, Osaka 560-0043, Japan (ktokiwai@ess.sci.osaka-u.ac.jp)

Dehydration of hydrous minerals is one of the important elementary steps in the subduction processes. In this study, dehydration behaviour of muscovite was studied by in situ high-temperature IR microspectroscopy by using a heating stage.

Muscovite has an infrared absorption peak around 3620 cm⁻¹ due to stretching vibration of Al-OH. Changes with temperature of the OH band and its integral molar absorptivity were first investigated. The peak position of OH in muscovite showed a quasi-linear shift to lower wavenumber from 3627 cm⁻¹ at room temperature to 3618 cm⁻¹ at 500°C. Peak heights (absorbance) and areas (integral absorbance) were determined after a baseline correction on transmission spectra. Linear and integral molar absorptivities of OH in muscovite at room temperature were calculated by using a molar concentration of OH. Integral molar absorptivities of OH in muscovite decreased quasi-linearly from room temperature to 500°C (about 10% decrease).

Dehydration behavior of muscovite was then investigated at 750-875°C by using the same in situ IR microspectroscopy. Isothermal kinetic heating experiments at each temperature gave detailed decrease curves of the OH band area with time. These curves have been simulated by the 1st and 2nd order reactions or diffusion processes, and reaction rate constants, diffusion coefficients and activation energies were determined. Based on these results, dehydration mechanisms will be quantitatively discussed.

This novel in situ high-temperature IR microspectroscopic technique can be used to study dehydration behaviour of various hydrous minerals.

Hydrous aluminosilicate metasomatism in an intra-oceanic subduction zone: Implications from the Kurancali ultramafic-mafic cumulates within the Alpine Neotethys Ocean, Turkey

FATMA TOKSOY-KÖKSAL¹, ROLAND OBERHAENSLI² AND M. CEMAL GÖNCÜOGLU¹

¹Middle East Technical University, Department of Geological Engineering, Ankara, Turkey (ftkoksal@metu.edu.tr; mcgoncu@metu.edu.tr)
²University of Potsdam, Department of Geosciences, Potsdam, Germany (roob@geo.uni-potsdam.de)

The Kurancali ultramafic-mafic cumulate body, an allochthonous sliver in central Anatolia, is characterized by the presence of abundant hydrous phases as phlogopite and pargasite besides anhydrous phases as augitic diopside and plagioclase with accessory amounts of rutile, sphene, apatite, and calcite. Based on modes of the essential minerals, the olivine-orthopyroxene-free cumulates are grouped into six types as clinopyroxenite, clinopyroxenite with hydrous minerals and plagioclase, phlogopite, hornblende, layered gabbro, and diorite. Evidences from petrography and mineral chemistry suggest crystallization from a hydrous magma to form phlogopite with high Fe²⁺-Fe³⁺-Al⁶⁻-Ti, diopsidic-augite with high Ca-Al³⁻-Ti, Si-undersaturated pargasite with high Al⁴⁺-Ca-K-Na-Ti-contents and intercumulus plagioclase with a wide range of composition (an% = 40.61-98.58).

Whole-rock geochemical signatures of the cumulates including clinopyroxenite indicate that this hydrous magma is enriched in K, Rb, Ba, Sr, P, Th, U, and LREE, and depleted in HFSE (Nb, Ta, Zr, Hf, Ti), HREE, and is typical of subduction environment.

Petrographical, mineralogical and geochemical features of the cumulates show that this hydrous magma has high-K calc-alkaline affinity with slightly alkaline character, and infer a metasomatic origin. Our evidences imply that the metasomatizing component, modifying the composition of mantle wedge, is H₂O-, alkali-, carbonate-rich aluminosilicate melt which is likely to be derived from a subducted slab. We suggest that the metasomatic agents in subarc mantle lead to generation of the hydrous magma which produced the Kurancali cumulates in an intra-oceanic subduction zone during closure of the Izmir-Ankara-Erzincan branch of the Alpine Neotethys Ocean.
Trace Elements concentrations in apatites from the Sept-Îles Intrusive Suite – Implications for the genesis of nelsonites

N. TOLLARI1, S-J. BARNES1, H. NABIL2 AND R. A. COX1
1Université du Québec, Chicoutimi, Canada G7H 2B1, (ntollari@uqac.ca; sarah-jane_barnes@uqac.ca; richard_cox@uqac.ca)
2Consorem, Université du Québec, Chicoutimi, Canada G7H 2B1, hassan_nabil@uqac.ca

Cumulates of apatite and Fe-Ti oxides are formed during the later stages of crystallization in many layered intrusions. In some cases they occur as layers or lenses of nelsonite composed of about one third of apatite and two thirds of Fe-Ti oxides. Associated with nelsonite are troctolite or diorite enriched in oxides. Two different models have been proposed for the origin of these rocks. Both models suggest that a Fe-P-rich silicate liquid formed after considerable crystal fractionation of the mafic parental liquid. In the first model, Fe-Ti-oxide and apatite crystallize from this magma and accumulate on the crystal pile to form nelsonite. In the second model the silicate liquid splits into: a) an Fe-Ti-P liquid from which nelsonite forms and b) a SiO2-rich liquid.

We have investigated the whole rock and mineral compositions of nelsonites and associated rocks from the Sept-Îles Intrusive Suite, Quebec. In addition, we have determined the trace element concentrations of apatite in these rocks. Mass balance calculations show that apatite is the principle host for REE, Ca, U, Th and Sr in these rocks. To test the crystal accumulation model these trace elements were inverted to estimate the trace element composition of the magma at the time of apatite saturation. Mantle normalized trace element patterns of the estimated liquids are similar in shape to mantle normalized patterns from dykes believed to be feeders to the intrusion at this stratigraphic level. Apatite would not have been on the liquidus of magmas of the dyke compositions. A simulation (using PELE) was carried out in order to model crystallization of a magma derived from the dykes. The model mineral compositions and the trace element patterns including those of apatite match the observed compositions for Sept-Îles nelsonites and associated rocks. Thus we favour the crystal accumulation model for the formation of nelsonite and associated rocks.

Method of interpretation of in situ U-Pb zircon geochronology using data on melt and fluid inclusions

E.V. TOLMACHEVA1, T.E. SALTYKOVA1, N.G. BEREZHNAYA1, S.D. VELOKOSLAVINSKY2 AND S.A. SERGEEV1
1VSEGEI, Sredny pr. 74, 199106, St.-Petersburg, Russia (elena_tolmacheva@vsegei.ru)
2IGGP RAS, emb. Makarov, 2, St.-Petersburg, Russia, 199134 (sdj@sv1403.spb.edu)

In-situ U-Pb zircon geochronology is finding increasingly wide application and permits to define ages of separate zircon zones. Abundant evidence shows that zircons even from relatively simple in genesis rocks sometimes are zoned, and age values obtained from different zircon zones may vary in a wide range. Zircons from rocks formed in a result of different not related petrogenetic processes are much more complicated in structure, and their age values vary in more wide range. Obtained data should be interpreted in genetic terms: relations between dated zone and petrogenetic process which caused the origin of this zone should be emerged.

Mineralogical, cathodoluminescence and geochemical data are not always sufficient to obtain the reliable information on zircon genesis (1), and to locate the most perspective points for in-situ geochronology (2) as well. Cathodoluminescence data compared with optical data often provide insufficient information on zircon zoning, and substance being analyzed may be represented by mixture of several zircon zones. Cathodoluminescence images as a rule don’t reveal character of boundaries between neighbor zones: often it is not clear whether or not a margin of zone is corroded, suggesting break in zircon crystallization. Fluid and melt inclusions, areas of zircon recrystallization, zones, and fractures filled by fluid, which often distort analytical results, are not emerged on cathodoluminescence images as well. It is not quite evident that zircon core is on the surface of thin-section, or it is covered by a thin “layer” of a rim.

The most perspective features for reliable determination of zircon origin and hence for interpretation of obtained ages are direct genetic indicators – inclusions of mineral-forming environment represented by melt and fluid inclusions, which study allows distinguishing: zircons of magmatic and metamorphic origin (1); zircon of intrusive and volcanic origin (2); zircon zones, formed in result of a repeated metamorphism (3), igneous and sediment protolith origin (4). Optimal approach includes integrated study of melt and fluid inclusions from zircons and rock-forming minerals, comprehensive optical and cathodoluminescence data on zircons in a combination with their geochemical characteristics.
Helium isotope signatures in rocks, minerals, and related groundwater: Residence time of He in a sandstone – shale interlayering (Molasse Basin, N. Switzerland)

I. TOLSTIKHIN1, H.N. WABER2, H.H. LOOSLI3, I. KAMENSKY1, V. SKIBA1 AND D. NOVIKOV1

1Geological Institute, Kola Scientific Centre, RAS, Apatity
2Institute of Geological Sciences, RWI, University of Bern, Baltzerstrasse 1, CH-3012, Bern, Switzerland
3Physics Institute, KUP, University of Bern, Sidlerstrasse 5, CH-3012, Bern, Switzerland

In a rock-water system, an apparent residence time for He can be derived from the ratio of the He concentration in pore water to the He production in minerals given that 1) the rock-water system is at steady state and 2) the He flux from external sources is negligible. This second condition is crucial and needs to be assessed by the identification of the He sources in a given hydrologic environment.

In the Permo-Carboniferous shale – sandstone interlayering (PC-NCH; Molasse Basin, northern Switzerland) we investigated He and Ar isotopes and the parent element concentrations of whole rock samples and mineral separates. Shale and sandstone layers are similarly abundant in this ca. 800m thick low-permeability sequence.

In the shales, the parent elements U, Th, and Li are mainly concentrated in biotite, muscovite, clay minerals, and organic matter with ~95% of the produced He being lost from these phases. Hence, the 4He/3He ratio in the pore water can be assumed to be similar to that of the in situ production (1.3x10^7), provided that there is no external influx of He. Groundwater in the bounding aquifers has almost equal 4He/3He ratios (Pearson et al., 1991) so that such an external source can be excluded. This is also supported by the 40Ar/36Ar ratios.

Quartz, plagioclase and microcline have ratios of ~1 of measured 4He to mineral-produced 4He, and 4He/3He ratios are identical with those of the bulk rock (1.3x10^7). The low Li-content of these minerals cannot account for such ratios and they must have trapped their He from the pore water. This is supported by the higher 3He (~30x) and 4He (~4x) contents obtained for quartz and plagioclase of the sandstones compared to their production capacity. This further suggests that these minerals trapped He that was generated in the shales and migrated via the pore water into the sandstones.

Measurements of the migration of He-atoms through quartz crystals showed that equilibrium between internal (gas-fluid vesicles) and external He-concentrations is achieved during ~10 Kyr under PC-NCH temperature (70°C). By applying this new approach to constrain He isotope concentrations in pore waters across the entire PC-NCH cross section, similarly high concentrations were obtained, suggesting long He residence times in the order of tenth of millions years in the PC-NCH.

Distribution of mercury in soil near Idrija mercury mine, Slovenia

T. TOMIYASU1, A. MATSUYAMA2, R. IMURA1, M. HORVAT3, J. KOTNIK3, D. KOČMAN3 AND V. FAJON3

1Faculty of Science, Kagoshima University, Japan.
(tomy@sci.kagoshima-u.ac.jp)
2National Institute for Minamata Disease, Japan.
(matuyama@nimd.go.jp)
3Department of Environmental Sciences, Institute Jožef Stefan, Slovenia. (milena.horvat@ijs.si)

The distribution of mercury in soil near Idrija mercury mine was investigated. Soil samples were collected from 4 locations along the Idrija River. Location 1 is upper reaches of the mine and 2 is the nearest point of the mine. Locations 3 and 4 are 5 and 10 km lower reaches of the mine, respectively. At each location, soil samples were taken by core sampler at interval of ca. 30 m from the riverside toward a hill perpendicular to the river. The individual core samples were separated with layer and used for determination.

T-Hg in soil was determined by CVAAS after wet digestion at 230°C using H2SO4-HNO3-HClO4 mixture. For MeHg determination, soil samples were treated with KOH-ethanol solution and MeHg eluted in the liquid was extracted with toluene as dithizonates and determined by GC-ECD. Chemical composition of soil samples was determined by WD-XRF.

T-Hg in surface soil ranged 0.8 to 480 mg kg⁻¹ (dry basis) and the highest value was observed in location 2. The surface T-Hg concentration tended to decrease with distance from the river toward hill, which suggests the main source of Hg in study area is the transported Hg with river from the mine. The vertical variation of T-Hg in location 4 suggests a recent dispersion of Hg, in which the surface soils at 1st and 2nd points from the river showed the lowest concentration of Hg, while at 3rd and 4th points the highest concentration was observed at the soil surface and the value decreased with depth. MeHg concentration ranged 0.8 to 16 µg kg⁻¹ (dry basis) and the lowest value was observed at location 2. The MeHg % of T-Hg in surface soil increased with the distance from the riverside toward hill. From the observations, it was suggested that the dispersed mercury from river is subject to methylation in the forest area. The dispersion of Hg was also discussed with the results of XRF determination.
A snapshot of mantle metasomatism?

E.L. TOMLINSON1, A.D. BEARD2 AND J.W. HARRIS3

1Department of Geology, Royal Holloway University of London, Egham, Surrey, U.K. (e.tomlinson@gl.rhul.ac.uk)
2Department of Earth Sciences, University College London, Gower Street, London, U.K. (a.beard@ucl.ac.uk)
3Division of Earth Sciences, University of Glasgow, Lilybank Gardens, Glasgow, U.K. (Jeff.Harris@ges.gla.ac.uk)

A set of fibrous diamonds from the Panda kimberlite (Canada) contain coexisting fluid (H2O-carbonate-KCl) and single-phase silicate (olivine, garnet, clinopyroxene) inclusions. These samples have preserved a snapshot of a natural mantle system at >4 GPa and >900°C. The silicate inclusions have fertile compositions (low Mg#, high CaO); however moderate to high Cr2O3 and Ni contents indicate that this apparent fertility is due to a secondary process - metasomatism by the concomitant fluid [1]. We present trace element data for the fluid (LA-ICP-MS) and mineral (SIMS) inclusions and investigate partitioning between, and the compositional evolution of, the fluid and mineral components. The trace element composition of the fluid is very similar to the Panda kimberlite, except for enrichments in Ba and Th, and a steeper REE pattern (La/Nd = 3 to 8). We will also investigate the possibility of a relationship between metasomatism and kimberlite petrogenesis.

Spatial variability in the release of terrigenic He from the sediments of Lake Van (Turkey)

YAMA TOMONAGA1, MATTHIAS S. BRENNWALD1 AND ROLF KIPFER1,2

1Swiss Federal Institute of Aquatic Science and Technology (Eawag), Duebendorf, Switzerland (tomonaga@eawag.ch)
2Isotope Geology, Swiss Federal Institute of Technology (ETHZ), Zurich, Switzerland

Recent analytical progress let for the first time 3H and He profiles in the pore water of lacustrine and oceanic sediments to be analyzed, which allows to determine local He fluxes. This method provides a simple and direct approach to study the He emanation on small spatial scales.

The He profiles measured in 13 sediment cores from Lake Van (Turkey) suggest that the He release from the sediments into the open water mainly occurs in the deep basin of the lake, which seems to be formed by an ancient caldera. The actual isotope signature of the terrigenic He accumulating in the open water body indicates that this He is of mantle origin (3He/4He ~ 10^-5). Furthermore, the He isotope ratios in the open water and in the sediment pore water suggest that there are at least two geochemical reservoirs, which both inject isotopically light, but different He into the lake.

The fact that the He found in the sediment samples has a heavier isotope signature than the source of the water body indicates that the sampled sediment cores do not carry that component that is relevant for the He emanation in Lake Van. Therefore we conclude that He that accumulates in the open water body has to emanate at sites where no cores were taken. Our noble gas results and the 3H measurements from the pore water of 3 additional cores show that the He emanation occurs very heterogeneously (~10 km) in the spatial domain of the tectonic active region of Lake Van.

Advances in computational chemistry afford the capacity to predict quantitatively Mg isotope fractionations among high-temperature geological materials. High-precision MC-ICPMS measurements in turn provide the opportunity to test these predictions in well-characterized samples. We present new high-precision 25Mg/24Mg and 26Mg/24Mg measurements of mantle minerals and compare these ratios with predictions for temperature-dependent inter-mineral fractionations. Results show that systematic fractionations among minerals in high-temperature rocks are resolvable and are broadly consistent with theoretical predictions. Our first target was a spinel lherzolite from the San Carlos Arizona volcanic field. The crystal chemistry of the Cr-rich spinels from these mantle rocks suggests equilibration temperatures of between 800 and 820 ± 60°C (Uchida et al. 2005).

Analyte Mg was extracted from olivine (ol), spinel (sp), and clinopyroxene (cpx) mineral separates and purified using a two-column (AG50W-X12) cation exchange technique. Isotope ratios were measured using dry plasma and sample-standard bracketing to correct for instrumental mass bias.

Our initial analyses yield olivine δ25Mg and δ26Mg values of −0.079 ± 0.008 and −0.151 ± 0.011‰ (1σ), respectively, consistent with, but not identical to, previous measurements (Young and Galy 2004; Wiechert and Halliday 2007). Spinel δ25Mg and δ26Mg values are +0.333 ± 0.017 and +0.640 ± 0.025 ‰, respectively, and clinopyroxene δ25Mg and δ26Mg values are +0.117 ± 0.066 and +0.207 ± 0.011 ‰, respectively. The fractionations between sp, ol, and cpx have been estimated using density functional perturbation theory (Schauble et al., this meeting). Comparison of the measured sp-ol fractionation (A26Mgsp-ol = 0.79 ± 0.03) with these predictions yields a temperature of 835 ± 40°C, in good agreement with previous estimates. The cpx-ol fractionation yields lower T of 355 ± 20°C, suggesting disequilibrium or systematic errors involving the cpx predictions.

Determination of 33 elements in kimberlites from South Africa and China by ICP-MS

C. TOOYAMA1, Y. MURAMATSU1, J. YAMAMOTO2 AND I. KANEOKA3

1Department of Chemistry, Gakushuin University, Japan (chi-ki.blue.blue@hotmail.co.jp, yasuyuki.muramatsu@gakushuin.ac.jp)
2Institute for Geothermal Sciences, Kyoto University, Japan
3Earthquake Research Institute, University of Tokyo, Japan

In order to understand chemical characteristics of kimberlites from different areas we have determined 33 elements in 21 samples collected from South Africa and China (Shandong and Liaoning) by ICP-MS (inductively-coupled plasma mass spectrometry).

Homogenized samples (50mg) were decomposed with HNO3, HF and HClO3 in a teflon bomb. After dilution with HNO3 (2%), the elements such as Na, Mg, K, Ca, Sc, Cr, Nb, Sr, Y, Nb, Mo, Cs, Ba, REE, Ta, W, Th and U were measured by ICP-MS. For I and Br, samples (200mg) were heated in a quartz tube and evaporated I and Br were collected in a trap solution. They were measured by ICP-MS.

Concentrations of incompatible elements such as light REEs, Th, U, Ba and Hf were highly enriched in kimberlite samples compared to other ultramafic rocks, suggesting the small degree of partial melting in the formation of kimberlite magma. The Th/U ratios in the samples, with a special reference to the Chinese samples, were much higher than that in other common igneous rocks. The I/Br ratio of samples from China showed a significantly lower value than that in South African samples.

The chondrite-normalized REE patterns of the kimberlites from South Africa (11 samples), Shandong (5 samples) and Liaoning (5 samples) are shown in Fig.1, as their average values. It was found that light REEs were strongly enriched in all samples, whereas the levels of heavy REEs were very low. A marked difference was found between the concentrations of heavy REEs in two Chinese regions, i.e. the value in Shandong was much lower than that in Liaoning. The average REE patterns obtained for South Africa and Liaoning were very similar.

Figure 1: The chondrite-normalized REE patterns of the kimberlites
**Textural evolution of metal and sulphide in H-chondrites: Constraining parent-body structure**

M. J. TOPLIS, J. GUIGNARD, D. BARATOUX AND M. MONNEREAU
DTP-UMR5562, Observatoire Midi-Pyrénées F-31400, Toulouse, France

H-chondrites are samples of a single asteroidal parent body which show evidence for variable degrees of heating. The least "metamorphosed" members of the H-chondrite clan (H3) are mixtures of various components, clearly out of chemical and textural equilibrium. While the mineralogical and compositional effects of progressive heating have been studied in the literature, textural equilibration has received far less attention. We have therefore studied the textural characteristics of metal and sulfide in a series of H-chondrites (H4, 5, 6). These results provide constraints on the structure and thermal evolution of the parent body and have implications for the onset of processes leading to core segregation.

We have quantified: i) metal and sulfide proportions as a function of metamorphic grade; ii) the length of metal-sulfide contacts; iii) dihedral angles at silicate-silicate-metal/sulfide contacts; iv) the shape of metal/sulphide grains (circularity); v) the crystal size distribution (CSD) of metal and sulfide grain populations.

Proportions of metal and sulfide are independent of metamorphic grade, but the length of sulfide-metal contacts decreases significantly with increasing grade (metal and sulfide grains separate). Dihedral angles, grain circularity and CSD's for metal grains show little change between H4 and H5, but show significant changes between H5 and H6. These results may be rationalized in terms of textural equilibration and ripening involving diffusion. Published values for the temperature dependent diffusion coefficient of Fe in olivine have been combined with the results of thermal models describing the temperature-time paths at different depths within a parent body 180km in diameter heated internally by Al26. Comparison of the modeled length scales of Fe-diffusion relative to the average separation of metal droplets implies that the H5 samples come from a depth approximately 30km below the surface, in excellent agreement with independent estimates based upon peak metamorphic temperatures and Pb-Pb dating.

**U-Th, δ18O and paleomagnetic dating of a mid-Pleistocene lacustrine sequence: The Amora Formation, Mount Sedom, Israel**

A. TORFSTEIN 1,2, A. HAASE-SCHRAMM 3,4, N. WALDMANN 1,5, Y. KOLODNY 1 AND M. STEIN 2

1Institute of Earth Sciences, The Hebrew University, Israel (aditorf@pob.huji.ac.il, Kolodny@vms.huji.ac.il)
2Geological Survey of Israel, Israel (motis@vms.huji.ac.il)
3Max-Planck Institut für Chemie, Mainz, Germany
4GEOMAR, Forschungszentrum für marine Geowissenschaften, Kiel, Germany (ahaase@ifm-geomar.de)
5Department of Geology and Paleontology, University of Geneva, Switzerland (waldmann@terre.unige.ch)

Dating of mid-Pleistocene carbonate sediments may be possible with the 230Th-234U and 234U-238U methods, yet, analytical uncertainties and problems of open system and presence of detrital material and initial Th hamper the dating of samples older than 200-300 kyr. Here, we present a combined approach that utilizes the U and Th isotopes with floating δ18O stratigraphy and paleomagnetic constraints, and establish a high-resolution chronology of the mid to upper Pleistocene Lake Amora in the Dead Sea basin.

The application of the δ18O record as a floating chronometer is based on the correlation found between δ18O values of synchronously deposited upper-Pleistocene and Holocene lake sediments, East Mediterranean foraminifers and Judean Mountain speleothems (Kolodny et al., 2005). The lacustrine Amora Formation consists of laminated aragonite and detritus, Ca-sulfate minerals, halite and clastic units. The sediments were deposited in the lacustrine environment of the paleo-Dead Sea basin and were later uplifted and tilted by the rising Sedom diapir, exposing ~330 m of the formation on the eastern flanks of Mt. Sedom.

δ18O values range between 6.0 and ~1.0‰, shifting periodically between glacial and interglacial sequences throughout the sedimentary section, marking corresponding shifts in the global marine records. Paleomagnetic data indicate the entire section was deposited after the 780 ka Matuyama-Brunhes magnetic transition.

Data compilation renders the age of the base of the exposed Amora Fm. to be ~750 to 700 ka BP (MIS 18 to 17), and the age of its capping sediments to be between ~200 and 130 ka BP (MIS 6 and the transition to MIS 5). Climatic-limnologic shifts throughout the sedimentation period are recorded by the lithological, chemical and isotopical properties of the sediments, and are correlated to global and regional events.

Ancient subduction recorded in the isotope characteristics of ~1.8 Ga Fennoscandian carbonatites

O. A. TORPPA AND J. A. KARHU
Dept. of Geology, University of Helsinki, Helsinki, Finland
(akseli.torppa@helsinki.fi)

The Svecofennian ~1.8 Ga post-collisional magmatism in the Fennoscandian Shield gave rise to a suite of high-Ba-Sr granites and shoshonitic lamprophyres interpreted to originate from a metasomatically enriched lithospheric mantle (Eklund et al., 1998, Andersson et al., 2006). In southern Finland the bimodal suite is accompanied by rare occurrences of intrusive carbonatites showing distinctively low δ13C values relative to that of average mantle carbon at around -5 ‰ (PDB). Carbonate samples from a carbonatite dike at Halpanen show δ13C values varying from -12.2 to -12.4 ‰ (n=7) while those from a carbonatite dike swarm at Panjavaara display an even stronger depletion in 13C, with values ranging from -15.3 to -16.5 ‰ (n=50).

The Halpanen carbonatite is a 10 m wide and up to 1.5 km long alvikite dike located in southeastern Finland some 200 km NE of Helsinki. The chemical composition of the dike is characterized by high contents of SrO, BaO, and REE (up to 3.63, 0.63 and 0.65 %, respectively). The Panjavaara carbonatite dike swarm is located some 180 km NE of Halpanen and comprises >50 carbonatite dikes and vein-dikes measuring 2 – 60 cm in width and from meters to tens of meters in length. The carbonatites of the Panjavaara dike swarm are also highly enriched in SrO, BaO and REE, with concentrations reaching 2.3, 3.9 and 10.0 %, respectively. Conventional U-Pb dating on monazite suggests an emplacement age of ~1.8 Ga for both the Halpanen and Panjavaara carbonatites. The Sr and Nd isotope data indicate an age of ~1.8 Ga for both the Halpanen and Panjavaara carbonatites.

The chemical characteristics of the studied ~1.8 Ga Fennoscandian carbonatites suggest a metasomatically enriched mantle source for these rocks. The depletion in 13C relative to the average mantle value could be related to subduction of organic-rich crustal material. In comparison to other carbonatites, the Halpanen and Panjavaara are notably depleted in 13C. Equally low δ13C values have been, however, reported for many eclogitic diamonds (e.g., Shirey et al., 2002).

Anaerobic nitrate-dependent oxidation of pyrite mediated by Thiobacillus denitrificans

C. TORRENTÓ1, G. SOUTHAM2, J. URMENETA3, J. CAMA1 AND A. SOLER4

1Institute of Earth Sciences “Jaume Almera”, CSIC, Lluís Solé i Sabaris s/n, 08028, Barcelona, Spain
(torrento@ija.csic.es)
2Department of Earth Sciences, University of Western Ontario. London, Ontario, Canada
3Department of Microbiology, Faculty of Biology, University of Barcelona, Spain
4Department of Mineralogy and Mineral Deposits, Faculty of Geology, University of Barcelona. Spain

Introduction

NO3 reduction in nitrate-polluted groundwater may result from oxidation of organic matter and/or pyrite present in the aquifer rock. Although no direct laboratory proof exists that nitrate can serve as a pyrite oxidant under abiotic conditions, several field studies have provided indirect evidence for pyrite oxidation by NO3 mediated by autotrophic denitrifying bacteria. The present laboratory experiments are directed towards studying the mechanism and kinetics of water denitrification and pyrite oxidation, being mediated by Thiobacillus denitrificans.

Results and discussion

Anaerobic, nitrate-dependent dissolution of pyrite mediated by Thiobacillus denitrificans was studied by means of percolation-columns filled with pyrite powder and pyrite cubes run for 8 weeks. Input solution (thiosulfate-free specific medium for T. denitrificans growth) was supplied to the columns at a flow rate of 1 mL day-1 and the leachate was sampled once a week. Reacted samples after 1, 2, 4 and 8 weeks were examined by SEM-EDX and ex situ AFM.

Pyrite dissolution was confirmed by sulfate release to solution and nitrate reduction. Release of sulfate and iron to the solution was lower than that stoichiometrically predicted by the overall reactions:

\[ \text{NO}_3^- + 5 \text{FeS}_2 + 4 \text{H}^+ \rightarrow 7 \text{N}_2 + 10 \text{SO}_4^{2-} + 5 \text{Fe}^{2+} + 2 \text{H}_2\text{O} \]

\[ \text{NO}_3^- + 5 \text{Fe}^{2+} + 6 \text{H}^+ \rightarrow \frac{5}{2} \text{N}_2 + 5 \text{Fe}^{3+} + 3 \text{H}_2\text{O} \]

After 8 weeks precipitation of secondary minerals (ones rich in Fe(III), S and K and others rich in P and Ca) over the pyritic surfaces was detected by EDX analyses. SEM and AFM images revealed that bacteria cells were attached to surface of pyrite fragments and grains, sparsely distributed, and that the surface roughness increased throughout the experiments. Secondary minerals and organic matter coating the surface did not prevent bacterial metabolism and consequent nitrate reduction.

Although T. denitrificans is capable of catalyzing complete reduction of nitrate to nitrogen gas, over most of the entire experimental run nitrate mostly reduced to nitrite and production of gaseous compounds were not evident.
Application of the Pitzer ion interaction model to the Fe$_2$(SO$_4$)$_3$-H$_2$SO$_4$-H$_2$O System

N. J. TOSCA, A. SMIRNOV AND S. M. MCLENNAN

Department of Geosciences, State University of New York at Stony Brook, Stony Brook, NY 11794-2100 USA

Ferric iron-bearing acid sulfate systems are important to a variety of industrial and surficial environments, specifically areas affected by acid mine drainage (AMD). Accurately describing the thermodynamic properties of such highly concentrated waters has been hindered mainly by the lack of experimental data for the Fe$_2$(SO$_4$)$_3$-H$_2$SO$_4$-H$_2$O system. However, with the recent availability of isopiestic measurements yielding solvent activities for [Fe$_2$(SO$_4$)$_3$-H$_2$SO$_4$] mixtures [1,2], the Pitzer ion interaction model may be applied and used as an additional tool in describing the equilibrium state of many natural systems. Hydrolysis at low pH and the importance of sulfate-bisulfate equilibria present complications in applying the Pitzer approach to the Fe$_2$(SO$_4$)$_3$-H$_2$SO$_4$-H$_2$O system. Here, we describe the application of an extended Pitzer model based upon the Clegg et al. [3] model for H$_2$SO$_4$(aq). The model fits available isopiestic data for [(1-y)Fe$_2$(SO$_4$)$_3$-yH$_2$SO$_4$] mixtures to 3.00 molal and 0.0435 \( \leq y \leq 0.9370\). A slightly less accurate representation of a more extended molality range to 5.47 molal extends over the same y values. A more limited isopiestic dataset at 323.15 K is also analyzed with the Pitzer model. Available solubility data are examined using a recent calorimetric study of ferricopiapite and rhomboclase. We also discuss some examples of model applications to geochemical problems in AMD environments. The resulting Pitzer model provides an important step toward a more detailed picture of Fe-sulfate mineral stability in AMD systems. In turn, controls on the cycling of acidity and toxic metals in AMD environments may be better predicted and identified.

Dept. of Chemistry and Biochemistry, Univ. of Maryland, College Park, MD 20742 USA (tossell@umd.edu)

Since the chemical and biological reactivity of As sulfides depends strongly upon their speciation, it is important to determine exactly what species are present within a given environment. Spectral probes such as Raman and UV can give partial information about speciation, but uncertainties and ambiguities generally remain. We are engaged in a program to perform state-of-the-art quantum mechanical studies of the structures, stabilities, spectra (Raman and UV) and acidity of As sulfide species in aqueous solution. We typically use very high level methods, such as CCSD with triple zeta, doubly polarized basis sets for the gas phase part of the calculation, and a lower-level polarizable continuum or nanocluster approach to simulate the effect of hydration. Anharmonic vibrational effects are calculated using 2nd order perturbation theory within a HF – DFT hybrid method. Using this approach we can accurately reproduce the Raman spectra of thioarsenious acid, As(SH)$_3$, and its conjugate bases. The Raman spectra of As(SH)$_3$ is also reproduced with errors of less than 10 cm$^{-1}$ and the As–O(H) distances with errors of only 0.02 Å. Such calculations establish that the neutral species in arsenious acid solutions is indeed As(SH)$_3$ rather than HAsO$_2$. This assignment is also supported by our calculated UV spectra. However, accurate calculation of the Raman spectra of the conjugate bases of As(SH)$_3$ requires the inclusion of both explicit waters and counterions. Trends in the acidity of As acids with changing oxidation state, ligand and degree of protonation are well reproduced, but accurate absolute values for the oxidic species are elusive. Possible reasons for the overestimation of pKas for the oxidic species are presented. We have established computationally that the conjugate bases of As(SH)$_3$ are susceptible to sulfidation by H$_2$S, while As(III) sulfides such as AsS(SH)$_2$– are susceptible to oxidation to As(V) by elemental sulfur or polysulfides. By contrast the addition of H$_2$S to AsS(SH)$_2$– to form As(SH)$_3$– is calculated to be unfavorable. We can thus generate a comprehensive picture of speciation based upon direct quantum mechanical calculation of a number of properties for possible candidate species.
Hf-W constraints on the formation and differentiation of the Moon

M. TOUBOUL\textsuperscript{1}, T. KLEINE\textsuperscript{1}, B. BOURDON\textsuperscript{1}, H. PALME\textsuperscript{2}, AND R. WIELER\textsuperscript{1}

\textsuperscript{1}Institute for Isotope Geochemistry and Mineral Resources, ETH Zürich, Clausiusstrasse 25, 8092 Zürich, Switzerland (touboul@erdw.ethz.ch)
\textsuperscript{2}Institut für Mineralogie und Geochemie, Universität zu Köln, Zülpicherstr. 49b, 50674 Köln, Germany.

Hf-W chronometry is well suited to investigate the timescales of early lunar differentiation because Hf/W ratios are variable amongst the products of the lunar magma ocean \cite{1,2}. Application of Hf-W chronometry to lunar whole-rock samples however is hampered by the production of \textsuperscript{182}W via neutron-capture of \textsuperscript{181}Ta during prolonged cosmic-ray exposure of the lunar surface \cite{3}. Almost all lunar samples contain some metals, which contain virtually no Ta and hence no cosmogenic \textsuperscript{182}W. The age of magma ocean crystallization has been derived from the W isotope composition of lunar samples \cite{4}. Almost all lunar samples contain some metals, which contain virtually no Ta and hence no cosmogenic \textsuperscript{182}W. The age of magma ocean crystallization has been derived from the W isotope composition of lunar samples \cite{4}. All lunar metals contain some metals, which contain virtually no Ta and hence no cosmogenic \textsuperscript{182}W. The age of magma ocean crystallization has been derived from the W isotope composition of lunar samples \cite{4}. Here we present new W isotope data for metals from a comprehensive set of lunar samples. Our new data are significantly more precise than most of the earlier data, mainly because we processed \approx 4 times more material than was used in earlier studies \cite{1,4,5,6}. All lunar metals separated from KREEP-rich samples, low- and high-Ti mare basalts have indistinguishable \textsuperscript{182}W/\textsuperscript{184}W ratios, which are identical to those previously reported for KREEP \cite{4}. In contrast to earlier studies \cite{4,7} we do not find systematic variations in the \textsuperscript{182}W/\textsuperscript{184}W ratios of lunar samples, despite the large variations in Hf/W ratios of the source areas. This indicates that solidification of the lunar magma ocean continued until after the effective life-time of \textsuperscript{181}Hf (i.e., \approx 60 Myr) and might have continued until \approx 200 Myr, as indicated by \textsuperscript{146}Sm-\textsuperscript{142}Nd systematics \cite{5,6}. Our new data reveal that the lunar and terrestrial mantles have indistinguishable W isotope compositions, which could indicate that the Moon mainly consists of material derived from the Earth's mantle. This however is inconsistent with constraints from dynamical simulations of the giant impact. Alternatively, W isotopes re-equilibrated during the giant impact, as has been proposed to account for the similarity in O isotope composition of the Earth and Moon \cite{8}. Whether this process can effectively equilibrate W isotopes remains to be investigated.

Dynamic metal speciation analysis by stripping chronopotentiometry at scanned deposition potential (SSCP)

\textsc{Raewyn M. Town\textsuperscript{1} and Herman P. van Leeuwen\textsuperscript{2}}

\textsuperscript{1}Institute for Physics and Chemistry, University of Southern Denmark, Campusvej 55, DK-5230 Odense, Denmark (rm@ifk.sdu.dk)
\textsuperscript{2}Laboratory of Physical Chemistry and Colloid Science, Wageningen University, Dreijenplein 6, 6703 HB Wageningen, The Netherlands (Herman.vanLeeuwen@wur.nl)

In the broad context of stripping voltammetric techniques, the depletive mode of stripping chronopotentiometry, SCP, has fundamental advantages for metal speciation analysis. Complete voltammetric potential-current curves are inherently rich in information content: as measurements are made from the foot of the wave to the limiting deposition current region the relevant part of the stability distribution and corresponding parts of the rate constant distribution are scanned. Conventional DC steady-state voltammetry lacks the necessary sensitivity for measurements at environmentally relevant concentrations, however analogous curves, denoted as SSCP waves, can be constructed by plotting the magnitude of the SCP stripping peak as a function of deposition potential. Analogous to the Deford-Hume expression for voltammetric waves, speciation parameters derive from the change in half-wave deposition potential that occurs on complexation, and the magnitude of the limiting plateau. The distinctive features of SSCP include (i) an effective getting around part of the Nernstian extension of the reoxidation process, leading to (ii) greater resolution than conventional stripping voltammetries, (iii) a certain insensitivity to electrochemical irreversibility, especially at a microelectrode, (iv) practically freedom from induced metal ion adsorption interferences, (v) no requirement for excess ligand during stripping, and (vi) ability to provide a certain unambiguous measure of any chemical heterogeneity in the metal speciation. In case of kinetic currents, i.e. systems with limited association/dissociation rates, invoking the Koutecky-Koryta approximation allows a rigorous expression to be obtained for the full SSCP wave. These features are illustrated by practical examples.

Thermal events documented in Hadean zircons by ion microprobe depth profiles

D. TRAIL1,2, S.J. MOJZIS1 AND T.M. HARRISON3

1Geological Sciences, University of Colorado, UCB 399, Boulder, Colorado 80309-0399 USA (mojzsis@colorado.edu)
2Earth & Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY 12180, USA (trail@rpi.edu)
3Earth & Space Sciences, IGPP, University of California, Los Angeles, California 90095-1567 USA (tmh@argon.ess.ucla.edu)

We report the first U-Th-Pb ion microprobe depth profiles for four Hadean zircons from the Jack Hills and Mt. Narryer supracrustal belts of the Narryer Gneiss Complex (NGC), Western Australia. This ultra-high spatial resolution technique probes the age and origin of sub-micron features in individual crystals that can record episodes of zircon growth. Near-surface grain dates 2700 Ma or older are coincident with post-depositional growth/modification. Some ages may coincide with documented pre-deposition metamorphic episodes for the NGC and igneous emplacement at ca. 3700 Ma. Separate events that do not correlate in time with known geologic episodes prior to the preserved rock record are also present within pre-4000 Ma zircons. We find evidence for a ~3.9 Ga event (Fig. 1), which is coterminous within age uncertainty with one or several large basin-forming impacts (e.g. Nectaris) on the Moon and attributed to the late heavy bombardment of the inner solar system.

Figure 1. Example depth profile data for a 4.18 Ga zircon from Mt. Narryer, Western Australia.

Chemical heterogeneity in the mantle: Inferences from seismology and mineral physics

JEANNOT TRAMPERT

Department of Earth Sciences, POBOX 80021, 3508 TA Utrecht, NL (jeannot@geo.uu.nl)

The first claims by geophysicists of significant chemical heterogeneity in the lower 1000 km of the mantle were made about 15 years ago. I will briefly review the evolution of ideas, which were mainly based on results from classical tomography. Classical inversion methods, however, are not free of caveats which can make interpretations ambiguous. Probabilistic tomography, on the other hand, allows to infer robust probability density functions (pdfs) for long wavelength models of bulk-sound and shear wave speed, density and boundary topography in the mantle. Using appropriate depth-dependent sensitivities, these pdfs can be converted into likelihoods of variations in temperature, perovskite and iron content throughout the mantle. The sensitivities are calculated using full uncertainties in mineral physics data and, more importantly, in the thermo-chemical reference state of the mantle. We find that bulk-sound speed (density) variations are an excellent proxy for perovskite (iron) variations, and that shear-wave speed is not highly correlated to temperature as is often assumed. Compositional variations are found to be essential to explain the seismic, gravity and mineral physics data. In particular, the regions of low shear-wave velocity in the deep mantle (> 2000 km) beneath Africa and the Pacific, usually referred to as super plumes, are mainly due to an enrichment in iron, which makes them denser than the surrounding mantle. We performed comparisons with some chosen models of thermo-chemical convection. A stable and ubiquitous layer of dense material is unlikely to be present at the bottom of the mantle. Models of piles entrained upwards explain the observations significantly better.
Shock effects in quartz: compression versus shear deformation – An example from the Rochechouart impact structure, France

CLAUDIA A. TREPMMANN
Institut für Geologie; Mineralogie und Geophysik; Ruhr-Universität Bochum; D-44780 Bochum; SFB 526 (claudia.trepmann@rub.de)

The effects of the shock wave-associated stress resulting from a large meteorite impact are recorded in the microstructures of naturally shocked rocks. Quartz is especially useful to provide information on the stress conditions during shock, given the widespread occurrence of this mineral in the Earth's crust and its comprehensive experimental calibration. This study compiles effects in quartz resulting from compression due the high shock pressure, which is as a first approximation the mean stress of the shock wave-associated stress tensor, and from shear deformation due the high differential stresses during shock in target rocks and impact breccias from the Rochechouart impact structure. Microstructures that result from compression/decompression are pockets of new quartz grains surrounded by intensely shocked quartz (Fig. 1) that shows intense mosaicism, as indicated by TEM analysis. This microstructure suggests that it formed by annealing of diaplectic glass. A high density of very fine rhomboedral planar deformation features (PDFs) that can merge into a mosaicism structure in TEM is common in shocked quartz from the Rochechouart impact breccia. These features indicate high shock pressures (20-35 GPa). Shock effects in quartz that record shear deformation are mechanical Brazil twins and planar fractures. These shock effects indicate high differential stresses on the order of a few GPa. Shock effects indicating high differential stress never occur together with those indicating high shock pressure. This suggests that the differential stresses at high shock pressure (>20 GPa), i.e. at high mean stress, are ineffective to cause shear deformation. Whereas at attenuated mean stress (<20 GPa) the differential stress gets relatively more effective.

Figure 1: Pockets of newly crystallised quartz surrounded by intensely shocked quartz.

Sediment-microbe interactions in permeable sediments at hydrocarbon seeps in the Santa Barbara Channel, California

T. TREUDE AND W. ZIEBIS
University of Southern California, Department of Marine Environmental Biology, Los Angeles, USA (treude@usc.edu)

Sediments of marine cold-seep areas exhibit high rates of hydrocarbon discharge and are unique dynamic systems with specific microbial communities connected to methane and/or oil degradation processes. Microbial activity in such systems is in general tightly coupled to advective transport mechanisms of fluids and hydrocarbons as well as to geochemical gradients in the sediment. Seeps in coastal shallow-water areas are, in contrast to deep-sea mud, characterized by sandy permeable sediments, thus enabling enhanced substrate exchange due to accelerated pore water transport processes. We investigated sandy sediments off Coal Oil Point (Santa Barbara Channel, California), one of the world’s largest hydrocarbon-seep area, to study the effect of pore water transport processes on microbial methane and sulfur turnover, biogeochemical gradients as well as microbial community structure. Our results show accelerated microbial activity of anaerobic oxidation of methane and sulfate reduction in areas where reduced fluids, rich in hydrocarbons, are seeping through highly permeable surface sediments. Vertical and horizontal biogeochemical parameters such as sulfide, oxygen, methane, and sulfate reveal gradients and small-scale distribution patterns that differ from cold-seep systems of the deeper oceans. We suggest that these gradients and the resulting microbial activity are a result of pore water transport processes, where the supply of substrates is not limited to diffusion. Our data indicate that fast substrate supply and removal of inhibitory end products is an important factor enabling efficient microbial consumption of methane in marine sediments.
Timing of protoplanetary disc dissipation and planetesimal formation in the early solar nebula

M. TRIELOFF
Mineralogisches Institut Universität Heidelberg, Heidelberg, Germany
(trieloff@min.uni-heidelberg.de)

The lifetimes of protoplanetary disks of 3-6 Ma [1] around young stars constrain the time scales of planetesimal formation. Most studies suggest that formation of asteroid-sized planetesimals in the early solar system occurred within a few Ma [e.g. 2-4], indicating that the building blocks of terrestrial planets were already present when the disk was dissipated. However, it is not yet clear, if full-sized terrestrial planets accreted within the presence of disk gas or not. While for the outer gas or ice giant planets rapid accretion and attraction of disk gas as major constituent is mandatory, the terrestrial planets obviously needed significantly longer time for complete accretion, as indicated by Hf-W ages of complete core formation of 10 Ma for Mars and 33 Ma for Earth [5]. The question if terrestrial planets accreted with the presence of gas or after disk dissipation can be answered using neon isotopes [6-10], particularly utilizing advances in high precision neon isotope measurements in recent years [11-14]. These results provide increasing evidence that Earth’s precursor planetesimals acquired solar neon as solar wind-implanted ions (“Ne-B”), similar to carbonaceous chondrite [15] or Rumuruti parent bodies. For the latter, thermochronological modelling [16-18] suggests very early brecciation and irradiation. Several irradiation scenarios are possible: 1) irradiation before disk gas dispersal, due to planetesimal orbits with high inclinations (possibly triggered by gravitational disturbances of Jupiter) 2) late accretion of fine, irradiated dust to Earth, e.g. after the moon forming impact 3) disk gas dissipation 3-4 Ma after CAIs in the inner solar system, possibly triggered by photoevaporation of the disk.

50Ti anomalies in primitive and differentiated meteorites

ANNE TRINQUIER, MARTIN BIZZARRO AND DAVID ULFBECK

Axiom laboratory, Geological Institute, Denmark

We analyzed relative 50Ti abundances in primitive and differentiated meteorites (whole-rock carbonaceous, ordinary, enstatite chondrites, eucrites, angrites, ureilites, SNCs, NWA 2976, Itqiy and silicates of mesosiderites) and terrestrial rock standards, in order to characterise possible correlations with neutron-rich isotopes of Ni and Cr and with O isotopic systematics of early Solar System objects. Chemical purification of Ti from meteorite matrices was achieved on anion exchange resin, with chemical yields in excess of 90% and total procedural blanks < 10 ng Ti. Ti isotopic ratios were determined by MC-ICPMS using the sample-standard bracketing technique, analysing each sample 5-12 times. The accuracy and precision of our analytical protocol were estimated through replicate analyses of terrestrial standards doped with a Ti isotopic tracer, yielding a long-term reproducibility for 50Ti/47Ti of 20 ppm (2sd).

Carbonaceous chondrites are characterised by 50Ti excesses, while ordinary chondrites record deficits. Except for NWA 2976, which shows a 50Ti excess identical to that of CR chondrites, all meteorites or iginating from differentiated planetesimals record 50Ti deficits. Enstatite chondrites have a terrestrial 50Ti abundance. The range of variation in 50Ti/47Ti between all meteorites studied here spans 0.7‰. We find that 50Ti anomalies correlate with 54Cr and 62Ni variations at the planetary scale [1-2], constraining the existence of two reservoirs in the early Solar System. Further, because neutron-rich isotopes are believed to be formed in old supernova sources rarely associated with young star-forming regions, the well-preserved correlated variations may represent residual heterogeneity inherited from the molecular cloud. In addition, neutron-rich and O isotopes [3] define two mixing trends among CC and OC-D that support two distinct origins for O and Ti isotopic heterogeneities.

4GEMOC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, Sydney, NSW 2109, Australia (hhandley@els.mq.edu.au)

Merapi, a large Quaternary volcanic complex situated within the active volcanic front of the Sunda arc in Central Java, is one of the most active volcanoes in Indonesia. Its recent activity is characterized by the extrusion of high-K basaltic andesite lavas forming lava domes in the summit area and intermittent gravitational or explosive dome failures generating small-volume pyroclastic flows that are a permanent threat to life within the densely populated areas on the flanks of the volcano.

During the Holocene, Merapi erupted basalts and basaltic andesites of medium-K affinity in the earlier stages of activity and high-K compositions from ~1900 years BP to the present. This increase in K2O is accompanied by a marked increase in whole-rock 87Sr/86Sr ratios, but not by systematic variations in δ18O values, which are relatively constant and slightly elevated compared with mantle values. Whole-rock trace element and isotopic characteristics suggest that mantle source contamination played a significant role in determining the geochemical characteristics of the parental magmas of the two magmatic series. Subsequent differentiation of these magmas during ascent and storage in the arc crust involved a complex interplay of fractional crystallisation, recharge, magma mixing and assimilation of carbonates from the subvolcanic basement. Whole-rock analysis of the crystal-rich Merapi rocks can only provide a blurred picture of these processes and open-system processes, such as crustal contamination, are often masked in the whole rock isotope ratios. Therefore, a more complete picture of these processes has been assembled by combining crystal isotope stratigraphy, petrological analysis of magmatic and crustal xenoliths hosted in recent Merapi deposits and stable isotope analysis of fumarole gases. These studies indicate that magma-crust interaction and late-stage crustal contamination are volumetrically significant and have important implications for magma evolution and, potentially, the eruptive behaviour at this high-risk volcano.
Petrological characterization and tectonic implications of multi-stage garnet crystallization in eclogitic rocks from the southern Tongbai region

CHIN-HO TSAI1, HANWEN ZHOU2 AND YOSHIYUKI IIZUKA3

1Institute of Earth Sciences, National Hualien University of Education, Hualien 970, Taiwan (tsai@mail.nhlue.edu.tw)
2Faculty of Earth Sciences, China University of Geosciences (Wuhan), PR China
3Institute of Earth Sciences, Academia Sinica, Nankang, Taipei 115, Taiwan

We report some newly-discovered eclogitic rocks within the blueschist-greenschist unit in the southern Tongbai region, central-eastern China. This region is the NW extension of the Dabie-Hongan UHP orogenic belt. No UHP rock or true eclogite has been reported from this unit yet. The studied eclogitic rocks occur as discontinuous boudins or pods enclosed within dolomite-bearing marble. The eclogitic rocks contain mainly garnet, quartz, omphacite (Jd33-43), amphiboles, carbonates, and accessory minerals. The rock is heterogeneous in terms of mineral mode and texture.

Three textural types of garnet have been distinguished: Type I is the largest in grain size and with abundant inclusions; Type II is the medium-size and with an inclusion-free core and inclusion-rich rim; Type III is the smallest and relatively more euhedral. On the basis of chemical zoning of Type I garnet and distribution of inclusions, two stages (core and rim) of garnet crystallization have been identified. Major element compositions show that the rim part is Ca-enriched, but Fe- and Mg-depleted, relative to the core part. The core-rim chemical boundary is sharp, and in some cases, it shows an indication of resorption. Inclusions in the core of the Type I garnet imply an early greenschist-facies stage, whereas those in the rim indicate an epidote-amphibolite to eclogite-facies stage.

The eclogite-facies assemblage includes garnet + omphacite + rutile + quartz + carbonate. Glauconephane in the matrix indicates a blueschist-facies stage postdating eclogite-facies. One unique feature of the eclogitic rock is the abundant titanite rods (lamellae or needle-like) across or within garnet grains. The host rock marble shows no evidence of high-pressure metamorphism. Thus the rock association may represent a tectonic mixture. In summary, the Tongbai eclogitic rocks in the blueschist-greenschist unit record part of a subduction history that was not previously recognized.

Crystalchemical aspects and polymorphism in post-perovskite

OLIVER TSCHAUNER1,2, BORIS KIEFER3 AND HAOZHE LIU4

1High Pressure Science and Engineering Center, Department of Physics, University of Nevada, Las Vegas, Nevada 89154, USA
2Division of Geology and Planetary Sciences, California Institute of Technology, Pasadena, California, USA
3Department of Physics, New Mexico State University, Las Cruces, New Mexico, USA
4HPCAT, Advanced Photon Source, Argonne National Laboratory

We synthesized post-perovskite phases of aluminous and ferrous-aluminous magnesiummetasilicate. Diffraction patterns and Raman spectra indicate marked structural deviations from the calculated CaIrO3-type structure of post-perovskite. Combined modelling of alternative post-perovskite structures based on sets of crystallite reflections spanning a reciprocal space lattice and on ab-initio calculations show our data to be consistent with postperovskite structures composed of kinked MgO- and SiO2-layers that have previously been proposed by Oganov, A.R. et al. (2005) Nature 438, 1142-1144. The transition to perovskite has been reversed in our experiments. These new phases appear to be intermittent between perovskite- and CaIrO3-type silicate. Kink density may correlate with chemical parameters and has a significant effect on the perovskite-kinked ppv phase boundary. Hence, the paragenesis of deepest mantle rock may be markedly different for depleted mantle and eventual enriched or primitive reservoirs.

$^{87}$Sr/$^{86}$Sr of mafic microgranular enclaves in the Inagawa Granite, Ryoke belt, southwest Japan

M. TSUBoI

Department of Chemistry, School of Science and Technology, Kwansei Gakuin University, Sanda, Hyogo, 669-1337, Japan (tsuboimot@hotmail.com)

The Inagawa Granite is located in the eastern part of the Cretaceous Ryoke metamorphic belt, southwestern Japan. The radiometric ages of the Inagawa Granite are: 63 – 72 Ma by K-Ar biotite method [1], c. 77 Ma with an initial $^{87}$Sr/$^{86}$Sr ratio ($\text{SrI}$ = 0.7095 by Rb-Sr whole-rock isochron method [2], 71.5 ± 2.4 Ma, 63.0 ± 2.0 Ma and 67.4 ± 1.4 Ma by Rb-Sr mineral whole-rock isochron method [3], and 81.9 ± 1.4 and 82.6 ± 1.8 Ma by CHIME monazite method [4].

The Inagawa Granite in the study area (Asuke area) is divided into four intrusive units; Type I (medium-grained hornblende-biotite tonalite, granodiorite and monzogranite), II (coarse-grained porphyritic hornblende-biotite granodiorite and monzogranite), III (coarse-grained hornblende-biotite granodiorite and monzogranite) and IV (coarse-grained hornblende-bearing biotite monzogranite) [5]. Sr isotopic study of apatite revealed the initial $^{87}$Sr/$^{86}$Sr ratio heterogeneity ($\text{SrI} = 0.7093 - 0.7107$) within the pluton [3].

Type I and II granite often contains mafic microgranular enclaves (MME) of diorite. The enclaves are irregularly shaped and vary from 3 to 16 cm across. The boundary between host granite and the mafic enclaves is gradual. The enclave consists of subhedral to anhedral phenocrysts of biotite and clinopyroxene. In this study, $^{87}$Sr/$^{86}$Sr ratios of plagioclase in a matrix dominated by plagioclase, quartz, and mafic microgranular enclaves (MME) of diorite. Lapland Granulite Belt: A 50 Ma cycle from burial to exhumation

P. TUISKU1, H. HUHMA2 and M. WHITEHOUSE3
1Dept. of Geosciences, Box 3000, 90014 University of Oulu, Finland (pekka.tuisku@oulu.fi)
2Geol. Survey of Finland, Box 96, 02151 Espoo, Finland (hannu.huhma@gsf.fi)
3Swedish Museum of Natural History, Box 50007, 10405 Sweden (martin.whitehouse@nrm.se)

Lapland Granulite Belt consists of migmatitic metagreywackes and an arc-type norite-enderbite series. Both record granulite-facies metamorphic maximum at about 850°C and 6-8 kbar and a subsequent cooling and decompression to about 650 °C and 2-3 kbar. However, only the metagreywacke sequences demonstrate pre-maximum heating, with abundant partial melting and migmatization. The evolution began with the deposition of the metagreywackes, which probably came to end due to tectonic burial as late as 1930 Ma. The provenance of greywackes varies from Archaean to Proterozoic, just predating the burial. These ages are shown by SIMS U-Pb ages of detrital zircons. The metagreywacke sequence was intruded by the igneous series at about 1920 to 1905 Ma, shown by the TIMS and SIMS ages of magmatic zircons. The high-grade metamorphism began at about 1910 Ma by dehydration melting which is shown by the U-Pb age of monazite in leucosomes. A lot of homogeneous round shaped zircon was grown in both neo- and palaeosomes at about 1905-1890 which probably indicates the age of metamorphic maximum. Later rims, having as young ages as about 1870 are grown around cores both in metagreywackes and enderbites. These are interpreted to have formed during exhumation in the stability field of andalusite + K-feldspar. The reason for their crystallization might be fluid liberated from crystallizing neosomes.

This all would imply that the evolution cycle of the Lapland granulite belt took about fifty million years from burial to exhumation. Tectonic setting was changed from arc to continent-continent collision and further to uplift and erosion of a mountain belt during the cycle. The cycle was preceded by a relatively short deposition phase, most probably in forearc deep marine basin.

What the Nonsberg–Ultental Region tells us about subduction zones

S. TUMIATI1, G. GODARD2 AND S. MARTIN1
1Univ. Insubria, Como, Italy (simone.tumiati@uninsubria.it)
2IPGP, Paris, France

Since Godard et al. (1996), the Nonsberg–Ultental Region (NUR) of the Eastern Alps is thought to represent an exhumed portion of a slab subducted during the Variscan orogeny to P ≈ 2.7 GPa and T ≈ 850°C (Nimis and Morten, 2000). The mélangé is constituted mainly of migmatites enclosing minor mantle-wedge peridotites and eclogite. Locally, metasomatic contacts between migmatite and peridotite are preserved. Challenging topics concerning NUR are: i) the partial melting of the slab metasediments and ii) the metasomatism of the enclosed peridotites and the crust–mantle interaction. Isotopic Sm–Nd (grt-cpx-wr), Rh–Sr (wr) and U–Pb (zir) data define a geochronologically synchronous event at about 330 Ma (Tumiati et al., 2003; 2007). This event likely corresponds to the P–T peak, the migmatization of the metasediments and the principal metasomatic interaction between pelites and peridotites. This implies that metapelites started to melt at (U)HP (2.7 GPa?), although till now none found (U)HP-metamorphic peak. Recent works (e.g. Hermann et al., 2006) demonstrated that metasediments may melt at T > 700°C at 2.7 GPa in water-present conditions, but T < 850°C are required in water-absent conditions. Therefore, Tumiati et al. (2007) suggested a wet melting of metapelites rather than a decompressional dehydration melting. Excess fluid prompted melting in pelites and metasomatism of the peridotite bodies tectonically enclosed in the crustal slab, emphasized by the crystallization of dissakisite-(La) in amphibole-bearing peridotite (Tumiati et al., 2005). However, Scambelluri et al. (2006) suggested that peridotites could have suffered also a former metasomatism prior to the slab emplacement.

Wet partial melting of metasediments occurred at (U)HP in the NUR. This suggest a massive entrapment of crustal fluids within subduction zones down to at least 80 km.

Effect of rapid diagenetic calcite deposition on carbonate associated Sulfate and Calcium isotopes

ALEXANDRA V. TURCHYN1 DONALD J. DEPAOLO1, CARL I. STEEFEL2 AND DANIEL P. SCHRAG3

1Department of Earth and Planetary Science, U.C. Berkeley
2Lawrence Berkeley National Laboratory, Berkeley, CA
3Department of Earth and Planetary Sciences, Harvard University

Carbonate minerals remain the primary mineral proxy used for reconstructing paleoclimate and paleoceanographic changes throughout Earth History. Recent work has expanded the use of these minerals to include the sulfur and oxygen isotopic composition of structurally bound carbonate-associated-sulfate ($\delta^{34}$S and $\delta^{18}$O$_{SO4}$ of CAS) and calcium isotopes ($\delta^{44}$Ca). While carbonate minerals are available nearly continuously over the past billion years of the rock record, they are susceptible to diagenetic alteration. Understanding and quantifying the effect that diagenesis may have on both CAS and $\delta^{44}$Ca is critical for proper interpretation of the geochemical record. In addition, the high rates of calcite precipitation in sediments where there is rapid sulfate reduction may produce effects on pore fluid calcium that shed light on calcium isotope fractionation in natural systems.

We measured both the $\delta^{18}$O$_{SO4}$ the $\delta^{34}$S of pore fluid sulfate and coexisting CAS from ODP sites 1123 (New Zealand) and 1063 (Bahamas). At both sites the $\delta^{18}$O$_{SO4}$ and the $\delta^{34}$S of CAS track the increase in the $\delta^{18}$O$_{SO4}$ and the $\delta^{34}$S of sulfate in the pore fluid. These results have implications for the fidelity of the CAS proxy. We also measured the $\delta^{44}$Ca at ODP site 1082 (West Africa). Calcium concentrations at this site decrease at the top of the core from 10mM to ~3mM, reflecting rapid calcite deposition. The $\delta^{44}$Ca, which remains at seawater values through the zone of rapid precipitation, gives a view of calcium isotope fractionation due to calcite precipitation at natural rates. We have added formulations for O, S, and Ca isotope fractionation to CRUNCH, the multicomponent reactive transport code, for the purpose of further exploring the effects of diagenesis on these proxies. We will quantify calcite recrystallization from incorporation of isotopically altered sulfate into CAS, to explore natural calcium isotope variation and fractionation, and to assess how both these proxies are affected by carbonate diagenesis.

Widespread Os isotope evidence for a magmatic pulse at the onset of Oceanic Anoxic Event 2

S.C. TURGEON AND R.A. CREASER
Dept. Earth & Atmos. Sciences, University of Alberta, Canada
(st23@ualberta.ca; robert.creaser@ualberta.ca)

The Cenomanian-Turonian Boundary Event (CTBE; ca. 93.5 Ma) is one of the best studied global Oceanic Anoxic Event (also referred to as OAE2) that punctuate the Cretaceous stratigraphic record. The CTBE is the most extensive of the Cretaceous OAEs, with global temperatures apparently the highest of the last 115 Ma (Clarke and Jenkyns, 1999; Huber et al., 2002; Wilson et al., 2002). This OAE is characterised by a positive global carbon-isotope excursion in both carbonates and organic matter. The similarity of $\delta^{13}$C curves at distant locations hint at the global nature of this event.

During this time, high amounts of organic carbon were buried in ocean basins due to an increase in primary productivity and/or enhanced preservation of organic matter owing to anoxic bottom waters. Debate, however, still surrounds the identification of the actual “trigger” mechanism of these periods of carbon sequestration.

Rhenium-osmium isotopic analyses were performed on two sample sets located in different basins during the CTBE: the Livello Bonarelli from the Furlo section in central Italy located in the western reaches of the Tethys Sea and, as Site 1260B of ODP Leg 207, located on Demerara Rise just off the ENE coast of South America, in the southern proto-North Atlantic. At Furlo, several minor C$_{org}$-rich intervals (“black levels”), generally thought to be precursor events, are interbedded with siliceous limestones beneath the Bonarelli.

Initial results from the black levels show upward increasing Os contents, peaking abruptly at the base of the Bonarelli (~10 ppb), then decreasing to 0.1-0.2 ppb: the CTBE at Site 1260B shows a similar trend, with Os contents of 25 ppb at the base of the CTBE decreasing to <0.1 ppb upwards. The initial $^{187}$Os/$^{188}$Os, calculated for individual samples and reflecting contemporaneous seawater Os isotopic values, are fairly high (0.7-1.2) in the black levels, indicating a continental weathering dominated Os system. The initial Os ratios at the base of the CTBE are, however, very low (~0.14-0.15) in both sections, and gradually increase upward to ~0.5-0.6. Such low values at the onset of the CTBE suggest a strong magmatic/hydrothermal influence (no evidence of bolide impact has been reported near this stage boundary), while the upward increase probably documents a return to a weathering-dominated source of Os in the oceans.

**Geochemistry of fossil bones and teeth – Reconstruction of past environments**

**T. TÜTKEN**
Department for Analytical and Applied Palaeontology, University of Mainz, Mainz, Germany (tuetken@uni-mainz.de)

Skeletal tissues such as bones and teeth are often the only remains of vertebrates that are preserved in the fossil record. They represent important archives for the reconstruction of life-history and environment because the skeletal apatite integrates chemical signals over the period of tissue formation. The isotopic composition of the food and/or drinking water ingested by the animal depends on the environmental conditions (e.g., climate, vegetation, geology). This might be incorporated into the biogenic apatite either unchanged or with fractionations during metabolism and tissue formation (vital effects).

In palaeoecology, archaeology, and palaeontology the isotopic composition of fossil bones and teeth are increasingly used for the reconstruction of diet, niche partitioning, climate, provenance, migration, metabolism and biomineralization processes (Figure 1).

However, diagenesis and recrystallisation of the microcrystalline biogenic apatite might severely bias original in vivo compositions. On the other hand chemical and mineralogical changes during diagenesis yield information about the thaphonomy. Especially postmortem-uptake of rare earth elements or uranium into the biogenic apatite enable to characterize the diagenetic milieu, detect fossil reworking or radiometrically (U/Th, Lu/Hf) date early diagenesis.

If diagenesis is carefully considered, the isotope compositions of fossil bones and teeth can yield important quantitative information about the palaeoecology and palaeoecology of fossil vertebrates and their palaeoenvironment. Results of different case studies will be discussed to demonstrate the broad application potential of isotope analysis on phosphatic vertebrate skeletal tissues.

**Bone oxygen isotope profiles (SIMS, Micromill) – Implications for archosaur growth and biomineralization**

**THOMAS TÜTKEN**<sup>1</sup>, **CLAIRE ROLLION-BARD**<sup>2</sup>, and **MARTIN SANDER**<sup>3</sup>

<sup>2</sup>Centre de Recherches Pétrographiques et Géochimiques, Vandœuvre-lès-Nancy, France (rollion@crpg.cnrs-nancy.fr)
<sup>3</sup>Institute for Palaeontology, University of Bonn, Bonn, Germany (martin.sander@uni-bonn.de)

Accretionary, non-remodelled bone tissue can provide a multi-year proxy record of ingested meteoric water and/or body temperature. Seasonal oxygen isotope cyclicity may be used as annual time marker of osteogenesis and thus for skeletochronology of extant and extinct vertebrates such as dinosaurs (Figure 1).

Long bones of extant crocodiles (*Alligator mississippiensis*) and ostriches (*Struthio camelus*) of known individual age as well as of different sauropod dinosaurs were serially sampled to measure high-resolution oxygen isotope time series. Analyses of bone growth increments were performed with two different techniques and spatial resolutions: (1) in situ oxygen isotope measurements on polished, gold-coated bone thin sections of the same specimens with a CAMECA IMS 1270 ionprobe SIMS (20 to 30 µm resolution), (2) sampling with a Merchantek Micromill (100 µm resolution) from polished bone cross-sections and analysis of their oxygen isotope composition (δ¹⁸O<sub>CO₃</sub>) after chemical pre-treatment.

Oxygen isotope results of both techniques will be compared. Implications for skeletochronology, growth rate, and biomineralization processes of archosaurs (crocodiles, birds, and dinosaurs) will be discussed.
**Determination of PVTX data and the phase change of crustal fluids**

YOSHIHARU UCHIDA AND KENSHIRO OTSUKI

Department of Geoenvironmental Science, Graduate School of Science, Tohoku University (uchida@dges.tohoku.ac.jp; otsuki@dges.tohoku.ac.jp)

Crustal fluids are the aqueous solution of salts (NaCl, KCl, CaCl2 etc.) and gases (CO₂, CH₄, N₂ etc.), most commonly a H₂O-CO₂-NaCl system. However, because of the effects of charged species, we have a little information on the phase change and the thermodynamic properties over the wide range of P and T, especially, around critical region for the ternary system. The equation of state (EOS) is the most important for understanding several geochemical processes. However, the EOS that is specified for high salinity (>25wt%) systems has not been also established yet, because experiments have not been done successfully around the critical point. In this study, we have determined the fundamental thermodynamic properties (PVTX relation and phase change) experimentally using new apparatus up to 200MPa and 600°C.

We have developed a new experimental apparatus, which is composed of a mini-piston/cylinder system set in the pressure vessel and CO₂ injector. PVT data is measured continuously and synchronously and error of measurement is within 1%. The phase change can be determined from differential V with respect to P or T. We verified the performance of our apparatus by comparing our experimental data with EOS for pure water, H₂O-CO₂ and H₂O-NaCl binary system over the P-T conditions attainable. Those results are in good agreement with preexisting EOS within accuracy of about 3%. Our experimental method serves for the determination of the thermodynamic properties on high saline crustal fluids with high CO₂ concentrations around critical region.

**Preliminary geochemical results on the CO₂ Georeactor sequestration test at the Ogachi HDR site**

⁴Research Institute of Innovative Technology for the Earth, 9-2 Kizugawa-dai, Kizu, Soraku-gun, Kyoto, Japan (Ohsumi@rite.or.jp; koikato@rite.or.jp)

This paper reports a preliminary result of field experiments of CO₂ sequestration into the Ogachi HDR site, where a part of CO₂ will be expected to be fixed as carbonates by interaction with rocks (Georeactor; Ca extraction from rocks and carbonate fixation). The Ogachi HDR (Hot-Dry Rock) field is situated at the northeast Japan and have been studied to produce geothermal electricity.

**Experimental Procedure**

River water had been continuously injected (380 L/min, 15 MPa) into an injection well (OGC-1) and produced (40 L/min) from a production well (OGC-2) during the experiment (2 weeks). After the fluid flow rate became constant, CO₂ dissolved water (0.2 wt%) was injected with tracers (KI; 2kg/200L and uranine; 150g/18m³). The fluids from OGC-2 were geochemically monitored for their isotope and chemical compositions. The final output temperature at the OGC-2 well site is 127.5 ºC.

**Results and Discussion**

During the experiments, major chemical compositions of fluids from OGC-2 are almost constant. The tracers are first detected at 34 hours after the injection and showed the maximum concentration at 67 hours. The dilution rates of the observed to injected concentrations of KI and uranine are calculated to be 6×10⁻⁵ and 1×10⁻³, respectively. CO₂ concentrations in the fluids varied from 600 to 200 mg/L with time and showed no correlation with those of the tracers. This is due to the high dilution rate with reservoir fluids. In this field experiment, we could not discuss the fixation rate of CO₂ as carbonate.
Melting condition and origin of arc magmas beneath the Sengan region, Northeastern Japan

KENTA UEKI AND HIKARU IWAMORI

Department of Earth and Planetary Science, University of Tokyo, Japan
(kenta@eps.s.u-tokyo.ac.jp; hikaru@eps.s.u-tokyo.ac.jp)

Subduction zone processes play important roles in the evolution of the crust and mantle, yet are poorly constrained at present. Recent geophysical and geological studies suggest that there are periodical structures with about 50km wavelength in the mantle wedge and crust beneath Northeastern Japan (Tamura et al., 2002). In this study, we investigate 3-D thermal and compositional states of the mantle wedge and crust beneath the volcanic front of Northeastern Japan, based on the compositional variations of volcanic rocks collected from 28 Quaternary volcanoes in a volcanic region, the Sengan region (30km-30km).

Volcanoes in the Sengan region are divided into two groups. Compositional variations of the first group can be reproduced by fractional crystallization from a basaltic magma, based on thermodynamic calculation using MELTS (Ghiorso and Sack, 1995). These volcanoes are mainly distributed on the outer rim of the cluster. Magma mixing between high-MgO andesite and dacite associated with fractional crystallization is observed in the second group, based on AFC calculation and mineralogy. The second group is distributed at the central part of the volcanic cluster associated with voluminous welded tuff and granitic pluton. Major element compositions of these voluminous silicic rocks show a similar range to those reported for partial melts of amphibolite (e.g; Beard and Lofgren, 1991).

Melting conditions in the mantle wedge have been estimated to minimize the difference between the composition of partial melt calculated at a given P, T, H2O-content (Ghiorso et al., 2002) and that estimated from the observed volcanic rocks, assuming olivine maximum fractionation. The estimated mantle condition shows that the mantle beneath the central part of the cluster has a higher H2O-content than that beneath the outer rim. It is suggested that mantle-derived wet magma had supplied heat and H2O to the crust and induced crustal melting/magma mixing at the central part of the volcanic cluster. On the outer rim, basaltic magma ascended to the surface without causing crustal melting.

Radiocarbon analysis in tree rings of Yaku-cedar by AMS for investigating secular variation of atmospheric 14C/12C ratios

H. UENO1, Y. MURAMATSU1, H. MATSUZAKI2 AND Y. SUNOHARA-TSUCHIYA2

1Dept. of Chemistry, Gakushuin University, Tokyo, Japan
(uenohiroki@hotmail.com, yasuyuki.muramatsu@gakushuin.ac.jp)
2Micro Analysis Laboratory, Tandem accelerator (MALT), University of Tokyo, Japan

Atmospheric radiocarbon is produced in the stratosphere by cosmic ray reaction with nitrogen (14N(n,p)14C). The produced 14C enters into the carbon cycle in the air, and it is absorbed photosynthetically by plants. Therefore, by measuring 14C/12C ratio in tree rings, it is possible to obtain information on the secular change of cosmic ray intensity.

In this study, we have used an old cedar tree (1680 year-old) from Yaku island (Kagoshima Prefecture, Japan). Samples (about 20mg) were collected from annual tree rings, and α-Cellulose, which is immovable constituent and recorded 14C/12C ratios at the time of the absorption, was extracted by treatments with acid and alkaline. The obtained α-Cellulose (about 3mg) was oxidized to CO2 and purified with a glass vacuum line. Then it was reduced to pure graphite which was used as a target (about 1mg) for the determination by Accelerator Mass Spectrometry (AMS).

Using a small sample size, as mentioned above, we could measure 14C/12C ratios with reasonable precision and accuracy by AMS at MALT. Results obtained at this time are shown in Fig.1 (for the period 524-775 A.D.) together with the IntCal04 data. The values were not on the straight-line, which is extrapolated from the year 1950 with the half-life of 14C, suggesting there were considerable variations of the 14C production. Some periods (e.g. around 660A.D.), in which Δ14C values were higher than those of IntCal04, were observed. Since IntCal04 was mainly composed from western data, our results from Yaku-cedar should be useful to understand secular variation of 14C/12C ratios in Japan.

Nb-Ta oxide minerals in granites and pegmatites: Tracers of magmatic to post-magmatic evolution

P. UHER AND P. CHUDÍK
Dept. of Mineral Deposits, Comenius University, Bratislava, Slovakia (puher@fns.uniba.sk)

Accessory Nb-Ta oxide minerals occur in some highly fractionated granites and granitic pegmatites. Their internal zoning, compositional variations and breakdown products are sensitive indicators of magmatic to post-magmatic evolution of the parental rocks.

Regular fine to coarse oscillatory zoning of columbite-tantalite and Nb-Ta-rich rutile with repeated Nb- and Ta-rich zones indicates their primary magmatic crystallization. Increasing Ta/Nb, (Nb+Ta)/Ti and Mn/Fe ratios in the Nb-Ta phases traces the degree of magmatic fractionation, whereas W, Sn, Sc, Zr, Y, U and Mg contents reflect mainly their local compositional environment. Moreover, presence of Ti,Fe³⁺-rich Nb-Ta minerals (titanian ixiolite, rutile) could serve as an indicator of higher oxygen-fugacity (fO2) conditions in comparison to the Ti-poor, Fe⁵⁺-rich ordered columbite-tantalite + ferrotapiolite assemblage. Minerals of the foordite-granite/pegmatite cooling and uplift.

Primary phases and element redistribution during Nb-Ta rutile, ixiolite); they indicate a breakdown of the Nb-Ta oxide minerals in granites and fractionated granites and granitic pegmatites. Their internal Mosaic patchy zoning of Nb-Ta-Ti phases manifest their widespread. Complex irregular convoluted zones reveal partial leaching and replacement of the primary phases; erratic Nb-Ta distribution is typical for the secondary columbite-tantalite. Mosaic patchy zoning of Nb-Ta-Ti phases manifest their recrystallization probably due to younger thermal/pressure metamorphic overprint. Subsolidus exsolution textures are typical for Fe⁵⁺,Ti,Sc,W,Sn-rich, primary Nb-Ta phases (e.g. Nb-Ta rutile, ixiolite); they indicate a breakdown of the primary phases and element redistribution during granite/pegmatite cooling and uplift.

Increasing of fluid activity and fO2 during late- to post-magmatic stage caused a breakdown of Sn²⁺-bearing foordite-thoraeulite and precipitation of secondary cassiterite + columbite-tantalite. Moreover, an influx of late-magmatic to hydrothermal Na,Ca-rich fluids facilitates replacement of columbite-tantalite, ixiolite and Nb-Ta rutile by fersmite, pyrochlore-group and other alkali-rich Nb-Ta minerals. Rarely, an activity of Sb,Ph-bearing hydrothermal fluids caused a precipitation of specific secondary Nb-Ta minerals (plumbomicrolite, stibiobetafite, stibiotantalite, Nb,Ta-rich römëite etc.).

Thermodynamic price tags for a wet mantle

G.C. ULMER¹ AND E. WOERMANN²

¹Geology Dept., Temple University. Philadelphia, Pa., 19122 (gulmer@temple.edu)
²Josef Ponten Str 57, Aachen-Richterich, Germany, D 52072

The exciting discovery of Wadsleyite as mineral host for hydrogen or as a "hydrous material" in the mantle has redox-equilibria-implications relative to other published redox models for the Earth’s mantle. Such redox models for the Earth’s mantle suggest that along the geotherm, shallow mantle conditions range from the log fO2 given by the buffer (FMQ) to levels of redox of ∆(FMQ) ≈ -2. These models have been based on studies that include: (1) xenolith studies by several methods (as reviewed by Ulmer et al., 1987) (2) stability of diamonds relative to other redox buffers (for example, Eggler and Baker, 1982 or Ulmer et al., 1978). Most redox models for the Earth’s mantle do incorporate more reduced conditions for greater depth in the mantle: the log fO2 given by the buffer (IW) at the core mantle boundary is one logical reason for this model. Deeper xenolith studies also suggest this. (Haggerty and Tompkins, 1983 or Ulmer et al., 1987). Even more reduced conditions for the mantle are implied by the abundant existence of the mantle mineral, Moissanite (SiC) whose redox stability in log fO2 can be represented by ∆(IW) ≈ -8 at pressures up to 9.0 GPa and temperatures up to 1730 K. Furthermore, the kinetics of oxidation of SiC exposed to carbonates or iron oxides from 2.0 to 15.0 GPa and temperatures as low as 1173 K has been measured in hours, not days or months! (Ulmer et al., 1998).

To have mantle phases, either with hydroxyl, or as true hydrates, that can be compatible in the redox state of the mantle seems a possibility? A companion manuscript at this meeting explores redox EOS calculations of water stability in the mantle. (cf., Woermann et al.). To our thinking, one possibility may be the influence of defects in the Wadsleyite. No direct data yet seem available for this suggestion; it is by analogy to the large range of redox values demonstrated by defect olivines that this idea should be pursued.

Uranium(IV) oxide surface reactivity

K.-U. Ulrich1, A. Singh1, S.F. Dixon1, E. Schofield2, J.R. Bargar2 and D.E. Giammar3

1Dept. of Energy, Environmental & Chemical Engineering, Washington University, St. Louis, USA (k.ulrich@seas.wustl.edu; giammar@wustl.edu)
2Stanford Synchrotron Radiation Laboratory, Menlo Park, USA (bargar@slac.stanford.edu)

The success of bioremediation of uranium-contaminated sites will depend on the long-term stability of the U(IV) oxide formed by microbially induced reduction of soluble U(VI). This contribution is part of a research project establishing the local and long-range structure and reactivity of biogenic uraninite generated under different environmental conditions in comparison to its closest abiotic analog, UO2-x (0 < x < 0.25). An abiotic uraninite solid was produced by thermal reduction of uranium peroxide with H2 yielding particles with a star-like prism shape and a size of ~700 nm. Powder XRD proved an fcc crystal lattice of cubic uraninite. Its stoichiometry was identical to that of a reference sample of UO2.0, as shown by EXAFS spectroscopy.

The dissolution kinetics of abiotic uraninite have been examined in batch and flow-through experiments as a function of pH, dissolved inorganic carbon, and dissolved oxygen. Dissolution rate constants are calculated from a mass balance approach, accounting for equilibrium solubility and the decrease of particle size as dissolution progresses. Batch dissolution experiments under anoxic conditions have shown dissolved uranium concentrations close to or even higher than predicted from published thermodynamic data. In the range of pH 6 to 9, dissolution rate constants were on the order of 1.3-3.1·10^-13 mol m^-2 s^-1, but they increased by two orders of magnitude under atmospheric conditions. Under anoxic conditions, a flow-through experiment has shown an initial U-release peak, suggesting removal of more soluble U phases from the surface. However, carbonate as a complexing agent for U(VI) did not immediately change the dissolution kinetics of abiotic uraninite, but gradually altered its surface toward higher solubility, which was a reversible reaction.

Dissolved U(VI) showed high affinity for abiotic uraninite. Further experiments will quantify the adsorption/desorption behavior, the surface reactivity and dissolution kinetics of uranium oxide as the most important factors for promoting immobilization and long-term stability in the subsurface.

Nd isotope mixing during thermal ionisation mass spectrometry: Implications for accurate 142Nd measurements

D. Upadhyay, E.E. Scherer and K. Mezger

Zentrallabor für Geochronologie, Institut für Mineralogie, Univ. Münster, Corrensstr. 24, 48149 Münster, Germany

Deviations from the exponential-law mass-bias curve are observed during some high-precision runs of the La Jolla Nd standard. The resulting measured isotope ratios (X/144) are generally higher than predicted by the exponential law (Fig. 1) and characterized by increased scatter. The onset of the deviations correlates with a distinct change in the mass-bias trajectory (from normal to reverse) of the isotope ratios.

Similar effects during Ca isotope measurements [1] were attributed to isotope mixing during mass spectrometry. For Nd isotopes, the effects of mixing during measurements are not clearly understood even though several studies have documented an apparent breakdown of the exponential mass-bias law [e.g., 2 and 3].

Figure 1: Deviations of the isotope ratios from the exponential curve during a run segment modeled as mixtures of ions from differentially fractionated sample reservoirs

This study shows that the divergence from exponential-law can be modeled as mixtures among reservoirs on the theoretical fractionation curve (Fig. 1). Such differentially fractionated reservoirs can form because of temperature gradients or heterogeneous sample distribution on the filament. Mixing of ions derived from these reservoirs can modify the composition of the ion beams significantly causing deviations from the exponential-law curve. Mixing results in an apparent reversal of mass fractionation because isotopically light ions from less fractionated reservoirs are ionized together with those from more fractionated ones.

Such mixing during mass spectrometry is a great concern when measuring the generally very small 142Nd anomalies because deviations up to 56 ppm have been observed for the 142Nd/144Nd ratios. This deviation is far greater than the variations expected for most applications. The ultimate accuracy and reproducibility of the isotope ratios is dictated by the extent of isotope fractionation and mixing in addition to instrument electronics and ion counting statistics.

Integrated air quality assessment - PM$_{0.1}$ to PM$_{10}$ magnetic particles

M. URBAT, E. LEHNDORFF AND L. SCHWARK
Institut für Geologie und Mineralogie, Universität zu Köln, Cologne, Germany (m.urbat@uni-koeln.de)

Approach
In our multidisciplinary approach atmospheric air quality in the Greater Cologne Area (GCA, NW-Germany) was studied using pine needles as passive samplers. Here we report accumulation histories, particle size dependency and spatial distribution of remanent magnetic pollutants as to approximate the dust load. Environmental magnetic results are interpreted in conjunction with complementary trace element and persistent organic pollutant data.

Results
Variability between sites proofs to be significantly higher than within sites. Established accumulation rates predominantly reflect anthropogenic emissions. Minor natural processes comprise canopy effects and abrasive removal of particles. Emission specific concentrations and grain size distributions (Fig. 1) are readily detected by magnetic parameters and allow for source allocation in spatially highly resolved data sets.

Conclusions
The correlation of magnetic particles, trace elements and PAH yields a far more complete picture of air pollution in that source allocation is more readily achieved.

Sub-µm size high precision analysis of δ$^{18}$O in zircon by SIMS

T. USHIKUBO$^1$, F. Z. PAGE$^1$, N. T. KITA$^1$, L. R. RICIPUTI$^2$, AND J. W. VALLEY$^1$

$^1$Dept. of Geology & Geophysics, Univ. of Wisconsin, Madison, WI, U.S.A. (ushi@geology.wisc.edu)
$^2$Oak Ridge National Laboratory, Oak Ridge, TN, U.S.A.

Oxygen isotopic ratios ($δ^{18}$O) of rocks provide important insights to understand igneous and metamorphic processes. Zircon is a valuable accessory mineral to study such processes because (1) it is common in igneous, metamorphic, and sedimentary rocks, (2) it provides U-Pb ages, and (3) it is retentive of primary composition. However, because zircons are small (typically 10 to 100 µm) with internal zonation, in situ microanalysis is required.

An in situ O isotopic analysis technique with ~0.5 µm$^2$ spot and an analytical uncertainty of 1.0 ‰ (1σ) has been developed using a Cameca ims 1280 SIMS. This technique was applied to a zoned zircon from a partially melted metasediment (Daniel’s Road, near Saratoga Springs, NY) in the granulite-facies Adirondack Highlands [1], which consists of a detrital igneous core (1353Ma) and a metamorphic overgrowth (1019Ma) with $δ^{18}$O values of ~ 6‰ and 12‰, respectively [2].

Five traverses with 2 µm steps, totaling 36 sub-1µm $δ^{18}$O analyses, were performed to determine the $δ^{18}$O gradient at the core/overgrowth boundary that is clearly seen by CL. The figure shows the CL image of the sample and positions of ~30 µm pits from previous SHIRIMP U-Pb analyses and ~0.8 µm dia. pits for $δ^{18}$O analyses of this study. We found a steep $δ^{18}$O gradient at the boundary that indicates O isotopic exchange between the core and the overgrowth occurred over a distance less than 2 µm. Modeled for a 50 Myr isothermal period [3], an O diffusion coefficient in zircon of ~10$^{-23}$ cm$^2$/s best fits the data. The preservation of such a steep gradient and the inferred low diffusion coefficient indicate that the zircon preserved $δ^{18}$O from crystallization through high-grade metamorphism. We envision that sub-µm stable isotope analyses will permit new investigations of materials that are rare, precious or zoned, including those of biological origin.

PGE geochemistry, mineralogy and Os-isotope signature in the mantle-hosted ophiolitic chromitites from the Kahramanmaraş area, SE-Turkey

I. UYSAL1, F. ZACCARINI2, G. GARUTI3, T. MEISEL4, M. TARKIAN5, M.B. SADIKLAR1

4Leoben University, Leoben-Austria
5Hamburg University, Hamburg-Germany

Mantle-hosted ophiolitic chromitites from the Kahramanmaraş area (SE-Turkey), have been investigated as to their chromite composition, Platinum-group elements (PGE) concentration and mineralogy, as well as Os-isotope geochemistry. Chromitites vary from Al-rich to Cr-rich, however they indifferently display enrichment in Os-Ir-Ru over Rh-Pt-Pd, with concentrations of PGE lower than 510 ppb. Consistently, the most abundant Platinum-group minerals (PGM) are Ru-Os-Ir sulfides and alloys. They occur as small grains (less than 15 µm), mainly included in fresh chromite. Base metals sulphide (BMS), Na-rich amphibole and rare phlogopite were also identified forming inclusions in chromite. Their textural position and morphology indicate that these inclusions are magmatic in origin. Based on textual relations, paragenesis and composition, it was possible to establish that PGE alloys crystallized before than PGE and BM sulfides, at temperature comprised between 1300 and 1000 degrees and under increasing sulphur fugacity. The presence of abundant hydrated primary silicates suggests that the Kahramanmaraş chromitites formed in the presence of water and volatile- and sodium-rich fluids. This observation is also supported by the Re/Os ratio relatively high, that points a mixing of mantle-derived Os with Os from a source characterized by relatively high radiogenic signature, possibly fluids originated in a supra-subduction zone (SSZ). If a SSZ setting is accepted, the concomitant presence of Al-rich and Cr-rich chromitites suggests chrome precipitation from melts varying in composition from back-arc basalts (Al-rich chromite) to boninites (Cr-rich chromite), possibly at different mantle levels (i.e. deep for the Cr-rich chromitites and close to the Moho-Transition Zone for the Al-rich ones).

Potential problems in the annealing of zircon

T. VÁCZI1, L. NASDALA1, R. WIRTH2, B. WANTHANACHAISAENG3 AND T. HÄGER3

1Institut für Mineralogie und Kristallographie, Universität Wien, Austria (tamas.vaczi@univie.ac.at, lutz.nasdala@univie.ac.at)
2GeoForschungsZentrum Potsdam, Germany (wirth@gfz-potsdam.de)
3Institut für Geowissenschaften, Johannes Gutenberg-Uni. Mainz, Germany (wanthana@students.uni-mainz.de, tobias.haeger@uni-mainz.de)

Annealing experiments are often employed to study the recrystallisation behaviour and the real structure of radiation-damaged zircon. This includes dry annealing in air and hydrothermal annealing; in the latter case the reconstitution is controlled by fluid-driven reaction fronts (Geisler et al., 2003). It is well-known that the temperature-induced recovery of strongly radiation-damaged zircon involves an intermediate stage (at about 900–1100 °C) where nearly amorphous ZrSiO4 decomposes into oxides (Nasdala et al., 2002). This is explained by the preferred nucleation of tetragonal ZrO2 over ZrSiO4 (Garvie, 1965). Dry annealing of moderately radiation-damaged zircon, in contrast, does not involve this intermediate stage but rather results in a gradual reconstitution of zircon.

We have found that under certain conditions ZrO2 may also be observed in the annealing of lowly metamict zircon, and at temperatures as high as 1600 °C. For instance, we found baddeleyite on the surface, or in the entire volume, of annealed zircon crystals that were treated at 1400 °C. We attribute the high-temperature formation of baddeleyite to be an artefact, for which we see two potential causes. First, if volatile alkali elements are present in the furnace atmosphere, they may react with silica to form Na-silicate glass. Second, if annealing is done using corundum crucibles, there may be a reaction of the silica component with corundum (for instance by formation of mullite). The latter idea seems to be confirmed by recent observations that during high-temperature treatment of gem-quality ruby, baddeleyite may form at the surface of included zircon crystals (Wanthanachaisang et al., 2006). It is therefore important to consider doing annealing experiments in a controlled environment (no contaminants reaching the sample) and choosing suitable materials (e.g., Pt crucibles).

X-ray photoelectron spectroscopy study of coals with different rank

B. VALENTIM1, A. COSTA1, A. GUEDES1, D. BOAVIDA2, M. MARQUES1 AND D. FLORES1

1Centro and Departamento de Geologia da Faculdade de Ciências da Universidade do Porto, Porto, Portugal (bvvalent@fc.up.pt)
2Instituto Nacional de Engenharia, Tecnologia e Inovação (INETI), Departamento de Engenharia Energética e Controlo Ambiental (DEECA), Lisboa, Portugal

Nowadays the increasing amounts of NOx and N2O converted from coal nitrogen, led to the investigation of the combustion processes and coal properties that contribute to maximise the nitrogen production and influence the variation in the emissions. Therefore it is important to determine the molecular structure of nitrogen in coal.

X-ray Photoelectron Spectroscopy (XPS) analyses were performed in vitrinite-rich coals of increasing rank to determine the nitrogen functionalities (pyridine at 398.8 eV, pyrrol around 400.2 eV, quaternary nitrogen around 401-402 eV and nitrogen-oxide around 403 eV). Nitrogen in the studied coals was found to be predominantly pyrrol. However, the coals storage procedure determined the degree of nitrogen oxidation and the other nitrogen functionalities (Fig. 1 and 2). Due to this fact, the ratios of pyridinic to pyrrolic nitrogen and pyridinic to quaternary nitrogen vary with increasing rank and also with the oxidation of the coals. The analyses of a set of non-oxidised coals with rank lower than 1.41% vitrinite reflectance permitted the observation of the decreasing of pyrrolic and quaternary nitrogen and an increase of the pyridine with increasing coal rank.

Figure 1: Representative XPS spectra of nitrogen (1s) obtained on oxidised coal.

Figure 2: Representative XPS spectra of nitrogen (1s) obtained on non-oxidised coal.

Synthetic isotope mixtures for the calibration of ion current ratio measurements in carbon and oxygen in carbon dioxide

S. VALKIERS, M. VARLAM AND M. BERGLUND

Institute for Reference Materials and Measurements, EC-JRC, B-2440 Geel (B)

Different sets of synthetic isotope mixtures for the calibration of carbon and oxygen ion current ratio measurements obtained by mass spectrometry have been prepared by mixing carbon dioxide isotopically enriched in 18O (natC18O2) and natural carbon dioxide (natCnatO2), and by mixing different natural CO2 gases with slightly different carbon and oxygen isotopic compositions [1].

These mixtures act as Primary Standards to the SI-scale for carbon and oxygen isotope amount ratio measurements in CO2. They will help to anchor existing carbon Isotope Reference Samples (i.e. NBS19, IAEA-CO-9) and therefore offer the basis for comparability of carbon (and oxygen) isotope measurement results, without any assumptive correction for the oxygen isotopes.

Via such ‘absolute’ isotope amount ratio measurements of carbon and oxygen on CO2 produced from the Primary Standard to the VPDB-scale NBS19, calibrated by means of synthetic isotope mixtures, ‘absolute’ isotope amount carbon and oxygen ratios corresponding with the zero point of the VPDB conventional scale were calculated to be $R_{13/12} = (11 137 6 ± 16) \cdot 10^{-7}$ and $R_{18/16} = (208 824 ± 48) \cdot 10^{-8}$ respectively.

Evidence of the earliest crust on Earth

JOHN W. VALLEY

Dept. of Geology & Geophysics, University of Wisconsin, Madison, WI, 53706, USA, (valley@geology.wisc.edu)

Understanding the earliest crust on Earth has long been considered the realm of planetary geology. Since all crust older than 4 Ga was apparently destroyed on Earth, older mafic to ultramafic rocks from Mars and the moon provided analogs. However, growing evidence from zircons is finally providing direct testimony of the first 500 myr on Earth.

Detrital and xenocrystic zircons older than 4.0 Ga, without identified parent rocks, are found in highly mature conglomerates and sandstones, and occasionally in granites, almost exclusively from the northern Pilbara of Western Australia. The oldest grains cluster at 4.35 to 4.4 Ga and are among the most intensely studied samples on Earth. Compositions and ages are variable within single grains and careful study involves imaging and in situ analysis correlated to textures [1]. Many zircons have younger overgrowths or altered domains, and bulk ages should be interpreted with caution. Some zircons are actually small “rocks”, containing a granitic suite of inclusions including: quartz, K-feldspar, and plagioclase [2]. No evidence of shocked zircon (planar fractures, detrital zircons, etc.) is seen in young ocean crust [3] or from the moon [4]. A number of tests support these results as primary including: magmatic zoning, U-Pb concordance, Th/U, type 1 REE profiles [1], and slow diffusion rates in zircon [5]. The picture emerges of an early Earth with differentiated buoyant crust, cool (perhaps cold) surface temperatures, and oceans, which was hospitable for the emergence of life by 4.2 Ga and perhaps earlier.

The composition of the earliest crust and its tectonic setting are less constrained. Nd, Hf, and Pb isotopes have long pointed to early formed protocrust. Recently, $^{176}$Hf/$^{177}$Hf ratios and low Ti in zircons were interpreted to indicate the existence of wet S-type granites, continental crust, and plate tectonics before 4.4 Ga [6], but questions remain [7].

Why are rocks older than 4.0 Ga preserved on Mars and the moon, but not Earth? Impacts and melting, commonly before 4.4 Ga [6], but questions remain [7].

Fractionated HSE in suboceanic mantle: Assessing the influence of refertilization processes on upper mantle peridotites

D. VAN ACKEN1,2, H. BECKER1,2, F. WOMBACHER1, R.J. WALKER2, W.F. MCDONOUGH2, R.D. ASH2 AND P.M. PICCOLI2

1Freie Universität Berlin, Institut für Geologische Wissenschaften (dvana@zedat.fu-berlin.de; hbecker@zedat.fu-berlin.de, fwo@zedat.fu-berlin.de)
2Department of Geology, University of Maryland (rjwalker@geol.umd.edu; mcdonough@geol.umd.edu, rdash@geol.umd.edu, piccoli@geol.umd.edu)

The Totalp ultramafic massif in Eastern Switzerland consists of peridotites interlayered with pyroxenites, that have been exposed on the seafloor of the Jurassic Ligurian ocean. Petrographic observations, whole rock major element and Re-Os data in peridotites from the Totalp massif suggest refertilization of the peridotites by percolating melt parental to the associated pyroxenites. Here, we examine the behaviour of other highly siderophile elements (HSE).

Peridotites from the Totalp massif have Ir contents between 1.7 and 4.3 ppb, typical for mantle-derived lherzolites. Osmium abundances range from 2.7 to 5.2 ppb, Ru abundances range from 4.8 to 12.7 ppb, both within the range previously reported for mantle peridotites. Os/IrN and Ru/IrN are broadly chondritic to slightly suprachondritic within a range of 1.0 to 1.9 and 1.3 to 1.9, respectively. Platinum abundances range from 2 to 7 ppb; Pt/IrN varies from subchondritic to slightly suprachondritic within a range from 0.72 to 1.19. Palladium abundances range between 4 and 15 ppb, Re abundances between 0.21 and 0.76 ppb. In a few samples, Pd/IrN and Re/IrN are enriched by factors of up to 4 and 5, respectively, compared to typical upper mantle lherzolites.

Associated pyroxenites are enriched in incompatible PPGE while compatible IPGE have slightly lower abundances compared to the peridotites. Websterite layers display Pd/IrN as high as 40 and Re/IrN of up to 9; Pt/IrN and Ru/IrN are only slightly elevated, to factors of up to 3.8 and 2.1, respectively.

Single grain in situ analyses of Ni-Fe-sulfides (pentlandite, pyrite, godlevskite; alongside native copper) in pyroxenites by LA-ICP-MS yield roughly chondritic Os/Ir and chondritic to suprachondritic Ru/Ir and Pd/Ir of up to 23 and 50, respectively. Re/Ir is subchondritic to slightly suprachondritic by a factor of 2. Both HSE abundances and inter-element HSE ratios vary significantly within one sample, indicating heterogeneous distribution of HSE on grain to thin section scale.

In summary, whole rock and in situ single grain HSE data indicate that melt migration by mafic mantle derived melts produced suprachondritic Pd/Ir and Re/Ir and negligibly affected Pt and more compatible HSE.
Fluvial systems are driving landscape evolution in active tectonic settings. Examining differential denudation rates associated with specific channel and hillslope morphology contributes to understand the transient response of a landscape following uplift. Here, we explore the relationship between landscape morphology and erosion by quantifying basin-wide denudation rates of various morphological zones in the Southern Ecuadorian Andes. Cosmogenic radionuclides (\(^{10}\)Be) in quartz of river sediment were employed to constrain basin-wide denudation rates \((10^4-10^5 \text{ yr})\). Along an east-west transect across the Cordillera Real, we carefully selected small basins \((< 250 \text{ km}^2)\) to cover a wide range of morphological settings, and to be representative of specific areas of transient adjustment. Channel and slope morphology vary systematically from east to west, reflecting the transition from high-relief, strongly dissected topography in the eastern side of the Cordillera Real into relatively low-relief topography in the Inter-Andean valley. Basin-wide denudation rates range by nearly two orders of magnitude, from \(~4 \text{ mm/kyr}\) to \(~400 \text{ mm/kyr}\), and show good correlation with channel and hillslope steepness indices.

The spatial pattern of differential denudation rates across the Cordillera Real reflects the transient adjustment of the landscape to rapid river incision following tectonic uplift. Relative high denudation rates \((> 200 \text{ mm/kyr})\) are measured in the eastern part of the Cordillera Real, where slopes and channels are steep and actively adjusting to rapid incision of the trunk stream. Basin-wide denudation rates are about ten times lower in the central part of the Inter-Andean valley. The presence of smooth concave river profiles indicates that the incision signal has not yet propagated into the Inter-Andean valley.

Modern riverine chemistry and discharge is commonly used to estimate the long-term flux to the oceans of the many chemical species that have their primary source in the continental crust. Here we suggest that measurements of many modern rivers, only a few thousand years after a glacial period, are not representative of the long-term flux and we quantitatively assess the implications of such a suggestion for key marine geochemical budgets.

Blum and co-workers [e.g. 1] first developed the idea that physical grinding during glacial periods of the Quaternary was followed by rapid chemical weathering of fresh soils during the warm, wet conditions of interglacials. Recently [2], Pb isotopic records of the oceans were shown to be consistent with pulses of rapid weathering during the early stages of interglacials. The consequences for long-term Quaternary chemical weathering rates and the Sr isotopic record of seawater have been explored previously [1]. Here we focus on another important implication: that the instantaneous weathering rates implied by modern riverine cation flux are higher than the long term average. In our estimation, for regions that were glaciated 20 kyr ago but that are now ice-free, present day chemical weathering rates are a factor of 3 to 4 higher than the average rate for the past 2 to 3 Myr.

This finding has major implications for long-standing problems in ocean chemistry. For example, it remains a puzzle that the hydrothermal flux of Sr required to balance the modern riverine flux is much greater than is suggested by the extent of alteration of the oceanic crust [3]. Indeed, while there is growing convergence between ocean floor hydrothermal fluid flux estimates based on independent tracer exchanges [e.g. 4] and simple thermal calculations, estimates based upon the oceanic \(^{87}\)Sr or Mg balances that rely on the quantification of the modern riverine flux are more than an order of magnitude greater. For elements such as Sr and Mg, with long oceanic residence times, modern riverine measured fluxes do not provide appropriate estimates of the long-term inputs. The changes in weathering rates also imply dramatic variation in the supply of alkalinity and nutrients to the ocean, with consequences for atmospheric CO\(_2\).

Combined Nd and Hf isotope analyses have become widely used in solid Earth geochemistry studies, but their application for low-temperature processes is still limited. The residence time for both of these elements in the ocean is thought to be similar (500 – 2000 years) and there is a growing number of studies addressing the sources of Nd and Hf as well as internal cycling processes in the ocean. In the case of Nd, these studies have been accompanied by a number of emerging applications of Nd isotopes as a tracer for past water mass mixing and ocean circulation, since the Nd isotopic composition of various archives in the ocean has been shown to record the Nd isotopic composition of ambient seawater reliably. Due to very low concentrations of Hf in seawater and hydrothermal fluids, and associated analytical difficulties in measuring Hf isotope compositions, our overall understanding about fractionation processes and internal cycling of Hf in the ocean is not as well developed as for Nd. However, recent studies have shown that direct measurements of seawater and river waters are feasible.

The global Nd-Hf isotope systematics can be described by two linear arrays in Nd-Hf isotope space, the global silicate Earth array (“the terrestrial array”) and the global ferromanganese crust and nodule array (“the seawater array”). The offset between these two arrays provides evidence for the sources and mechanisms by which these elements are added to seawater. However, the reason for this offset is under debate, with the two preferred hypotheses being (i) incongruent release of Hf during continental weathering and (ii) hydrothermal supply of Hf to seawater.

In this paper we revisit the cause for the offset of the seawater array from the terrestrial array using simple mass balance considerations. We use these calculations for a test to what degree the seawater array can be a product of preferential weathering of “non-zircon minerals” of the upper continental crust, implying retention of zircons in the solid residue of weathering. Lutetium-Hf and Sm-Nd evolution and mixing calculations show that the global seawater array can be generated with continental sources only. On the other hand, a predominantly hydrothermal origin of Hf in the ocean is not possible because the seawater Hf isotopic composition is significantly less radiogenic than hydrothermal sources and requires a minimum contribution of 50% continental Hf. While hydrothermal sources may contribute some Hf to seawater, continental contributions are unambiguously required to balance the budget.

Reaction between ascending melt and peridotite: An experimental investigation

G. VAN DEN BLEEKEN\textsuperscript{1}, O. MÜNTENER\textsuperscript{1,2} and P. ULMER\textsuperscript{3}

\textsuperscript{1}Institute of Geological Sciences, University of Bern, Switzerland (greg.vandenbleeken@geo.unibe.ch)
\textsuperscript{2}Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland (othmar.muntener@unil.ch)
\textsuperscript{3}Institute for Mineralogy and Petrology, ETH Zürich, Switzerland (peter.ulmer@erdw.ethz.ch)

Melt-rock reaction in the upper mantle is known from a variety of ultramafic rocks and is an important process in modifying melt composition on its way from the source to the surface. Evidence for depletion or enrichment by melt percolation is found in ophiolites, mantle xenoliths, and mantle sections exposed along MOR’s. It includes disequilibrium textures, changes in major-to-trace element compositions and isotopic ratios.

In this experimental study, we present a consistent set of data to evaluate the compositional and time-dependent evolution of ascending magma over a range of temperatures and pressures as a function of initial melt and peridotite compositions. In order to simulate melt-peridotite reaction processes, we perform nominally dry piston cylinder experiments with a 3-layered setup: a bottom layer composed of vitreous carbon spheres (serving as a melt trap) overlain by a peridotite layer and on top a “melt layer” corresponding to a primitive MORB composition. The peridotite layer is mixed from pure separates of orthopyroxene, clinopyroxene and spinel (Balmuccia peridotite), and San Carlos olivine. Melt from the melt layer is forced to move through the peridotite layer into the melt trap. Therefore this setup allows us to simulate reactive melt flow, as opposed to other experimental studies in which diffusion is the main driving force for reaction between a melt and a mantle rock.

Experiments have been conducted at 0.8 GPa with peridotite of variable grain sizes, in the temperature range 1200 to 1320°C. In this P-T range, representing conditions encountered in the thermal boundary layer beneath MOR’s, migrating melt is subjected to fractionation, whereas the peridotite is partially melting (solidus around 1260°C). Results show a strong dependence between phase relations in the melt layer and changes in the modal composition of the peridotite layer. Textural and compositional evidence demonstrate that reaction between percolating melt and peridotite occurs by a combination of dissolution-reprecipitation and, to a lesser degree, by solid-state diffusion. Glass compositions in our melt layers resemble those from crystallization experiments on the pure starting liquid at similar P-T conditions (Villiger et al., J. Petr., 2007), but change progressively in the peridotite layers. Silica and alkali enrichment are the most significant changes.
Unravelling the sources of silica in early-Archaean cherts with silicon isotopes
S.H.J.M. Van den Boorn 1, M.J. Van Bergen 1, P.Z. Vroon 2 and W. Nijman 1

1 Department of Earth Sciences, Utrecht University, Utrecht, The Netherlands (boorn@geo.uu.nl)
2 Faculty of Earth and Life Sciences, Free University Amsterdam, Amsterdam, The Netherlands (pieter.vroon@falw.vu.nl)

Significant controversy exists regarding the origin of silica in early-Archaean cherts and the mechanism of their formation. Solving these questions is opportune, since recent studies have used oxygen and silicon isotopic signatures of cherts to infer high temperatures for early-Archaean oceans (Knauth and Lowe, 2003; Robert and Chaussidon, 2006). For example, do these cherts represent primary precipitates from a silica-saturated Archaean ocean or are they the products of hydrothermal emanations (Kato and Nakamura, 2003)?

We present silicon isotope data for a suite of samples from well-studied chert outcrops (3.0-3.5 Ga) in the Pilbara greenstone belt (Western Australia). Our samples cover a range of depositional environments, and include both stratiform and dike cherts. Based on mineral assemblages (sericite, Ti-oxide and zircon versus Fe-(oxy)hydroxides), major element chemistry (e.g. Al2O3 content) and Eu and Y/Ho anomalies, we distinguish chemically precipitated cherts (sericite, Ti-oxide and zircon  versus Fe-(oxy)hydroxides), major element chemistry (e.g. Al2O3 content) and Eu and Y/Ho anomalies, we distinguish chemically precipitated cherts

Genesis of intermediate to silicic igneous rocks at the end of the Sveconorwegian (grenvillian) orogeny
J. Vander Auwera, M. Bogaerts and O. Bolle

Department of Geology, University of Liège, Belgium (jvdauwera@ulg.ac.be)

The origin of voluminous granitoids at convergent plate margins and in postcollisional settings is a key question in understanding the evolution of the continental crust. In southern Norway, the end of the Sveconorwegian collision orogeny (1.13-0.9 Ga) was marked by the emplacement of abundant ferroan, metaluminous granitoids (0.96-0.95 Ga) mainly in the center of the Telemarkia terrane. These granitoids are dominated by intermediate to silicic compositions but rare mafic facies do also occur. We present here a quantitative assessment of the possible process linking these mafic facies to the dominant intermediate compositions using a combination of available major and trace elements as well as experimental data. Fractional crystallization of an ilmenite bearing noritic cumulate from the parent mafic composition produces a residual liquid with an appropriate intermediate composition after 67% crystallization. There is also a good match between the calculated and observed trace elements as well as H2O contents of the residual liquid. However, the calculated La and Ce contents are lower than the observed ones. 20% to 30% non modal batch melting of an amphibolitic source equivalent in bulk composition to the mafic facies also provides a good match between observed and calculated major and trace elements composition. Moreover, considering an H2O content of the amphibolitic source of 1.25%, the produced intermediate liquid has an H2O content ranging from 4 to 6 wt % in agreement with experimental constraints on the H2O contents of the intermediate facies (5-6 wt % H2O). This degree of partial melting is in agreement with modelled melt escape threshold which allows segregation and transfer of magma towards the upper crust. Thus both fractional crystallization and non modal batch melting satisfactorily predict the geochemical features observed in the granitoids and it is possible that both processes occurred simultaneously. Interestingly, both processes produce abundant mafic rocks, either as cumulates or residues, which must be equivalent to twice as much as the observed granitoids. As geological and geophysical evidence for large volumes of dense mafic rocks in the mid svecconorwegian crust is lacking, we suggest that these dense mafic rocks were produced in the lower crust but at a pressure lower than about 1 GPa as the low La/Yb of this magmatic suite precludes the involvement of garnet in their petrogenesis. Formation of these granitoids thus contributed to the vertical stratification of the proterozoic continental crust from a mafic lower crust to a more evolved upper crust.
Thermochronological age – elevation profiles, denudation rates and relief development

PETER VAN DER BEEK
Laboratoire de Géodynamique des Chaînes Alpines, Université Joseph Fourier, Grenoble, France (pvdbeek@ujf-grenoble.fr)

Sampling age – elevation profiles has become a standard technique in thermochronology to determine temporal variations in denudation rates. In general, however, these analyses have considered the problem as one-dimensional, implicitly assuming that the samples record a common thermal history because the profile is vertical or denudation rates are regionally constant, and thus neglecting potential effects of topography or laterally varying denudation rates on age-elevation profiles. Although the influence of temporally steady-state topography on thermochronological age-elevation profiles is well understood, the potential effects of transient topography have not as yet been addressed in detail.

We explore the capacity of low-temperature thermochronology data, in particular thermochronological age-elevation profiles, to provide joint constraints on the denudation and relief history of mountain belts. To answer the question whether we can differentiate regional changes in exhumation rate from relief changes by analyzing thermochronological age-elevation profiles, we combine a three-dimensional thermal-kinematic model to predict thermal histories and thermochronological ages from an input denudation and relief history, with an inversion scheme based on the neighborhood algorithm. We explore both synthetic data and a new thermochronological (zircon and apatite fission-track, apatite (U-Th)/He) dataset collected along an age-elevation profile in the French western Alps, a region that has experienced modest tectonic activity but intense glaciation during the last few myr. Our results suggest that multiple thermochronometers are required along an elevation profile to discriminate between different denudation and relief history scenarios, and that relief has increased significantly in our study area over the last few myr, possibly resulting from focused glacial valley erosion during Quaternary glaciations.

Blueschist-facies rehydration of eclogites: Constraints on subduction channel fluid-rock interaction from the Tian Shan (China)

F. VAN DER STRAATEN¹, V. SCHENK¹, T. JOHN² AND J. GAO³

¹Institut für Geowissenschaften and SFB 574, University of Kiel, Germany (fs@min.uni-kiel.de)
²Physics of Geological Processes (PGP), University of Oslo, Norway (timm.john@fys.uio.no)
³Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, PR China (gaojun@mail.igcas.ac.cn)

Exhumed eclogites from orogenic belts may show a retrograde blueschist-facies overprint with still preserved eclogite-facies relics. This overprint occurs during uplift when infiltrating fluids cause the growth of hydrous minerals such as sodic amphibole, epidote and white mica. We are studying this rehydration process and its P-T-X conditions to unravel the source of the retrograde subduction fluids and the exhumation path.

In eclogites from the Tian Shan, garnet, omphacite and rutile represent the assemblage of the eclogite stage. If a blueschist-facies overprint has occurred, omphacite and garnet are partially replaced by glaucophane, white mica and epidote. This rehydration was associated with massive growth of carbonate, pointing to an infiltration of an H₂O- and CO₂-rich fluid. Whole-rock major and trace element analyses show an increase of LILE (K, Cs, Rb and Ba) and volatiles in the rehydrated blueschist, presumably incorporated in white mica. The increase of Mn, Mg, Fe and CO₂ leads to the precipitation of ankerite. Partially dissolved apatite, epidote minerals and garnet released significant amounts of REE, Pb, Sr, U and Y into the infiltrating fluid. From mass-balance calculations it is evident that up to 25 % of the REE were mobilized while the eclogite has been transformed to blueschist.

Based on geothermobarometry, the P-T evolution during rehydration under blueschist-facies conditions is characterized by contemporaneous cooling and decompression. The most likely uplift path is the so called ‘subduction channel’ which is the serpinentinized part of the mantle wedge above the downgoing slab. Fluids can infiltrate eclogites, rehydrate them and force their uplift because of reduced density and the resulting buoyancy. In addition, this process is aided by the high H₂O-content and the modified rheology of the mantle wedge. The observed data indicate that the subduction channel fluids do not only change the petrophysical properties due to metamorphic reactions, they also induce metasomatic changes in the reacting rocks.
**14C lipid biomarker ages in surface sediments off the five great Russian arctic rivers**

**Bart E. van Dongen**<sup>1,2</sup> **Igor Semiletov**<sup>3</sup> AND **Örjan Gustafsson**<sup>1</sup>

1Stockholm University, Dept. of Applied Environmental Science, Stockholm, Sweden, (orjan.gustafsson@itm.su.se)

2University of Manchester, School of Earth, Atmospheric and Environmental Sciences, Manchester, United Kingdom, (Bart.vandongen@manchester.ac.uk).

3International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, Alaska, USA, (igorsm@iarc.uaf.edu)

Numerical climate models forecast an amplified warming in the Arctic continental region, making it reasonable to expect that substantial effects of global warming will be first observed here. This will involve effects on the huge amounts of ‘old’ organic matter stored in Siberian soils. However, existing studies are inconclusive whether there is currently a climate-warming induced release of ‘new’ old carbon from the existing studies are inconclusive whether there is currently a climate-warming induced release of ‘new’ old carbon from the existing studies are inconclusive whether there is currently a climate-warming induced release of ‘new’ old carbon from the existing studies are inconclusive whether there is currently a climate-warming induced release of ‘new’ old carbon from the...

The effect of ‘realistic’ depth-dependence of viscosity and other material properties is also assessed.

In contrast to the $F_{\text{modern}}$ bulk values, which show a decrease across the climosequence from 0.69-0.83 in the west to 0.39-0.50 in the east, CSRA of both the isolated HMW $n$-alkanes and $n$-alkanoic acids were investigated for their lipid biomarker composition and high molecular weight (HMW) $n$-alkanes and $n$-alkanoic acids were isolated and used for compound-specific radiocarbon analysis (CSRA) to obtain information on the $^{14}$C-based reservoir age of the OM currently released from the Russian-Siberian permafrost.

In contrast to the $F_{\text{modern}}$ bulk values, which show a decrease across the climosequence from 0.69-0.83 in the west to 0.39-0.50 in the east, CSRA of both the isolated HMW $n$-alkanes and $n$-alkanoic acids indicate on average the release of relative older terrestrial material organic material (OM) by the Western GRARs ($F_{\text{modern}}$ 0.24-0.34), compared to the Eastern ($F_{\text{modern}}$ 0.31-0.50).

Global warming is expected to affect the permafrost areas in the continental Siberian Arctic, causing them to shrink. This will probably lead to a deeper water penetration of the soil and, consequently, the liberation/transport of ‘older’ terrestrial material stored in these layers. The eastern GRARs CSRA results indicate that the majority of the source of this terrestrial OM transported to the estuaries in these areas are originating from the ‘top’ (relative younger) part of the soil. In contrast, the western areas are present much less influenced by permafrost, indicating that the water can penetrate deeper and consequently can liberate/transport ‘older’ OM to the estuaries. In addition, this ‘older’ OM is most likely more degraded, which agrees with the biomarker analyses.

Although this benchmark study suggests presently no major release of remobilized ‘old’ OM through the eastern GRARs, the results of the western GRARs shows how amplified warming in the Arctic might influence the stored OM; a scenario which would have major implications for the global carbon cycle and climate.

**Effect of self-consistently generated plate tectonics on stirring by mantle convection in a 3-D spherical shell**

**Hein van Heck**<sup>1</sup> AND **Paul J. Tackley**<sup>2</sup>

1Institut für Geophysik, ETH Zürich, Switzerland (grotebaas@hotmail.com)

2Institut für Geophysik, ETH Zürich, Switzerland (ptackley@ethz.ch)

The stirring of heterogeneities by mantle convection is a key process in explaining geochemical observations, but to date most studies have been performed in only two-dimensional geometry. If 3-D convection has only poloidal motion, then its stirring efficiency is similar to that of 2-D convection [Coltice and Schmalzl, 2006], but the presence of toroidal motion could make a major difference because it can lead to chaotic stirring paths even in a steady-state flow [Ferrachat and Ricard, 1998].

Toroidal flow is mainly associated with plate motions. Two previous studies have assessed the influence of steady-state present-day plate motions on mantle stirring [van Keken and Zhong, 1999; Stegman et al., 2002]. Here we instead study flows in which time-dependent plate tectonics is self-consistently generated by the rheology, similar to [Tackley, 2000] but in a spherical shell, and has a toroidal:poloidal ratio in the range observed for the Earth. Several diagnostics are used to measure the efficiency of dispersion and stretching and their spatial variation. Stirring in plate tectonics convection is compared to stirring in other convective flows that have similar convective vigor and wavelength but without plate tectonics. Three-dimensional “plate tectonic” flows are also compared to equivalent two-dimensional flows, in order to test whether the findings of [Coltice and Schmalzl, 2006] still hold when toroidal motion is also present in the 3D cases. The effect of ‘realistic’ depth-dependence of viscosity and other material properties is also assessed.

Tantalum is a high-tech metal which is mainly mined from rare-element pegmatites. Although the mineralogy of tantalum is well constrained, very little is known about the mineralizing processes, and in particular the role of fluids in the formation of Ta ore. In many Ta deposits, the high-grade Ta ore is associated with late micaceous alteration of central pegmatite zones. Such metasomatism was commonly interpreted as hydrothermal (i.e., due to aqueous pegmatitic fluids). However, the recent discovery of melt inclusions with extremely high concentrations of volatiles (H2O, B, F, etc...) has provided an alternate explanation. Such melts could be at the origin of the metasomatic alteration commonly encountered in granitic pegmatites.

In the Tanco pegmatite, one of the world's major tantalum deposits, micas are common accessory phases that are intimately associated with the successive stages of Ta mineralization, from the wall zone to the central zone where micaceous replacement is pervasive. The different generations of micas, both primary and secondary, associated with Ta oxides, were analyzed by electron microprobe and LA-ICP-MS in order to investigate the magmatic-metasomatic transition in the Tanco pegmatite. Their chemical composition trends permit to determine whether they crystallized from a melt or an aqueous fluid.

The primary micas range from dioctahedral muscovite to trioctahedral lepidolite and show high Li-F as well as Ta (100 to 250 ppm) contents. On the other hand, replacement micas consist of end member muscovite with high B and low Li-F and Ta (around 40 ppm) contents. The B-rich and Na-Li-Ta-poor compositions of replacement micas compared to primary micas suggest that they crystallized from a B-rich aqueous fluid. This fluid would have coexisted with a late Li-rich, Ta-saturated melt, which is consistent with an immiscibility model as advocated by Veksler and Thomas (2002).

Aluminum diffusion and Al-vacancy association in MgO

JAMES A. VAN ORMAN1, CHEN LI1-2, KATHERINE CRISPIN1 AND YINGWEI FEI3
1Case Western Reserve University, jav12@case.edu
2University of Arizona, Department of Geosciences
3Geophysical Laboratory, Carnegie Institution of Washington

Periclase, with end-member formula MgO, is the second most abundant mineral in Earth’s lower mantle and may play a significant role in chemical exchange across the core-mantle boundary. Aluminum and other trivalent cations diffuse very rapidly through periclase, orders of magnitude faster than divalent cations such as Mg. This is opposite to what is observed in most silicate minerals, where highly charged cations are generally among the slowest diffusing species. The culprit appears to be a highly mobile defect associate consisting of a cation vacancy electrostatically bound to a trivalent cation [1]. Lidiard [2] developed the theory for divalent cation diffusion in alkali halide crystals, and we extend it to describe the functional dependence of trivalent cation diffusivity on concentration in alkaline earth oxides. The theory is applied to Al diffusion profiles in MgO obtained from experiments over a wide range of pressures and temperatures (1 atm to 25 GPa and 1577 to 2273 K). A family of synthetic diffusion profiles was calculated numerically, for various combinations of Al-vacancy pair diffusivity and binding energy, and the best fit for each experimental profile was determined by chi-square minimization. The binding energy for all but one experiment is in the range 0.45-0.42 eV, slightly lower than theoretical values [3] of 0.65-0.71 eV, and shows no clear dependence on temperature or pressure. The activation energy for Al-vacancy pair diffusion is 2.1 eV, and the activation volume is 2.9 cm3/mol.

Reconciling $^{210}$Pb deficits with the physics of melt extraction

JAMES A. VAN ORMAN$^1$ AND ALBERTO E. SAAL$^2$

$^1$Case Western Reserve University, Department of Geological Sciences, (james.vanorman@case.edu)
$^2$Brown University, Department of Geological Sciences, (Alberto_Saal@brown.edu)

Short-lived intermediate daughters in the uranium decay series have a broad range of half-lives suitable for timing melt production and transport processes beneath mid-ocean ridges. The discovery two decades ago of $^{226}$Ra excesses in mid-ocean ridge basalts constrained the time between Ra-Th fractionation and eruption to be on the order of 1000 years or less. The recent discovery of $^{210}$Pb deficits, correlated with $^{226}$Ra excesses in mid-ocean ridge basalts [1], indicates that the timescale must be much shorter still—less than 100 years.

A critical question is what part of the melting process the $^{210}$Pb-$^{226}$Ra disequilibrium is timing. If the fractionation can only be produced during partial melting in the mantle, then the observed disequilibrium implies melt transport rates on the order of km/yr, which would present a serious challenge to our physical understanding of melt extraction. Another possibility is that the $^{210}$Pb-$^{226}$Ra disequilibrium results from crustal processing. Numerical models have shown that shallow-level diffusive exchange with gabbroic cumulates is capable of producing $^{226}$Ra excesses (or deficits) in the melt [2,3]. We have found that the same process leads to $^{210}$Pb deficits.

A plagioclase or clinopyroxene grain interacting with its surroundings develops internal steady-state daughter concentration profiles, which represent a balance of radioactive production and decay and diffusive fluxes. Because the half-life of $^{210}$Pb is short compared to the timescale for Pb diffusion, the spatial distribution of $^{210}$Pb activity within each mineral closely follows that of $^{226}$Ra. Ra is much less compatible than Pb, and $^{210}$Pb is thus more depleted within the interior of the mineral grain than it would be if partitioning equilibrium were achieved. The result is that $^{210}$Pb is absorbed far more readily than $^{226}$Ra from any melt it comes in contact with, leaving the melt with a $^{210}$Pb deficit. This deficit develops rapidly, and reaches a steady-state value on a timescale comparable to the half-life of $^{210}$Pb, about 20 years. The magnitude of the deficit is only weakly dependent on the enrichment of the melt and on the relative diffusivities of Ra and Pb in the minerals, but is sensitive to the melt/rock ratio and to the relative mineral/melt partition coefficients of Ra and Pb. A typical value of the $^{210}$Pb/$^{226}$Ra activity ratio following gabbro exchange is ~ 0.1.

Carbon and iron isotopic evidence for photosynthesis in a 3.5 Ga old shallow marine depositional environment

M. A. VAN ZUILEN$^1$, C. THOMAZO$^1$, B. LUAIS$^2$ AND P. PHILIPPO$^1$

$^1$Laboratoire Géobiosphère Actuelle et Primitive, Institut de Physique du Globe de Paris, CNRS & Université Denis Diderot, France, (vanzuilen@ipgp.jussieu.fr)
thomazo@ipgp.jussieu., frphilippo@ipgp.jussieu.fr,
$^2$CRPG-CNRS, Vandoeuvre-les-Nancy, France, (luais@crpg.cnrs-ancy.fr)

Different abiologic and biologic models exist for the oxidation of Fe(II)aq in the upper part of the Archean ocean; UV-induced photochemical reactions, anoxygenic photosynthetic iron oxidation, or reaction with free oxygen generated by oxygenic photosynthesis. In the O$_2$-poor, and CO$_2$-rich Archean ocean these processes would have competed with direct precipitation of Fe-carbonates. Here we discuss the origin of Fe-oxides that occur in the 3.49 Ga old Chert-Barite-Unit of the Dresser Formation at North Pole (Pilbara Drilling Project, Western Australia). This unit represents a shallow water depositional environment within a volcanic caldera, and has experienced low-grade metamorphism (<350°C). It consists from bottom to top of bedded cherts, barite-sulfide beds, and bedded Fe-rich carbonates. An underlying network of barite- and silica-feeder dikes suggests synsedimentary hydrothermal activity. Towards the top of the unit, a succession of thin alternating bands of hematite and Fe-rich carbonate occurs, that includes kerogenous laminations that resemble typical microbial mats. These laminations display a distinctly different iron isotope signature than the underlying barite-sulfide beds (-0.7 to -0.4‰), that is distinctive from the δ$^{56}$Fe of kerogen in the underlying silica dikes (-34 to -31‰). The isotopic discrepancy between these two pools of kerogen cannot be explained by metamorphism. The hematite bands display a strong positive δ$^{56}$Fe (+0.1 to +1‰), compared to the Fe-rich carbonates (-0.6 to +0.4‰) and underlying barite-sulfide beds (-0.7 to -0.4‰). These petrographic and isotopic observations exclude abiologic oxidation of Fe(II)aq by UV-induced photolysis, and suggest that oxygenic and/or anoxygenic photosynthesis were directly involved in the formation of Fe-oxides in this Early Archean shallow marine depositional environment.
Geochemical characteristics of the Quaternary volcanic rocks from Hatay region, Southern Turkey: Evidence for lithospheric mantle source

E. VAROL 1, R. FREI 2, M. ALPASLAN3, M. A. KURT3 AND A. TEMEL1

1 Hacettepe University, Dept. of Geol. Engineering, 06800, Beytepe-Ankara, Turkey (elvarol@hacettepe.edu.tr; atemel@hacettepe.edu.tr)
2 Geological Institute University of Copenhagen, Oster Voldgade 10, DK-1350 Copenhagen, Denmark (robertf@geol.ku.dk)
3 Mersin University, Department of Geology, 33343, Çiftlikköy-Mersin, Turkey (malpaslan@mersin.edu.tr; malikurt@mersin.edu.tr)

The Hamam–Reyhanli (Hatay) region located in southern part of Turkey, consists of two distinct phases of Quaternary basaltic volcanism that display different geochemical characteristics. The first phase includes alkaline basalts and the second one tholeiitic basalts with SiO₂ contents ranging from 45.55-46.4 and 48.94-50.56 respectively. The former group contain high LILE, LREE, low HREE, Y contents, low Sr and high Nd isotopic values and display negative K, positive Nb, Ta anomalies as compared with the latter group. The geochemical data indicate that all the volcanic rocks are derived from a metasomatically enriched mantle source. The crustal contamination is not an important process in the evolution of the samples. The trace elements and isotopic characteristics of both group suggest that they were derived by partial melting of different depth of a lithospheric mantle source. The crustal contamination is not an important process in the evolution of the samples. The trace elements and isotopic characteristics of both group suggest that they were derived by partial melting of different depth of a lithospheric mantle source. The higher La/Yb, Zr/Y and La/Nb (<1) ratios reveal that the first group volcanic rocks are derived from a deeper mantle source than the second group.

The relative tempo of weathering and erosion controls supergene metal accumulation

P.M. VASCONCELOS

The University of Queensland, Earth Sciences, Brisbane, Qld, Australia (paulo@earth.uq.edu.au)

When the balance between weathering and erosion favors the former, chemically and mineralogically stratified weathering profiles may develop. Weathering may promote the supergene enrichment of mineralized lithologies or the formation of ore deposits from unmineralized substrates. In the first case, weathering is an ore-enrichment process; in the second, weathering is an ore-forming process. Geochronological constraints indicate that under conducive climatic and tectonic conditions, supergene enrichment of some ore deposits may occur extremely fast (less than 1 Ma; e.g., Ok Tedi). Weathering geochronology, on the other hand, indicates that supergene ore bodies in stable cratonic areas may be continuously exposed to weathering for more than 70 Ma (e.g., Carajás). Protracted exposure suggests that some supergene deposits may not reflect any one specific climatic condition, but record the combined effects of changing climates through time. Variations in precipitation, evapotranspiration, vegetation cover, and biological activity ultimately control the composition of the weathering solutions and the mechanisms affecting the dissolution, transport, and redeposition of ore elements in supergene systems. Weathering geochronology and cosmogenic isotope studies provide quantitative constraints on longevity of weathering profiles, rates of physical and chemical erosion, and rates of supergene transport and redistribution of ore elements in supergene systems. Particularly significant are contributions from 40Ar/39Ar geochronology of supergene Mn-oxides and alunite-group sulfates; (U-Th)/He dating of supergene Fe-hydroxides; and 20Al, 10Be, and ³He constraints on erosion rates. Results from these studies reveal that the most supergene ore bodies preserved on the surface of the planet are younger than ca. 70 Ma (some much younger); resulted from protracted and episodic dissolution and reprecipitation of ore minerals, with effective leaching of deleterious elements; and are preserved in areas of low to very low (less than 1 m.Myr⁻¹) erosion rates. The application of these analytical approaches on a global scale indicates that paleoclimates in the late Cretaceous-early Paleocene, the early Eocene, and the early to mid Miocene were especially conducive to weathering-driven ore forming processes.
A reassessment of prebiotic sources of carbon in the early Earth

ARON VECHT

A major reassessment of the sources of carbon is required to explain a range of anomalies associated with carbon distribution in the early earth and in the post Hadean periods.

Among these we might list:-

A. The early earth crust whether sub-continental:-acidic or granitic, or sub-oceanic:-basic or basaltic contains a very small concentration of carbon, less than 100 ppm. The sedimentary rocks which are assumed to be directly or indirectly derived from these materials contain well over 5% of carbon.

B. The earliest sources of carbon can not be assumed to have been derived from living matter and a prebiotic source of carbon must have existed in realistic quantities. Even if the micro-structural and isotopic evidence for the existence of life around 3.8Ga is assumed, which is an open question, a source of carbon must be established.

C. The large deposits of methane hydrates as well as the more recent sources of methane (Lake Kivu) cannot be explained as purely to organic sources.

To explain the above anomalies we wish to propose the concept of ‘reactive minerals’. We believe that a considerable number of reactive minerals exist well below the earths surface. Such minerals would react with water, water vapour and/or oxygen when approaching the surface. We could cite carbides and sulphides as examples, more specifically calcium and aluminium carbide. It is well known that these compounds are stable at high temperatures but react if exposed to water or oxygen. In the former case they would initially yield methane or acetylene if confined to a neutral or reducing environment, or under oxidising conditions they would yield CO2. This in turn would form carbonates and at higher temperatures result in the formation of oxides and silicates.

The existence of such reactive minerals would explain how prebiotic sources existed from which living matter could have developed. It will also show that our present figures regarding the actual carbon content of the earth are low and true values would now be in line with the carbon content of other planets and interstellar materials.
Kinetics of liquid immiscibility in the system K$_2$O-CaO-FeO-Al$_2$O$_3$-SiO$_2$

I.V. VEKSLER$^1$, A.M. DORFMAN$^2$, R. WIRTH$^1$ and D.B. DINGWELL$^2$

$^1$GeoForschungsZentrum Potsdam, Telegrafenberg, Potsdam, D-14473 Germany (veksler@gfz-potsdam.de)
$^2$Ludwig-Maximillian University, Theresienstrasse 41, Munich, D-80333 Germany (dingwell@lmu.de)

Our previous experiments on natural ferrobasaltic liquids showed that silicate liquid immiscibility may be seriously hampered by slow kinetics, metastable crystallization of tridymite, and the formation of sub-micron immiscible emulsions. Here we present new experiments on three synthetic compositions in the system K$_2$O-CaO-FeO-Al$_2$O$_3$-SiO$_2$. Two of the selected compositions lie inside the known miscibility gaps on the joins fayalite-orthoclase-silica and fayalite-hedenbergite-orthoclase-silica. The third composition lies on the anorthite-fayalite cotectic, well outside of known regions of stable or metastable liquid immiscibility. The charges in sealed Fe containers were first kept for 24 hours at a constant super-liquidus temperature, and quenched. Then, they were rapidly re-heated to the same temperature, and subjected to in situ centrifugation for 4 hours under acceleration of 1000 g. The aim of centrifugation was to distinguish between sub-liquidus emulsions due to quench, and those that may have formed by stable, super-liquidus immiscibility. The final glasses were studied by electron microprobe and transmission electron microscopy (TEM).

High-temperature super-liquidus emulsions formed in all the three compositions. The emulsions showed a remarkable stability, and did not completely break during centrifugation. Phase separation appears to be the fastest in the Ca-free composition on the fayalite-orthoclase-silica join. Here individual droplets readily grow to sizes of dozens and hundreds of microns, and merge to continuous liquid pools. The growth, coalescence and settling of droplets are significantly slower in the Ca-bearing fayalite-hedenbergite-orthoclase-silica composition. However, the most interesting and unexpected result was the formation of very fine, sub-micron emulsion in the composition on the anorthite-fayalite cotectic, where immiscibility had never been reported. The emulsion quenched to optically transparent glass, and could be revealed only by high-temperature centrifugation, electron microprobe profiles, and TEM.

Our results imply that the kinetics of silicate liquid immiscibility strongly depends on melt composition and viscosity. In some compositions, immiscibility may not develop beyond sub-micron scale for hours or days, and can be overlooked in conventional static experiments. If actual regions of silicate immiscibility are broader than presently thought, the petrogenetic role of immiscibility should be also revisited. In nature, large, slowly cooling magma chambers appear to offer enough time, and the best conditions for a full development of silicate liquid immiscibility.

Molecular and isotopic biogeochemistry of Neoproterozoic sediments in the Rio de la Plata Craton

M. VEKSLER$^1$, J.E. SPANGENBERG$^1$, C. GAUCHER$^2$ and P.C. BOGGIANI$^3$

$^1$Institut of Mineralogy and Geochemistry, University of Lausanne, Switzerland; Mariluz.Velasquez@unil.ch, (Jorge.Spangenberg@unil.ch)
$^2$Faculty of Sciences, Department of Geology, Montevideo, Uruguay; (gaucher@chasque.net)
$^3$Institute of Geosciences, University of Sao Paulo, Brazil; (boggiani@usp.br)

The Upper Ediacaran Arroyo del Soldado group (ASG) in Uruguay and Corumbá group (CG) in SW-Brazil were deposited on the same passive continental margin of the Rio de la Plata Craton. They contain a largely unmetamorphosed sedimentary sequence of alternating siliciclastic and carbonate rocks, that have been investigated by inorganic and organic geochemical methods in order to get new insight about changes in climate and chemistry of oceans during the Neoproterozoic in SW-Gondwana.

We report isotopic data from carbonates ($\delta^{13}$C$_{carb}$ and $\delta^{18}$O) and associated organic carbon ($\delta^{13}$C$_{ker}$ and $\delta^{15}$N$_{ker}$) together with hydrocarbon distribution and concentrations of major, trace and rare earth elements (REE). The $\delta^{13}$C$_{carb}$ values display coeval excursions in the two groups (ASG, CG) and range from −5.7 to 5.7‰. Dolostones from the Bocaina Formation in CG show the lowest $\delta^{13}$C$_{carb}$ values, a typical signature of cap carbonates worldwide. The $\delta^{13}$C$_{ker}$ values vary from −26.4 to −22.8‰ in CG and from −27.4 to −12‰ in the ASG reflect variations in the primary composition of organic matter as well as in the productivity rate during deposition. The $\delta^{15}$N$_{ker}$ values in the CG samples range between −3.3 to −3.1‰, suggesting a primary contribution of cyanobacteria. More positive $\delta^{15}$N$_{ker}$ values (1.8 to 5.2‰) in the ASG samples reflect most probably a higher planktonic contribution. Positive $\delta^{13}$C and $\Delta^{13}$C–ker excursions, higher concentrations of redox sensitive elements (Mn, Fe, U and V), REE, and variations in the Ce anomaly in dark organic limestones of both groups can be explained by an increased bioproductivity and preservation of organic carbon at unusually high rates of sedimentation.

The main resolvable compounds in the gas chromatograms of the hydrocarbon saturated fraction are n-alkanes in the C$_{15}$-30 (maxima at C$_{21}$) and C$_{14}$-15 (maxima at C$_{26}$) ranges for CG and ASG samples respectively, in both cases with no odd-even predominance. Most samples have a hump of unresolved complex mixture in the C$_{17}$-30 range. The predominance of C$_{18}$ of n-alkanes in the ASG samples confirm a marine planktonic input. The biomarker distribution (extended C$_{23}$ to C$_{34}$ hopanes, steranes) in the organic limestones of the CG are diagnostic for not strictly anaerobic bacteria and a diverse community of algae.
Open tube combustion method of organic samples for stable carbon isotope analysis

T. A. Velivetskaya 1, A. V. Ignatiev1 AND S. I. Kiyashko 2

1Far East Geological Institute FEB RAS, Vladivostok, Russia (velivetskaya@mail.ru)
2Institute of Marine Biology FEB RAS, Vladivostok, Russia (sekiyash@mail.ru)

A simple and effective conversion method of organic carbon into carbon dioxide for analysis of stable carbon isotopes ($\delta^{13}C$) in samples of solid and liquid substances and sedimentary rocks is presented. The conversion of organic carbon of the samples is carried out in a quartz reactor connected to a vacuum line for CO$_2$ freezing and purification. A solid organic sample mixed with CuO is placed at the reactor bottom and the reactor is subsequently filled up with a granular CuO. One end of the CuO column is preheated up to 850°C while the other end of the column in contact with the granular CuO. The column of CuO is heated to 850°C. Volatile liquid organic samples are introduced into the reactor through a septum using a micro syringe. Complete conversion is 10 minutes for solid samples and 3 minutes for volatile liquids. Precision of $\delta^{13}C$ analysis for solid and volatile liquid organic substances is ±0.1‰ and ±0.04‰ respectively.

The method presents an alternative to the well established sealed tube methods for combustion of organic material (Buchanan and Corcoran, 1959, Sofer, 1980)

The procedure of preparing the samples for combustion is simplified owing to the use of open tubes instead of sealed ampoules. The repeated use of reactors reduces considerably the consumption of expensive materials. Simultaneous use of several reactors enhances the economical aspects of the method. The method of carbon conversion demonstrates a high accuracy of $\delta^{13}C$ analysis for solids and liquids. Validity of results is confirmed by the comparison with data obtained by the universally recognized sealed tube combustion method and analysis of international standards reference materials.

Sulfide mobility during melt percolation: Implications for PGE and Os isotopes from the Oman ophiolite

M. Velz 1, AND G. Brügmann 2

1Institut für Geologie u. Mineralogie, Uni Köln, Zülpicher Str. 49b, 50674 Köln. (Michaela.kurth@uni-koeln.de)
2Max-Planck-Institut für Chemie, Abt. Geochemie, Postfach 3060, 55020 Mainz. (bruegman@mpch-mainz.mpg.de)

This study is focused on the origin of Os isotope heterogeneity in the Oman ophiolite in the context of melt percolation and sulfide mobility. Basically, two different sulfide populations occur: (1) Residual peridotites contain pentlandite (Pn) and chalcopyrite (Cp). Cp occurs either as thin lamellae or at the margin of Pn. In subgroup 1a, the grain sizes of the rare sulfides range from 10-60 µm. They are associated with opx as spherical inclusions, or they are located at triple junctions of olivines. Sulfides of subgroup 1b occur typically as interstitial, subhedral or anhedral grains with curvilinear boundaries. The grain sizes frequently range from 100 to 400 µm and they are closely associated with spinel and/or cp, suggesting precipitation from an immiscible sulfide melt. (2) Non-residual peridotites and pyroxenitic dikes: The relative abundance of sulfides strongly increases from the residual group to the non-residual group. The primary sulfide assemblage is composed of massive pyrrhotite + Cp + Pn. Large sulfide grains (up to 700 µm) are attached to coarse grained, subhedral cpx and/or spinel. The 1a type residual peridotites have very depleted trace element abundances (e.g. Yb$_{opx}$ (cpx) ~ 1.1; Ti$_{opx}$ (cpx) ~ 0.3), (Pd/Ir)$_{opx}$ ratios of < 1 and low $^{187}$Os/$^{188}$Os ratios ($^{187}$Os/$^{188}$Os$_{opx}=90$Ma) = 0.1149 and 0.1169. The unradiogenic Os compositions yield Re depletion ages of ~ 2 Ga. Type 1b residual peridotites have chondritic to suprachondritic Os isotopic ratios ($^{187}$Os/$^{188}$Os$_{opx}=90$Ma) = 0.1234 to 0.1318 and (Pd/Ir)$_{opx}$ ~ 1 to 2.

Samples from the non-residual group have suprachondritic Os isotopic ratios ($^{187}$Os/$^{188}$Os$_{opx}=90$Ma) = 0.1367 to 0.1675. The PGE and REE abundances of pyroxenitic dikes (Os = 0.13 ng/g; Pd = 6ng/g; (Pd/Ir)$_{opx}$ = 40.4) resemble those of mantle-derived melts. The PGE and REE distribution patterns of the non-residual peridotites are similar to or transitional between those of the residual peridotites and the pyroxenites. In a $^{187}$Os/$^{188}$Os vs 1/Os diagram the radiogenic samples define a mixing line having a depleted mantle and radiogenic pyroxenitic dykes as end members. It is suggested that the initial PGE and Os isotopic composition of the Oman mantle has been locally chemically overprinted by percolating melts, dissolving and re-precipitating sulfide liquids. In regions of high melting degrees and/or high melt/rock ratios, the initial PGE budget and Os isotope composition of a mantle rock may be completely replaced by sulfides derived from an Os radiogenic source.
Estimates of particle fluxes and boundary scavenging in the seawater around the Kerguelen Plateau using $^{230}$Th$_{xs}$ and $^{231}$Pa

C. Venchiarutti1, C. Jeandel1, M. Roy-Barmann2 and R. Freydier3

1LEGOS, OMP/UMR5566, 14 av. Edouard Belin, 31400 Toulouse
(venc@legos.obs-mip.fr, jeandel@legos.obs-mip.fr)
2LSCE/IPSL, 91198 Gif-sur-Yvette
3LMTG, OMP, 14 av. Edouard Belin, 31400 Toulouse

The Kerguelen Ocean and Plateau compared Study (KEOPS, 19 Jan.-13 Feb. 2005) took place in the wake of Kerguelen, characterized by a recurrent bloom allocated to natural fertilisation due to iron rich shelf inputs.

Particle dynamics (settling velocities, residence times) and dissolved/particle exchanges (boundary scavenging) are essential to understand the mechanisms responsible for the fertilisation over the Plateau. This work proposes to use two oceanic radionuclides $^{230}$Th and $^{231}$Pa –both decay products of soluble and conservative U and sensitive to scavenging- as particle dynamic tracers.

The measured dissolved and particulate $^{230}$Th and $^{231}$Pa data are consistent with other published data for near shelf area and open-ocean site. Dissolved excess $^{230}$Th (noted $^{230}$Th$_{xs}$) distributions increase linearly with depth down to 700 m at most of the stations. This linear trend reaches the bottom (1550 m) for both tracers at Kerfix, located west of the Kerguelen Plateau, with dissolved concentrations ranging from 0.6 to 11 fg/kg and from 0.02 to 1.8 fg/kg for $^{230}$Th$_{xs}$ and $^{231}$Pa respectively.

A reversible scavenging model using the $^{230}$Th$_{xs}$ dataset allowed us to estimate scavenging rates ($k_1$=0.3-0.9 y$^{-1}$), re-mineralization rates ($k_{-1}$=1.5 y$^{-1}$) and partition coefficients (average K=0.15±0.06). Assessed particle settling velocities S are 800 m.y$^{-1}$ at Kerfix and surprisingly lower over the biologically productive Plateau with ca. 500 m.y$^{-1}$. These latter velocities are nevertheless consistent with the high mineralization rates characterizing this area. The deep layers of the three stations located east of the Plateau display depleted tracer distribution (ca. 50% of the Th stock is lost) interpreted as reflecting intense scavenging due to the presence of nepheloid layers.

Single column procedure for quantitative separation and recovery of cadmium (Cd) for high precision isotope analysis by MC-ICP-MS

Sophie Verheyden1, Claude Maerschalk1, Alyssa E. Shiel2 and Nadine Mattielli1

1DSTE - Université Libre de Bruxelles (ULB) CP 160/02 Av. F.D. Roosevelt, 50, 1050 Brussels, Belgium.
sophie.verheyden@ulb.ac.be
2Dept. Earth and Ocean Sciences. University of British Columbia 6339 Stores Road, Vancouver, V6T 1Z4 Canada.

Cadmium isotopic analyses gain increasing interest since terrestrial Cd isotopic compositions can be measured with higher resolution and precision. However, Cd isotopic studies face analytical challenges related to potential low Cd contents, non-spectral matrix effects as well as molecular (M 40Ar+ and M160+) and elemental isobaric interferences of Sn (112, 114, 116), In (113) and Pd (106, 108, 110) (Wombacher et al., 2003). As a result, complete isolation of Cd from its sample matrix is important.

We propose a novel Cd separation procedure based on the Pb separation described in Lugmair and Galer (1992) as an interesting alternative to the current procedures of Wombacher et al. (2003) and Cloquet et al. (2005). The present chromatographic method is performed on a single stage micro column with AG1-X8 anion-exchange resin with a total processed acid volume of 7 ml.

For the 14 estuarine suspended particulate matter (SPM) samples passed through the column, total Cd recovery is better than 96%. The separation procedure removes more than 98% of the Sn present in the sample. Potential problematic elements such as Mo and Zr, inducing molecular interferences during MC-ICP-MS analyses, are not present (not detected with a Thermo Finigan element 2 HR-ICP-MS) in the Cd fraction and the recovery of Zn is less than 0.6%. No problematic presence of major elements (Na, K, Mg, Ca) was detected suggesting that a single column procedure should be sufficient for subsequent isotopic measurements on a MC-ICP-MS. Some Pb (up to 2% of the initial Pb) and Cr (up to 10%) are still present in the Cd fraction. A second processing on the same column displays a recovery of better than 96% Cd (n=3), no Sn, nor Zn and only 0.2% of Pb is recovered in the Cd fraction.

The $\delta^{114/110}$Cd value obtained on four duplicate (total chemistry) SPM samples is of 0.17±0.06(2sd)‰/amu against our in-house B-JMC Cd standard.

**CosmoCalc: An Excel add-in for cosmogenic nuclide calculations**

PIETER VERMEESCH
Institute of Isotope Geology and Mineral Resources, ETH-Zürich, (cosmocalc@gmail.com)

Today, we are facing a paradoxical situation: on the one hand, a better understanding of cosmogenic nuclide systematics has improved the accuracy of cosmogenic nuclide dating. But on the other hand, the increased sophistication of these methods has been an obstacle to their widespread use. CosmoCalc is an add-in to MS-Excel developed with the intention to alleviate this problem. The program as well as a spreadsheet with test data can be downloaded from the CosmoCalc website (http://cosmocalc.googlepages.com).

CosmoCalc presently implements four scaling models: Lal, Stone, Dunai and Desilets. Although the more recent models such as those by Dunai and Desilets are significantly more sophisticated than the early scaling model by Lal, they are just as easy to use in CosmoCalc. It is equally simple to compute topographic, snow and self-shielding factors. The nuclide concentrations and the product of the scaling and shielding factors are the only input required for all further calculations.

CosmoCalc uses the ingrowth equation of Granger and Smith, which is a summation of four exponentials: one for neutrons, two for slow muons and one for fast muons. Default values for the various parameters in this equation are those advocated by Granger, but alternative values can also be set.

Banana plots are sophisticated devices which depend on a large number of parameters, such as the production rates at sea level and high latitude, the scaling model, and the relative proportions of the various production mechanisms. CosmoCalc flexibility allows different kinds of Al-Be and Ne-Be plots to be generated on the fly.

CosmoCalc implements two numerical techniques to solve the non-linear systems of ingrowth equations. The default is Newton's method, which is a very fast and exact algorithm. The Metropolis algorithm is offered as a computationally more intensive, yet also more robust, alternative.

Different scaling models use different kinds of geographic input. For example, Lal's scaling model uses elevation whereas Stone uses atmospheric pressure and Dunai and Desilets atmospheric depth. Furthermore, Lal and Stone use geomagnetic latitude whereas Dunai uses geomagnetic inclination and Desilets cutoff rigidity. To facilitate the comparison of the various scaling models, CosmoCalc provides some easy-to-use conversion tools.

Regardless of the scaling model of preference, it is crucially important to use the same scaling model for the unknown sample and the calibration sites. For this reason, CosmoCalc specifies the production rates not explicitly but implicitly, by specifying the raw measurements of the calibration sites. The program comes with a set of default calibration sites, but this list can be modified by removing and adding new sites.

**The 940-864 Ma granites of the Yenisey Ridge and Taimyr foldbelts, western margin of the Siberian Craton: Geochemistry and geodynamics**

A.E. VERNIKOVSKAYA, V.A. VERNIKOVSKY AND A.M. YASENEV
Institute of Geology & Mineralogy, Russian Academy of Sciences, Novosibirsk (tonya@uiggm.nsc.ru)

The 940–864 Ma granites occur within Mesozoic Neoproterozoic greenschist and amphibolite facies metamorphic rocks of the ancient terranes in the Yenisey Ridge and Taimyr accretional belts of the western margin of the Siberian craton (Vernikovsky and Vernikovskaya, 2001; Pease et al., 2001; Vernikovsky et al., 2007). In all studied plutons, the granites have slightly peraluminous (rarely metaluminous) chemical compositions with widely variable Sm-Nd and Rb-Sr isotopic data, which allows referring to these rocks as S- and transitional I- to S-types granites. The S-type granites with epsilon Nd(940-864 Ma) = -7.14 – -4.48, 87Sr/86Sr = 0.71206 – 0.72163 and zircon saturation temperatures (T_z) approximately 800°C were generated on the early stage of the collisional process from crustal transitional hot-to-low-temperature melts, according to Miller et al. (2003). The granites of transitional I- to S-type were formed on the final stage of the collisional event from mantle-crustal low-temperature (T_clest < 800°C) melts with epsilon Nd(940-864 Ma) = -2.8 – -0.4 and 87Sr/86Sr = 0.7070 – 0.7192. On this stage the most evolved granitic melts are formed, having low Ca, Mg and REE contents and enrichment in Si and K.

It is likely that the 940 – 864 Ma granites were part of a microcontinent prior to the accretion and collision of its blocks (or terranes) with the Siberian continent.

The Neoproterozoic alkaline rocks of the Yenisey Ridge, western margin of the Siberian Craton: Mineralogy, geochemistry and geochronology

I.V. Vernikovskaya1,2, E.B. Sal’nikova3, A.E. Vernikovskaya1, N.Yu. Matushkin1,2 and A.M. Yasnenev1,2

1Novosibirsk State University, Russia, (visit_irena@mail.ru)
2Institute of Geology and Mineralogy, Russian Academy of Sciences, Novosibirsk
3Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, St. Petersburg

The Srednetatarka alkaline massif is composed of ijolites, forming the central zone and foyaites making up the outer ring area. These medium to coarse grained rocks were intruded by pegmatite dikes. The main minerals are alkali feldspar (mainly microcline), nepheline, aegirine (or aegirine-augite), alkali amphibole (mainly arfvedsonite) ± lepidomelane, ± eudialyte, ± astrophyllite-kupletskite. Among accessory minerals there are titanite, fluorite and zircon.

Enrichment of Zr, Nb and Ce in foyaites was discovered using electron microscope investigation and x-ray spectroscopic analyses. The water enriched fluid inclusions in fluorite from ijolite have homogenization temperatures from 175 ºC to 200 ºC. The rocks of the Srednetatarka massif are highly fractionated and enriched in Rb, Th, U, Nb, Ta, Hf, Zr, Tb and Y, and depleted in Ba, Sr, P and Ti. They also have large REE contents (ΣREE = 123 - 362 ppm), LILE enrichment (La/Yb~8-16) and negative Eu anomalies (Eu/Eu* changes from 0.2 to 0.9). The Srednetatarka foyaite yielded a U-Pb titanite age of 698±2 Ma. Together with the previously-dated 696 Ma (Ar-Ar, biotite) trachydolerite of the Zakhrebetninsk complex (Postnikov, 2005), these intrusive rocks are the oldest alkaline rock of the Yenisey Ridge which could be formed in anorogenic setting.

One of the most interesting facts about these alkaline rocks is that Nb, Ta, Zr mineralization and an Al deposit associate with the Srednetatarka massif.

4Department of Earth Sciences, Univ. Bristol, Bristol, UK, BS8 1RJ (j.prytulak@bristol.ac.uk)

We examine the Hf and Nd isotopic data for over 200 sediment samples in order to constrain Lu-Hf and Sm-Nd isotope systematics in the silicate Earth. The samples we have analyzed include sediments preserved on the continents and deposited in the ocean basins previously published [1] as well as unpublished data from >120 samples from 14 DSDP and ODP sites, chosen to represent the full range of sediment types and depositional environments. The most striking feature of the sediment data, as previously noted [1], is the strong positive correlation between Hf and Nd isotopes in these diverse terrigenous sediment samples. This sediment Hf-Nd array is coincident with the Hf-Nd mantle array as defined by MORBs and OIBs and collectively has been termed the terrestrial [1] or crust-mantle array. This array radiates from a depleted end-member with radiogenic Nd and Hf (εNd ~10; εHf ~16) toward evolved crustal values with very negative εNd and εHf values and represents mixing between components derived from the depleted mantle and components derived from continental crust.

The most prominent exceptions to this array, noted in the early Hf-Nd work on sediments [2,3], are ferromanganese crusts and nodules and metalliferous clays, which lie along a shallow slope above the terrestrial array. This anomalous array of authigenic sediments appears to represent, at least in part, the isotopic composition of seawater. This "seawater array" most likely results from the preferential dissolution of high Lu/Hf phases that are easily weathered such as apatite in old continental crust [4,5]. Regardless of the deviation from the terrestrial Hf-Nd array by metalliferous sediments and seawater, the tight coherency of the sediment Hf-Nd array indicates efficient mixing within the mantle through convection and on the Earth’s surface through diverse sedimentary processes, and also effective transfer between the two through the recycling of crustal materials via subduction zones.

Trace element partitioning between Mg-hastingsite and alkali basaltic melt in volcanic environment

MARCO VICCARO, CARMelo FERLITO AND RENATO CRISTOFOLINI
Dipartimento di Scienze Geologiche, Università di Catania, Corso Italia 57, 95129 Catania, Italy (m.viccaro@unict.it)

The occurrence of amphibole with no evidence of re-equilibration under low pressure conditions is rather rare in volcanic environment. The occurrence of a Mg-hastingsitic amphibole in trachybassic volcanic rocks of the 2001 eruption at Mt. Etna (Italy) has drawn the attention of many authors. However, the most intriguing character was found in the textures that show the original equilibrium at high P-haul between the amphibole and the surrounding glassy groundmass. This has allowed to calculate new accurate trace element partition coefficients (from LA-ICP-MS data) between Mg-hastingsite and basaltic-trachyandesite melt, well represented by the coexisting glass. Pressure and temperature conditions have been constrained on the grounds of geophysical and petrological data at 250 MPa and 980°C respectively.

In detail, commonly incompatible trace elements such as Nb and Ta can be more easily incorporated in the amphibole than Th, U and LREE. This means that, if Mg-hastingsite fractionation occurs in magma reservoirs, the trace element signature of the residual melt can be strongly affected, with a significant increase in the melt of trace element ratios such as U/Nb, Th/Ta, La/Nb, La/Ta. This can have a great importance especially for those systems where amphibole is unusual, so that its role as a phase fractionated from the magma can be recognised from uncommon trace element ratios.

Lithium-bearing pegmatite resources at Fregeneda-Almendra pegmatitic field (Spain & Portugal)

R. VIEIRA, A. LIMA, E. R.-ROBLES AND T. MARTINS
U.P – Geology Centre, Portugal (romeu.vieira@fc.up.pt)

Introduction

A geological exploration is being carried out in the Fregeneda-Almendra region. This field has different types of pegmatite veins, defined according to their mineralogy, morphology and internal structure. The veins intrude a pre-Ordovician E-W metasediments belt and are located to the north of the syn-Hercynian Média-Penedono-Lumbrales complex. This complex is mainly composed of a two-mica, peraluminous leucogranite. The veins have a zoned spatial distribution: the barren pegmatites are located near to the granitic complex and the rare-element enriched bodies occur further to the north. The Li-rich pegmatites are discordant, emplaced along the regional fracture system N-S to N030° E. Metamorphism isograd decreases with the distance from the granite and parallel to its contact: from sillimanite to chlorite isograd.

Methodology

Based on a stream sediment survey, the Li content of 2529 samples was analysed. Data was statistically studied and overlapped on region geological maps. This approach lead to the recognition of petalite- and spodumene-bearing pegmatites non identified until that moment.

Petalite- and Spodumene-bearing veins

Petalite-bearing veins only occur in the Portuguese part of the field. They are emplaced in the andalusite-sillimanite zone. Pombal and Vales outcrops exhibit a maximum extension of 500m and 10m width. The bodies do not show an evident internal zonation. Mineralogy assemblage is feldspars, quartz, and petalite as major constituents; minor muscovite, montebrasite and cassiterite. Fe-Mn phosphates and apatite appear as accessory minerals. Geochemical bulk analyses allow us to say that these veins are peraluminous (A/CNK>1), have low SiO₂ content and Na₂O>K₂O. They are also impoverished in Fe(t), MgO and CaO.

Spodumene-bearing veins outcrop close to the limit of the biotite/chlorite isograd. Vau and Alberto mine have variable thicknesses of 4m to 15m. Internal zonation is not observed. Mineralogy is simple: feldspars, quartz and spodumene as major constituents; minor muscovite, montebrasite and petalite; beryl, Fe-Mn phosphates and cassiterite as accessory minerals. Further studies are required.

Final Remarks

Stream-sediment geochemistry is a powerful tool on Li-pegmatite exploration and allowed an improvement on the pegmatitic field petrogenetic understanding. It also provided the increase of mineral resources for ceramics and glass industry, which already consume material from this region.
Sm-Nd and Rb-Sr isotopic systematics of suspended sediments transported by the Solimões and Madeira River: New insights about erosion and sediment provenance in the Amazon basin

J. VIERS¹, M. RODDAZ¹, N. FILIZOLA², F. GUYOT, F. SONDAG¹ and G. BOAVENTURA⁴

¹LMTG, Université de Toulouse, CNRS, IRD, Toulouse, France (viers@lmtg.obs-mip.fr)
²CEMETHI, Universidade do estado do Amazonas, Brazil
³LMTG, Université de Toulouse, CNRS, IRD, Casilla 18 1209 Lima 18, Peru (Jean-Loup.Guyot@ird.fr)
⁴Universidade do Brasilia, Brasililia, Brazil

The Amazon basin is the world’s largest Cenozoic fluvial basin with an actual drainage area of 5.8 \(10^6\) km² and a depositional area of approximately 2.5-3 \(10^6\) km². It supplies about 7% of the suspended load (Filizola and Guyot, 2004) to the world’s oceans. Filizola and Guyot (2004) give a mean annual suspended sediment flux close to 600 \(10^6\) t.yr⁻¹ at Obidos (Para state, Brazil). Ninety seven percent of this amount is contributed by Andean tributaries (62% from the Solimões River and 35% from the Madeira River).

This study reports the Sm-Nd and Rb-Sr isotopic systematics of materials being transported today by the Solimões Rio and Madeira Rio during the year 2004. Within the ORE (Environmental Research Observatory) HyBam (Hydrology of the Amazon Basin) (http://www.ore-hybam.org) monthly samples are collected from the Solimões River at Manacapuru station (A mazonas state, Brazil) and the Madeira River at Porto Velho station (Rondonia state, Brazil) (see Hybam website for more details).

The Nd isotopic composition ranges from -8.9‰ to 9.9‰ and from -10.8‰ to -12.1‰ for the Solimões and Madeira suspended sediments, respectively. The \(^{87}\text{Sr}/^{86}\text{Sr}\) ranges from 0.713 to 0.717 and from 0.728 to 0.740 for the Solimões and Madeira, respectively.

The purposes of this work are 1/ to assess possible systematic temporal variation in the Sm-Nd and Rb-Sr isotopic characteristics of the sediments, 2/ to use these potential differences of isotopic composition to constrain the geographic provenance of these sediments and the importance of bank erosion, and 3/ to estimate a global isotopic signature for sediments transported today by the Amazon River to the Atlantic ocean that can have important implications for the marine geochemistry of Nd.

Carbon and hydrogen isotopic compositions of petroleum hydrocarbons to trace alteration processes in reservoirs

A. VIETH, R. ELIAS AND H. WILKES

GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany (vieth@gfz-potsdam.de, elias@gfz-potsdam.de, wilkes@gfz-potsdam.de)

Hydrocarbons in petroleum reservoirs are subjected to viable abiotic and biotic alteration processes, such as evaporative fractionation, water washing and biodegradation. These processes cause significant changes in the molecular composition of the crude oil and therefore lead to a decrease in petroleum quality (e.g. lower API gravity, higher viscosity, higher TAN). Hence, the producibility of the respective fluids is negatively affected and the total volume of petroleum in place is reduced. Among the different alteration processes, biodegradation is responsible for the quantitative most important compositional changes in a petroleum reservoir, and therefore the ability to assess the extent of biodegradation is of particular interest for the petroleum industry.

Microbial processes favour the conversion of molecules containing lighter isotopes and therefore biodegradation leads to an enrichment of compounds with heavier isotopes (\(^{13}\text{C}, \text{D}\)) in the residual fraction. In general, hydrogen isotope fractionation tends to be at least one order of magnitude higher than carbon isotope fractionation, indicating higher sensitivity in the assessment of microbial degradation processes.

Recently it was shown that carbon isotope ratios of light hydrocarbons can be used to evaluate biodegradation processes in the Gullfaks reservoir, offshore Norway (Vieth and Wilkes 2006). However, it became clear that both source and also maturity effects have to be well constrained when using carbon isotope ratios for the assessment of biodegradation. In contrast to laboratory experiments, the hydrogen isotope ratios of light hydrocarbons in these crude oils from the Gullfaks field do not show a clear dependence on biodegradation processes. It is suggested that in petroleum reservoirs, besides differences in maturity and source, also the effects of hydrogen exchange between oil and formation water over geologic times have to be considered.

This study investigates the effects of biodegradation on carbon and hydrogen isotopes in crude oils. Here, we will present results of compound-specific isotope analysis on oil samples from different petroleum systems and demonstrate how carbon and hydrogen isotope ratios of petroleum hydrocarbons can be used to evaluate biotic as well as abiotic alteration processes in reservoirs.

Simulating physical weathering of basalt on Earth and Mars

HEATHER VILES¹, BETHANY EHLMANN², TOMASZ CEBULA¹, COLIN WILSON¹, LISA MOL¹ AND MARY BOURKE³

¹University of Oxford, UK, (heather.viles@ouce.ox.ac.uk)
²Brown University, Rhode Island, USA (bethany_ehlmann@brown.edu)
³Planetary Science Institute, Arizona, USA (mbourke@psi.edu)

Background
Despite its importance as a surficial rock type on Earth and other planets, few studies have been made of the response of basalt to physical weathering. Heating and cooling, with or without salts and moisture, may have severe impacts on basalt clasts in many extreme environments (Leask & Wilson, 2003). We report here on an integrated programme of simulations investigating physical weathering of basalt under Earth (hot desert) and Mars conditions using a Fison’s Environmental Cabinet and a specially constructed Mars Environment Simulation Chamber.

Methods
Small blocks (9 x 2.3 x 2.5 cm) of basalt were cut, and two groups prepared: (1) thermally pre-stressed and (2) thermally pre-stressed and immersed in saturated Na₂SO₄ solution. Sample strength was assessed before and after experimental weathering using a Grindosonic, and thin sections were produced for detailed petrological examination. Ambient, block surface and internal temperatures were monitored throughout the experiments. The Earth weathering regime was set up to reflect Negev desert conditions cycling between 296K and 345K; whilst the Martian regime cycled from 190K to 277K. Cycle length was 8 hrs. in each case. Both weathering regimes also included an element of radiative heating via lamps coming on for part of the heating cycle. The Mars weathering regime was carried out in 100% CO₂ atmosphere at 9 mbar pressure.

Results and conclusions
After 36 cycles under Earth and Mars conditions, changes in strength (few %) were apparent and some microscopic cracking was observed, although no visible weathering was produced. Blocks subjected to Mars-like conditions reacted differently to those subjected to Negev desert conditions especially with regard to whether salts caused strengthening or weakening.

B, Li and Sr isotopes as tracers of seawater-serpentinite interaction at MAR, ODP leg 209

F. VILS1, S. TONARINI2, H.-M. SEITZ3, A. KALT1 and L. PELLETIER1

1University of Neuchâtel, Switzerland (flurin.vils@unine.ch)
2IGGI, C.N.R. Pisa, Italy
3J. W. Goethe University, Frankfurt a.M., Germany

The samples presented in this study are altered spinel harzburgites from ODP Leg 209 (sites 1272A and 1274A) at the Mid-Atlantic Ridge (MAR) between 14°N and 16°N. The degree of serpentinisation varies between 70 and 100% in site 1272A and from 50 to 97% in site 1274A. Despite the high degree of serpentinisation, some relics of primary phases are still preserved (olivine ≥ orthopyroxene >> clinopyroxene).

In our previous study of the light element concentration in minerals of these samples we could show that boron is enriched in these rocks by reaction with seawater, and that the same process probably leaches lithium. Here, we present the results of strontium-, lithium- and boron-isotope analysis of these samples.

δ7Li varies between -28.46 and +7.17, δ11B ranges from +29.6 to +40.52. 87Sr/86Sr ratios (average 0.708726) are close to seawater values. Using the water-rock-ratio equation of McCulloch et al (1980), we obtain a low water-rock ratio (average 38.9).

Using the fractionation factors of Liu and Tossell (2005) for boron, we can model the compositional evolution of seawater to an evolved fluid (up to δ11B +70 in solution, corresponding to δ11B + 40 in the rock) in the course of its passage through the oceanic mantle rocks.

Our results show that at ODP leg 209, B, Li and Sr isotopes can successfully be used to quantify reactions between seawater and very young oceanic mantle rocks. Low water-rock ratios lead to extremely high δ11B values. This signature could potentially be transported into subduction zones. In general, however, the B, Li and Sr isotopic composition of altered oceanic mantle should be highly variable depending on water-rock ratios and on age.

Dynamic of pedogenic carbonates in a climatic gradient: The Kabini river basin, Deccan Plateau, South India

A. VIOLETTE1, J. RIOTTE1,2, J.J. BRAUN1,2, L. BARBIÉRO1,2, L. RUÍZ2, P. OLIVA1, M. SEKHAR2, M.S. MOHAN KUMAR2, S. SUBRAMANIAN2 and B. DUPRÉ1

1LMTG OMP-UMR 5563, 14, avenue E.Belin, 31400 Toulouse, France. (violette@lmtg.obs-mip.fr)
2Indo-French Cell for Water Sciences (IRD/IISc Joint Laboratory), IISc, 560 012 Bangalore, India. (braun@civil.iisc.ernet.in)

The chemical weathering of silicate rocks consumes atmospheric CO2. This has an impact on the long-term carbon cycle. In arid and semi-arid climatic conditions, the precipitation of pedogenic carbonates in soil, developed on silicate bedrock, is a potential carbon sink.

The West-East climatic gradient of the Deccan plateau, South Peninsular India, has induced various pedogenic carbonate occurrences, calcretes and nodules in the semi-arid zone and only nodules in the transition zone. The transition zone appears to be particularly sensitive to climatic changes and thus well designed for assessing the impact of climate change on the dynamic of pedogenic carbonates. In order to constrain the carbon sequestration in pedogenic carbonates, (1) the origin of Ca, (2) their age (U/Th dating) and (3) their current behavior (precipitation or dissolution), have to be determined.

Different types of nodules were sampled according to the structural study of the soil cover, in two representative watersheds of the transition zone. Soils, developed on a gneissic basement, show carbonate nodules either at the top of saprolite or within black soils (vertisols).

The 87Sr/86Sr isotopic ratios show that 2/3 of Sr in the carbonates originate from the parent rock and 1/3 from atmospheric inputs. This means that Ca mainly originates from the parent rock.

Preliminary U-Th ages of the well-developed nodules from the saprolite and black soils range from 15 to 23 ky while ages of soft tiny nodules from black soils would be less than 2 ky. Both populations of ages correspond to periods of weakness of the South West monsoon (drier climate). In this context, the pedogenic carbonates could be considered as paleo-climate proxies.

The current stability of the nodules was assessed by the stream chemistry of the watersheds. It indicates that the nodules are dissolving in the transition zone. The nodules dissolution significantly contributes to the output fluxes of Ca, Mg, U and REEs. However, the nodules trapped in the clayey matrix of the black soils seem to be protected from present-day chemical weathering.

Seasonal dynamics of molybdenum in a permanently anoxic lake

E. VIOLLIER1, A. THIAM1, P. ALBERIC2, I. CIGLENECKI-JUSIC AND D. JEZEQUEL1

1IPGP & Université Paris Diderot, (viollier@ipgp.jussieu.fr)
2IST Orléans, (patrick.alberic@univ-orleans.fr)
3IRB Zagreb, (irena@irb.hr)

Mo is an essential enzyme cofactor in nitrogenase and nitrate reductase, necessary to nitrogen assimilation by phytoplankton (cyanobacteria and microalgae respectively). Mo is also considered in sediment records as a proxy of anoxic paleo-environments where sulphide builds up and precipitate molybdenum. In order to understand dissolved Mo removal mechanisms in freshwater bodies we investigated the lake Pavin water column (Puy-de-Dome, France).

Lake Pavin is meromictic and at the bottom, about 30 meters out of 91 meters remain permanently anoxic and constitutes a natural “test tube”. The anoxic bottom layer overlaps a large density gradient layer (mesolimnion) where maximum reduced sulphur species concentrations are observed, and a more homogeneous layer where reduced compounds accumulate (monimolimnion).

The Mo size fraction was studied in the meso- and monimolimnion and compared to dissolved organic carbon (DOC) behaviour. Previous studies showed clearly Mo removal within the monimolimnion and chemical association of dissolved Mo with DOC. In this work, we demonstrate that this association is effective with large reactive organic polymers (> 1kD).

Monthly sampling of rivers input, water column solutions and solid samples (sediment traps) allowed to quantify Mo and nitrogen lake annual budget. Seasonal evolution of vertical profiles for dissolved Mo, nitrate, ammonium, sulphate and sulfide are compared and related to nitrate assimilation in the epilimnion and iron sulphide formation in the mesolimnion.

Li isotopic signature of the Reunion plume inferred from Li-Pb isotope systematic of Piton de la Fournaise historic lavas

I. VLASTELIC1, P. TELOUK2 AND T. STAUDAHER3

1Laboratoire Magmas et Volcans, Observatoire de Physique du Globe de Clermont-Ferrand, Clermont-Ferrand France (I.Vlastelic@opgc.univ-bp.clermont.fr)
2Laboratoire des Sciences de la Terre, Ecole Normale Superiéure de Lyon, Lyon, France
3Observatoire Volcanologique du Piton de la Fournaise, Institut de Physique du Globe de Paris, La Reunion

We have investigated short-term variations of \(^7\text{Li}/\text{Li}\) at Piton de la Fournaise volcano in order to better constrain the signature of the Reunion plume source and contribution of shallow-level processes. \(^7\text{Li}\) (with reference to the IRMM-016 standard) determined in 30 lava samples erupted between 1927 and 2006 (including basalts and oceanites) ranges from +3.4‰ to +4.9‰. \(^7\text{Li}\) does not correlate with the abundance of olivine xenocrysts (whose mass fraction reaches 50% in oceanites) ruling out diffusive fractionation of Li isotopes between olivine and melt as the main cause of \(^7\text{Li}/\text{Li}\) variability. However, the heaviest compositions (\(^7\text{Li} > +4.2\%\)) are found in oceanites. Contrasting with global scale systematics, \(^7\text{Li}\) correlates negatively with \(^{206}\text{Pb}/^{204}\text{Pb}\). More precisely, three distinct arrays converge toward a unique composition, suggesting mixing between a single plume component (with \(^7\text{Li} = +3.4\%\) and \(^{206}\text{Pb}/^{204}\text{Pb} = 18.90\)) and distinct contaminants. The dominant array may reflect interaction of plume melts with altered oceanic crust having unradiogenic Pb and heavy Li signature.

The Li isotopic signature of Reunion plume, as inferred from Li-Pb isotope relationships, is lighter than that of the Hawaiian plume and plumes sampling EM2 and HIMU mantle components, and is similar to that of DM and EM1 mantle components, as sampled by depleted MORB and Pitcairn lavas, respectively (Chan et al., 2006).

In agreement with previous inferences (Vlastelic et al., 2006) Li isotopes require little, or not at all, recycling of isotopically light continental sediments or isotopically heavy altered oceanic crust into the Reunion plume source.

Non-skeletal carbonate precipitates: Indicators of Molybdenum isotopic seawater composition?

A. R. VOEGELIN1, T. F. NÄGLER1, E. SAMANKASSOU2

1Institute of Geological Sciences, University of Bern, Baltzerstrasse 1+3, 3012 Bern, Switzerland
2Département de Géosciences, Université de Fribourg, Chemin du Musée 6, 1700 Fribourg, Switzerland

Studies on black shales and oxic manganese crusts indicate that the Mo isotopic signature is a suitable proxy for the detection and interpretation of changes in past ocean redox conditions (Siebert et al., 2003; Arnold et al., 2004, Barling et al., 2001). Carbonate rocks are a reservoir not yet investigated with respect to their Mo isotopic composition. Due to their occurrence during most of Earth’s history and in a wide variety of geological settings, their Mo isotopic signature has the potential to provide a continuous record of ocean redox chemistry.

We present Mo isotopic data obtained from modern ooid sands from the Bahamas and the Persian Gulf. Their isotopic composition approximates modern seawater signature, while modern skeletal material has a significantly lighter value. Also, our data from chemically precipitated marine cements from the Carboniferous of Spain and China exhibit a heavy isotopic composition similar to today’s ocean water and a distinct offset from their surrounding isotopically lighter sediment material. This has led us to hypothesize that the Mo budget of non-skeletal marine carbonates is controlled by seawater and may serve as an archive of ocean water Mo isotopic composition. As a pilot study we analyzed a variety of geological settings, their Mo isotopic signature has the potential to provide a continuous record of ocean redox chemistry.

Colloid formation in aerated Fe(II) and As(III) containing water: Effect of phosphate, silicate and Ca on local coordination by XAFS spectroscopy

A. VOEGELIN1, R. KÄGI2, D. VANTELON3, S. J. HUG4

1ETH Zurich, Switzerland (voegelin@env.ethz.ch)
2Eawag, Dübendorf, Switzerland (ralf.kaegi@eawag.ch)
3Synchrotron SOLEIL, France (vantelon@psi.ch)
4Eawag, Dübendorf, Switzerland (hug@eawag.ch)

Colloid formation due to iron oxidation and hydrolysis affects the cycling of nutrients and contaminants in environmental and technical systems. The extent of As oxidation and uptake by colloids and the composition and colloidal stability of the resulting colloids are major factors controlling the removal of As from As-rich anoxic drinking water. We investigated Fe(III)-colloid formation and concomitant As(III) oxidation and removal in synthetic carbonate-buffered groundwater (pH 7, 2-30 mg/L Fe(II), 0.5 mg/L As(III)) as influenced by phosphate (2-20 mg/L P), silicate (2-20 mg/L Si), and Ca (2.5 mM Ca- and 1.5 mM Mg-versus 8 mM Na-bicarbonate). The oxidation state of As and the local coordination of As, Fe, P, Si, and Ca in colloids collected after 4 hours of oxidation were investigated by X-ray absorption fine structure (XAFS) spectroscopy.

The removal of As from solution by uptake into settling colloids depends on a range of coupled processes such as the enhanced As(III) oxidation in presence of Fe(II), the competition of phosphate, silicate, and As for sorption sites on Fe(III)- colloids, and the effect of phosphate, silicate and Ca on molecular-scale colloid structure and colloid aggregation. While higher Fe(II) concentrations promote As(III) oxidation in solution, the associated increase of sorption sites on Fe(III)- colloids reduces anion competition, resulting in a higher fraction of colloidal As(III) (relative to total colloidal As). Increasing P/Fe ratios promote the formation of basic Fe-phosphates and increasing Si/Fe ratios the formation of ferrhydrite at the expense of lepidocrocite (which forms in the absence of P and Si). In the presence of P and Si, the P/Fe and Si/Fe ratios determine the extend to which basic Fe(III)-phosphate- and ferrhydrite-type colloids form. In the absence of Ca, colloids formed at low Fe concentration and high P/Fe ratio are colloidally stable, resulting in reduced As removal from solution. The presence of Ca promotes colloid coagulation by diminishing electrostatic colloid repulsion. Especially at high P/Fe ratios, we find that Ca is also directly incorporated into the colloid structure, suggesting the formation of mixed basic Ca-Fe(III)-phosphates. Spectroscopic data further suggest that also As(V) may be incorporated into these phosphates.

Molecular $\delta^{13}$C values of leaf wax components from plants growing in different tropical habitats

A. VOGTS, H. MOOSSEN, F. ROMMERSKIRCHEN AND J. RULLKÖTTER

Institute of Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, P.O. Box 2503, D-26111 Oldenburg, Germany (a.vogts@icbm.de)

Long-chain leaf wax components from tropical C₃ plants were analysed for their carbon isotopic composition. Averaged $\delta^{13}$C values for alkanes (weighted mean average of the n-C₂₇ to n-C₃₅ alkanes) were $-33.5 \pm 2.8\%$ for savanna plants and $-36.9 \pm 2.5\%$ for rain forest plants. The difference of 3.4% originates mainly from (1) the different isotopic composition of the source CO₂ caused by recycling effects in the closed canopy of the rain forest, and (2) the stronger discrimination of the heavier carbon isotope due to slower assimilation of CO₂ in the shady rainforest. Similar differences (3.3 to 3.8‰) were found by Ehleringer et al. (1987) for leaf tissue material of shrubs, trees, ferns and grass from open and closed canopy habitats.

In general, tropical vegetation changes from rain forests over savannas and finally to arid grasslands due to climatic conditions. Woody C₃ plant contribution decreases with an increase of grassy C₄ plants. The $\delta^{13}$C values of the n-C₂₇ to n-C₃₅ alkanes increase in the course of this vegetation change (Fig. 1). The C₄ grasses of the savanna have the highest values due to their different metabolic pathway.

![Figure 1](image)

**Figure 1.** Averaged $\delta^{13}$C values of n-C₂₇ to n-C₃₅ alkanes (weighted mean average) from leaf wax of C₃ grasses (circle, Rommerskirchen et al., 2006, n = 24) and rain forest C₃ plants (square, n =18).

These results give a clearer look at key data for studies estimating the variation of land plant biomarker contribution to dust, soils and sediments in tropical regions. Until now such research projects often only distinguished between the molecular carbon isotopic signatures of C₃ and C₄ plants. Our study provides data about a significant difference in the molecular $\delta^{13}$C values of C₃ plants from savannas and rain forests. This has to be taken into consideration, e.g., in palaeoclimatic studies.

Surface water freshening and high-latitude river discharge in the Eocene North Sea

SILKE VOIGT¹, ANNE ZACKE², MICHAEL JOACHIMSKI³ AND ANDY S. GALE⁴

¹IfM-Geomar Kiel, (svoigt@ifm-geomar.de)
²University of Cologne, (anne.zacke@uni-koeln.de)
³University of Erlangen, (joachimski@geol.uni-erlangen.de)
⁴University of Portsmouth, (asg@nhm.ac.uk)

A fish-teeth derived $\delta^{18}$Op record of the early Palaeogene North Sea mirrors the global oceanic temperature evolution, except of a 2-4 Myr period across the Palaeocene-Eocene transition, when unusually light $\delta^{18}$Op values in teeth of surface dwelling sharks indicate substantial surface water freshening. The $\delta^{18}$Op decrease with a magnitude of 6.3‰ commenced during the Palaeocene-Eocene thermal maximum (PETM), and prevailed until the early Ypresian. Coeval occurring bottom dwelling sharks indicate normal marine conditions and strong water column stratification in the early Ypresian North Sea. The magnitude of the negative $\delta^{18}$Op excursion suggests a depletion of surface water $\delta^{18}$Op by 3.6‰ relative to Eocene mean ocean water. This value is lower than that of coeval freshwater lakes and indicates that large rivers sourced by strongly fractionated precipitation drained into the North Sea. The investigated odontaspid and lamnid sharks are fully marine organisms and do not live in waters with salinities lower than 20 ppt today. We consider this value as the lower salinity tolerance limit for large predators. The construction of a mixing line between marine and brackish waters and their corresponding oxygen isotopic compositions in the Eocene results in $\delta^{18}$O values of -10 to -13‰ for river waters. These values are in a good agreement with the isotopic composition of Arctic precipitation, recently estimated from hydrogen isotopes in terrestrial plant-derived n-alkanes (Pagani et al. 2006), and suggest a high-latitude source of the river discharge into the North Sea. The commencement and duration of brackish surface-water conditions in the North Sea coincide with the main phase of effusive basaltic volcanism and associated tectonic uplift in the North Atlantic region. As a result, the North Sea probably became temporarily isolated and the fluvial catchment areas extended into the high latitudes. The marginal North Sea became reconnected with the North Atlantic Ocean during the transgression at 54 Myr, when normal marine conditions returned indicated by $\delta^{18}$Op in teeth from surface and bottom dwelling sharks.

The rheological behavior of samples from Tungurahua volcano, Ecuador

Department of Earth and Environmental Sciences, Section of Mineralogy, Petrology and Geochemistry, Ludwig-Maximilians Universität München (LMU), Theresienstrasse 41/III, 80333 München, Germany (Felix.v.aulock@googlemail.com)

For a better understanding of eruption mechanisms it is important to investigate the rheological behaviour of the magma during its ascent in the conduit. We can reveal this information by measuring the physico-chemical properties of volcanic ejecta. Between 16th and 18th of August 2006 a large eruption occurred on Tungurahua volcano including fire fountains, ash-, rock- and pumice falls and lava flows, as well as several pyroclastic flows. Shortly after this, we collected five different rock samples from the pyroclastic flow deposit which represent the most of the mass of rocks of the pyroclastic flows produced in this eruption. The rocks of the pyroclastic flows are:

a) 5% of dome material with a low porosity of about 15%;

b) 90% of bread crust bombs which have a higher porosity of about 30-50%.

A reconnaissance study of the rheological properties of our samples obtained via glass transition temperature ($T_g$) determinations was performed. To this end we have employed an advanced dilatometric method, newly developed by Helo et al. (2006).

By detecting the dilatometric softening temperature ($T_{g,soft}$) in successive runs with the same sample at constant heating and cooling rates, we observed a shift of $T_{g,soft}$ with increasing run number, presumably due to degassing of the supercooled liquid phase. The measured $T_{g,soft}$ for the dome material were 974 °C for the first run and 1030 °C for the 10th run, and 1060 °C up to ~1100 °C for the bombs. The increase of $T_{g,soft}$ in successive runs was higher for the dome material than for the bread crust bombs.

This was unexpected as the dome material is believed to be more degassed and should therefore have a higher $T_{g,soft}$ than bombs which had less time for degassing. But the results show the opposite trend: higher $T_{g,soft}$ and a faster rise in $T_{g,soft}$ for the porous bomb material. The results of this study will be discussed in terms of the relative degassing histories and kinetics of the dome versus bomb rocks as well as their crystalline textures.

How fast do the Alps erode? A cosmogenic nuclide study on Central Alpine river basins

F. von Blanckenburg1, H. Wittmann, T. Kruesmann, K.P. Norton and P.W. Kubik

1Institute for Mineralogy, Leibniz University of Hannover, Callinstrasse 3, D-30167 Hannover, Germany

2Institute for Particle Physics, Paul Scherrer Institute / ETH Zürich, CH-8093 Zürich, Switzerland

Cosmogenic $^{10}$Be, measured in river-borne quartz now routinely provides denudation rates at the river basin spatial scale and at the temporal scale of a few kiloyears (von Blanckenburg 2005). A north-south traverse through the Swiss Central Alps reveals that denudation rates correlate with recent rock uplift rates in both magnitude and spatial distribution. As a prerequisite, we took care to investigate the potential influence of shielding from cosmic rays due to snow, glaciers, and topographic obstructions, to calculate a possible memory from LGM glaciation, and to identify a watershed size that is appropriate for systematic sampling. Mean denudation rates are 0.27± 0.14 mm*yr$^{-1}$ for the Alpine foreland, and 0.9± 0.3 mm*yr$^{-1}$ for the crystalline Central Alps. The measured cosmogenic nuclide-derived denudation rates are in good agreement with post-LGM lake infill rates and about twice as high as denudation rates from apatite fission track ages that record denudation from 9-5 Myr. Cosmogenic nuclides now provide the ability to decipher correlations between denudation rate and geomorphic parameters. For example, the rates correlate with hill slope in the Mittelland catchments, but they are independent of angle in the high Alps. We interpret this to mean that high Alpine landscapes are at threshold hillslope, where slopes cannot increase any further before failure occurs. In general, denudation rates are high in areas of high relief and high altitude. Levelling measurements show that the Central Alps are uplifting today with 0.5-1.6 mm yr$^{-1}$ (Kahle et al. 1997). The similarity in the spatial distribution and magnitude of denudation rates and those of rock uplift rates can be interpreted in several ways: (i) postglacial rebound or climate change has introduced a transient change in which both uplift and denudation follow each other with a short lag time; (ii) the amplitude of glacial to interglacial changes in both is small and is contained in the scatter of the data; (iii) both are driven by ongoing convergence where their similarity might hint at some form of long-term quasi steady state; (iv) enhanced continuous Quaternary erosion and isostatic compensation of the mass removed accounts for the distribution of present-day rock uplift.

A new U/Pb-spike ($^{233-235}$U/$^{202-205}$Pb) for high precision zircon dating: First results of standard zircons, precision and accuracy

A. VON QUADT 1, S. GEORGIJEV 1 AND I. PEYTCHEVA 1,2

1 ETH Zurich, IGMR, (georgiev@erdw.ethz.ch; vonquadt@erdw.ethz.ch)
2 CLMK, BAS, Sofia 1000, (peytcheva@erdw.ethz.ch)

For high precision U/Pb zircon, xenotime and monazite analyses there is a new U/Pb spike ($^{233-235}$U/$^{202-205}$Pb) produced at ETH Zurich. The enrichment for the $^{205}$Pb isotope is greater than 99.95 and for the $^{206}$Pb isotope greater than 99.73. Important ratios of this new mixed double U/Pb spike are: $^{206}$Pb/$^{202}$Pb – (0.001132), $^{235}$U/$^{202}$Pb – (7.7351E-05), $^{208}$Pb/$^{202}$Pb – (10.0025) and $^{235}$U/$^{231}$U – (0.969945). The new U/Pb spike was calibrated against a highly pure metal solution based on NBS 982 and NBS 960. One of the aims to produce the new double lead and uranium spike ($^{233-235}$U/$^{202-205}$Pb was the to avoid the usage of external mass-fractionation, and to improve precision and accuracy of U-Pb measurements. In the past the instrumental mass-fractionation was estimated by repeated measurements of NBS 982 or NBS 981 material as well as of U 500 standard material.

The minimum amount of NBS Pb and U for the external fractionation correction is limited by Pb-blank, the temperature during the measurement and parameters of the ion counter system. Nevertheless, the measuring procedure needs more time for the measurement based on six Pb isotopes, three U isotopes and sometimes two additional isotope to correct interferences on the mass $^{202}$Pb.

To demonstrate the advantage of the new ($^{233-235}$U/$^{202-205}$Pb) U/Pb spike we have measured several zircons standards R33 (Black et al., 2204), 91500 (Wiedenbeck et al., 1995) and the PL zircon (Slama et al., 2006) using a “common” $^{235}$U/$^{205}$Pb and the new double U/Pb spike. First preliminary results show that the scattering of the $^{206}$Pb/$^{238}$U ages and the mean error of the $^{206}$Pb/$^{238}$U ages are much smaller compared to the use of the “conventional” $^{205}$Pb/$^{235}$U spike.

Identification of potential geochemical reactions in German subsurface storage sites of CO₂

HANS-DIETER VOSTEEN AND FRANZ MAY

Federal Institute for Geosciences and Natural Resources (BGR), Stilleweg 2, 30655 Hannover, Germany (Hans-Dieter.Vosteen@bgr.de)

Large scale CO₂ geological storage in Germany can be realized both in deep saline aquifers and in mature natural gas reservoirs. Some of the injected CO₂ will dissolve in the already highly mineralized Na-Ca-Cl brine to form CO₂ (aq) and carbonic acid. Such a change in brine composition can lead to dissolution or precipitation of minerals within the storage formation or the cap rock. Mineral dissolution will yield an increase in porosity. Depending on where it occurs, it can either increase the storage capacity or reduce the cap rock integrity. Mineral precipitation will either result in long term mineral storage of CO₂ or - if it occurs near to the well - it can yield technical problems during CO₂ injection. Numerical simulation of reactive transport processes and associated mineral reactions are generally used for predictions of such processes. But, reaction rates of silicates are very slow and reliable thermodynamic data obtained by experimental studies of mineral precipitation or dissolution is difficult to obtain. In many cases realistic thermodynamic data does not exist for all minerals within a rock formation. Data for lacking minerals such as mixed crystals has to be estimated. If we consider high-salinity brines, which are omnipresent in the North German Basin, the Pitzer formalism has to be used. Many simulation tools do not facilitate simulation of redox reactions or alumino silicate reactions in combination with the Pitzer formalism. These limitations result in potential unrealisitic and therefore uncertain interpretations of geochemical simulation results. Another way to identify and quantify potential alteration reactions is to study natural analogues. For the case of CO₂ injection, natural analogues can be found in regions with CO₂-rich water, e.g. in active volcanic regions. Potential alteration reactions, identified by natural analogue studies can further be used as comparison and for qualitative calibration of numerical simulations. For the German storage formations Bunter Sandstone and Rotliegend sediments such natural analogue studies yield the dissolution of calcite and chlorite and precipitation of dolomite. Another slow alteration reaction is the dissolution of albite and the precipitation of kaolinite. By studying natural analogues of the Rhenish Massif, May (2005) found that the alteration of greywacke and shale rocks by CO₂-rich water led to the dissolution of chlorite and feldspar and to the precipitation of kaolinite, iron-bearing carbonates, quartz and bicarbonate water.

Origin of UHP garnet lherzolite and serpentinised harzburgites from Pohorje, Eastern Alps, Slovenia

M. VRABEC1, J.C.M. DE HOOG2 AND M. JANAK3
1Dept. of Geology, University of Ljubljana, Ljubljana, Slovenia (mirijam.vrabec@ntfgeo.uni-lj.si)
2Dept. of Earth Sciences, University of Oxford, Oxford, UK
3Geological Institute, Slovak Academy of Sciences, Bratislava, Slovak Republic

The presence of former mantle rocks in continental crust sections from orogenic terrains may give important clues on the tectonic history of the region. The Slovenska Bistrica ultramafic complex (SBUC; Eastern Alps, Slovenia) occupies the south-eastern most part of the Pohorje mountains, which represent an extruded piece of continental crust subducted during the Cretaceous Eo-Alpine orogeny. The SBUC is the only known occurrence of ultramafic rocks within this nappe system apart from a few dismembered pieces in the near vicinity. The main body is composed of serpentinised harzburgites with local occurrences of garnet lherzolite, and as a whole it records a complex history of melt depletion, metasomatism, subduction and exhumation.

The harzburgites are highly depleted following melting within the spinel stability field, as exemplified by high whole-rock MgO, low Sc, LuN, and GdN/YbN, and high Cr# of Cr-spinel. Fluid-immobile trace elements (Th, Ti, Zr, Sc, V, HREE) correlate well and are consistent with a melt depletion trend. Other incompatible elements show little correlation and are probably strongly modified by the serpentinisation process. However, comparable LREE enrichment of all samples suggests that this piece of mantle was already metasomatised by melts or fluids before serpentinisation. In lherzolite CaO and Al2O3 contents were high enough to form garnet after spinel thus recording an UHP stage (4 GPa, 900°C) not visible in the harzburgites. Because of the evidence of an earlier lower pressure stage within the spinel stability field, the SBUC represents a piece of subducted mantle.

As subduction was intra-continental, the most obvious source of the SBUC is subcontinental lithosphere from the overlying continental slab, but this is in conflict with the strongly depleted nature of the rocks. Alternatively, it may have been part of the oceanic lithosphere after rifting of the N Apulia passive margin. This fits better with the geochemistry of the rocks, including negative Ce and positive Li and U anomalies - typical of weathering at the sea floor and commonly observed in abyssal peridotites. However, it is unclear how much these features are affected by serpentinization processes. A third possibility is that the SBUC represents subduction-modified depleted mantle from the hanging wall composed of S Apulia subcontinental mantle. A Re-Os isotope study is underway to obtain additional constraints on the origin of this piece of mantle.

Investigating the source of continental flood basalts: Insights from intra-lava flow osmium isotope variations

C.L VYE1, A. GANNOUN1,2, K.W. BURTON13, T.L. BARRY1, AND S. SELF1
1Dept. of Earth Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA. UK (cvye@open.ac.uk)
2Dept. of Earth Sciences, University of Oxford, Parks Road, Oxford, OX1 3PR. UK (mouhcine@earth.ox.ac.uk)
3LMTG, Universite de Toulouse, 14 Av. E. Belin, F-31400, Toulouse, France (burton@lmtg.obs-mip.fr)

Geochemical debates over the source of continental flood basalts usually assume that individual lava flows represent compositionally uniform and rapidly erupted products of large well-mixed magma reservoirs. This study presents an examination of intra-lava flow chemical and isotopic variations in relation to eruption sequence, which provide insights into the mechanisms of flood basalt petrogenesis.

The temporal variations implicated by the pahoehoe inflation model (Self et al. 1997) have been applied to a flow field, formed by a single flood basalt eruption, both vertically within each sheet lobe and laterally between the constituent lobes. This framework provides insight into sequential magmatic evolution during the timescale of one eruption.

We present results from a 2,660 km² flow field formed during a single eruption in the Columbia River Basalt Province, USA. Our findings show that small but statistically significant major and trace element intra-lobe variations were present at the time of emplacement e.g. MgO 3.09-4.55 wt%, Ni 17.5-25.6 ppm, indicative of fractional crystallisation. However, such data does not reveal other processes such as source variations and/or crustal contamination. In contrast, Re-Os isotopes indicate progressive crustal contamination of the magma over the timescale of a single flood basalt eruption. Initial 187Os/188Os ratios range from 0.287 (lava core) to 1.569 (lava crust) within a single 35m thick sheet lobe. These values are more radiogenic than any known enriched sources (normative mantle ~0.127, HIMU ~0.15) consistent with previous data for CRBs (Chesley and Ruiz, 1998) indicating that neither an enriched source nor the SCLM can be the cause of the radiogenic values. Preliminary data for an individual lava from the Deccan Traps indicate a similar process of contamination. These data have important implications for flood basalt genesis and the nature of their source, and indicate that uniformity of individual lavas cannot be assumed.

Large-scale matrix diffusion in crystalline rocks revealed by natural Cl, $\delta^{18}$O and $\delta^2$H tracers in pore water

H.N. Waber1, T. Gimmi1 AND J.A.T. Smellie2

1Institute of Geological Sciences, RWI, University of Bern, Baltzerstrasse 1, CH-3012, Bern, Switzerland
2Conterra AB, Box 8180, 104 20 Stockholm, Sweden

Matrix diffusion in crystalline rocks of low permeability has long been proposed as a retardation mechanism in radionuclide transport. However, its extent and efficiency under the conditions of underground repositories (ca. 400-700 m depth) have been difficult to define.

As part of the Swedish site investigation programme at Laxemar-Oskarshamn a continuous drillcore has been sampled, extending from a transmissive fracture zone into the low-permeability rock matrix at a depth of 112 m. Special sample-handling procedures allowed the rock to be retrieved in its saturated state and allowed its in situ water content to be measured, without modifications by drilling fluid or stress release. Pore-water chloride contents were then derived from out-diffusion experiments and the isotope composition from the diffusive isotope equilibration technique. The Cl time-series data from these experiments can be described by radial diffusion indicating that diffusion might well be important under in situ conditions. The chloride contents of the pore water are similar to that in the fracture water at the fracture-matrix interface. They describe a complex curved profile over the first 6 m of the drillcore, but then remain at background values (Figure 1) over several decametres (towards the next underlying conductive fracture). The $\delta^{18}$O and $\delta^2$H values show similar profiles. The variations in pore-water Cl, $\delta^{18}$O and $\delta^2$H reflect changes in the fracture-water composition over geological time, which can be correlated with the local hydrological history during the Holocene and Pleistocene.

Taking account of this history, the shapes of the profiles suggest diffusion-dominated transport. This indicates that in crystalline rocks, matrix diffusion occurs over decametres even under present-day conditions.

Figure 1: Changes in Cl and $\delta^{18}$O of pore water in crystalline rock as function of distance to a transmissive fracture.

Stable isotope geochemistry of amphiboles from alkaline igneous complexes

Zs. Waczek1, T. Vennemann1, C. Harris2, G. Markl3, AND M. Marks3

1Institut de Minéralogie et Géochimie, Université de Lausanne, Anthropole, CH-1015 Lausanne, Switzerland (Zsofia.Waczek@unil.ch, Torsten.Vennemann@unil.ch);
2Department of Geological Sciences, University of Cape Town, Rondebosch 7700, South Africa (chris.harris@geology.uct.ac.za)
3Institut für Geowissenschaften, AB Mineralogie und Geodynamik, Eberhard-Karls-Universität, Wilhelmstraße 56, D-72074 Tübingen, Germany (Gregor.Markl@uni-tuebingen.de; Michael.Marks@uni-tuebingen.de)

It is now well established that the hydrogen isotope composition of amphiboles from alkaline complexes can have an extremely wide range, but also extremely low $\delta^D$ values (between ~227 and ~70‰). It has been suggested that the extreme depletion in D is controlled by internally buffered magmatic processes that may be unique to highly peralkaline magmas (Marks et al., 2004). This possibility is further explored through a complete mineralogical and geochemical characterization of selected minerals from a number of well-described alkaline complexes, including examples from Greenland, the Kola peninsula of Russia, and NW Namibia.

Amphiboles selected have compositions typical for calcic, sodic-calcic, and sodic amphiboles. The O-isotope compositions, in contrast to those for hydrogen, are quite homogeneous and are compatible with amphibole formation from mantle-derived magmas (values close to 5.5‰). In the amphiboles, the influence of Fe$^{3+}$/Fe$^{2+}$ on $\delta^D$ values is negligible ($R^2_{Fe^{3+}/Fe^{2+}} = 0.3914$; $n=17$) and the control of iron content is small ($R^2_{Fe \text{ content}} = 0.6558$; $n=23$). Our data do not support interaction with a highly reducing fluid as a cause of the low $\delta^D$ values. However, a significant correlation ($R^2_{Na+K} = 0.8196$; $n=23$) between the alkali content and $\delta^D$ value from the Ilímaussaq complex is observed. These data suggest that H-isotope compositions are controlled by a combination of Fe-content but more notably the alkali-element contents in the amphiboles, implying complex fluid-mineral equilibration in these highly alkaline magmas.

Revisiting the elemental composition of Enstatite chondrites
J. Wade¹, S. J. Hammond², N. W. Rogers³ and M. M. Grady¹

¹PSSRI, The Open University, Walton Hall, Milton Keynes, MK6 7AA (j.wade@open.ac.uk)
²Dept. of Earth Science and Engineering, Imperial College London, London, SW7 2AZ.
³Dept. of Earth Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA

The enstatite chondrites are a group of metal- and sulphide-rich meteorites with a highly reduced composition. They have an oxygen isotope composition that is indistinguishable from that of the Earth-Moon system [1], and partly on this basis have been cited as model precursors for the Earth [2]. However, it has proven difficult to reconcile the bulk elemental abundances of enstatite chondrites with those of the Earth. In order to explore any compositional link that enstatite meteorites may have with other planetary bodies, a good understanding of the range of their compositions is required. Previous work has used a variety of methods to determine the minor and trace element composition of these materials, with individual work often focusing upon either a restricted range of elements and/or a restricted number of meteorite samples. The highly reduced nature of the meteorites and the chemical reactivity of some of the meteorite components implies that only samples from falls should be considered for analysis. This, inevitably, makes drawing any conclusions from their bulk compositions somewhat difficult.

Here we present compositional data from a comprehensive range of EH and EL meteorite falls, using a quadrupole ICP-MS technique for trace element analysis, together with ICP-OES for the major elements. The aim is to provide an internally consistent data set for a large elemental range, such that better constraints may be placed both upon the models of enstatite chondrite formation, and their genetic relationship with other planetary bodies.

Experimental growth of biofilms for studies on the impact of microbes on transport processes in groundwater systems
D. Wagner, K. Bateman, P. Coombs, H. Harrison, A.E. Milodowski and J.M. West
British Geological Survey, Keyworth, Nottingham, UK (dwagner@bgs.ac.uk)

Introduction
The effect of biofilm growth on the physical and chemical properties of rocks and sediments, and in particular how this might influence hazardous and radioactive waste transport, is poorly understood. A review of existing work on microbial transport has shown that the impact of rapid change of pH or ionic strength and valency on established biofilms are least well understood. This work builds upon a previous project (Redox Experiment in Detailed Scale – REX), investigating rock-water and microbial interaction using diorite and groundwater from the Åspö Hard Rock Laboratory, Sweden.

Experimental test work
Initial aims were to develop methodologies for biofilm cultivation and to observe their growth. A flow-through cell was built, which was packed with crushed and milled diorite from Åspö. Artificial groundwater adjusted to pH 7.5, prepared to simulate the geochemical conditions at Åspö, was continuously circulated through the cell, and the system was inoculated with a bacterium Pseudomonas aeruginosa. After 4 days, the flow cell showed visible signs of a developed biofilm, the presence of which was confirmed by staining using Acridine orange, fluorescent stain.

Conclusions
Initial experiments have shown that it is possible to grow a biofilm within a few days on a diorite substrate over which artificial groundwater containing minimal nutrients was circulated. Future investigations will focus on physical effects of rapid changes in pH, nutrient levels, and ionic strength on established biofilms as well as the effect of phage on biofilm development. Therefore, an experimental set-up of two columns, one with and one without biofilm would seem to be the most suitable method to trace physical and chemical property changes.

Impact of U-mining tailings on water resources in Mailu-Suu (Kyrg)

F. Wagner1, H. G. Jung1, C. Wanke2, C. Bunnenberg2, R. Michel3, and T. Himmelsbach1

1Federal Institute for Geosciences and Natural Resources, Hannover, Germany (frank.wagner@bgr.de)
2Center for Radiation Protection and Radioecology, University Hannover, Germany (wanke@zsr.uni-hannover.de)

From 1946 till 1968, uranium ore was mined and processed in the region of Mailu-Suu (Kyrgyz Republic). The residual waste rock and tailing material (≈3 Mio. m³) has been provisionally deposited in the Mailu-Suu valley in close vicinity of rivers and instable slopes, and may be eroded and mobilized through landslides and floods.

Findings presented here are dealing with the contamination state of the local water resources, based on 55 samples including seepage, ground and surface water. Analytical methods comprise IC, ICP-OES, ICP-MS for determining the hydrogeochemistry, γ- and α-spectrometry characterizing the radiolgy of the sampled water.

Results and Discussion

Aggravated by the complex and unclear hydrogeological situation, this study reveals local infiltration and extensive contamination of river and shallow quaternary aquifer by uranium and other contaminants. Major pollution source seems to be seepage water leaking from tailings with up to 36 mg/L U and the tributary river Kulmin-Say containing 170 µg/L with a flow rate of ≈10 L/s. More than half of the samples fail the chemotoxic WHO-guideline for drinking water for U (15 µg/L). Pollutants transport downstream (N→S) is evident in both shallow aquifer and Mailu-Say river. Hydrochemical fingerprints and multivariate statistics reveal their interconnection and allow genetical clustering of groundwater samples of uncertain origin.

In sampled water, uranium is not present in radioactive equilibrium relative to the uranium-radium decay chain. The activities of uranium strongly predominate relative to their daughter nuclides indicating transport processes of dissolved uranium, likely as carbonylated species. The measured mass and activity concentrations of uranium fit well considering that 1 µg U of natural isotopic composition corresponds to 12.45 Bq of U-238. Combining all data, the radiation dose of one example well possibly used for drinking purposes is estimated to exceed the EU guideline value of 0.1 mSv/a.

Conclusions and Outlook

Radiocuclides and other contaminants from U-mining activities have affected the water resources in Mailu-Suu and may be transported down to the Fergana Basin (Uzbekistan). Beyond design of a monitoring network and awareness rising of the local population, future investigations focus on the transport pathways and behaviour of uranium, incl. the role of deep aquifers with flooded U-mines and the characterization of solid and dissolved U-species.

Isotopic constraints on picritic magmatism, Iceland

Tod Waight1, Alan D. Brandon2, David W. Graham3 and Bjarni Gautason4

1Institute for Geology and Geography, University of Copenhagen, Oster Voldgade 10, 1350 Copenhagen K, Denmark (todw@geol.ku.dk)
2NASA, Johnson Space Center, Houston, TX 77058, U.S.A.
3College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR 9733, U.S.A.
4Orkustofnun and University of Akureyri, Rangarvelli, P.O.Box 30, 602 Akureyri, Iceland

New Sr, Nd, Pb and Hf isotope data are presented for a suite of 19 picritic samples from Iceland; Os and He isotope data for the same samples are presented by Brandon et al. (2007). The samples display compositions typical for neogene magmatism in Iceland; 87Sr/86Sr = 0.70290–0.70318, 143Nd/144Nd = 0.51230–0.51315, 206Pb/204Pb = 18.05–18.97, 207Pb/204Pb = 15.43–15.52, 208Pb/204Pb = 37.71–38.53, 176Hf/177Hf = 0.28315–0.28333. The samples span the spectrum from depleted to enriched samples (La/Sr = 0.31–1.83) and have isotopic and trace element signatures characteristic for Icelandic compositions with negative Δ207Pb (-0.3 – -3.5, excl. 1 sample), positive Δ208Pb (3.2 – 31.2, excl. 3 samples) and positive ΔNb (0.01–0.37).

Typical correlations are observed between various isotope systems (e.g. Sr-Nd, Pb-Nd, Pb-Pb etc.) and are consistent with the involvement of multiple source components. Of particular note are correlations between 3He/4He and 187Os/188Os and increasing 176Hf/177Hf, and increasing 3He/4He and 187Os/188Os with increasing 206Pb/204Pb and 208Pb/204Pb. These correlations indicate that the enriched component(s) of the Icelandic system, with radiogenic Pb isotope signatures indicative of high time-integrated U/Pb and Th/Pb, are also characterised by a non-radiogenic high 3He/4He signature. These observations are inconsistent with the high 3He/4He signature being the result of incorporation of a U-Th-poor component from the upper mantle (e.g. depleted lithosphere, olivine-rich domains) as these should also be expected to have non-radiogenic Pb isotope systematics.

In detail, two groups of data can be seen in plots of He, Pb and Hf isotopic compositions, with a subordinate group from the SW region of the western rift zone having high 3He/4He for a given 206Pb/204Pb. This provides evidence for the contribution of at least three components to magmatism in Iceland, and may suggest a spatial variation in these components beneath Iceland.

Simultaneous determination of mass-dependent isotopic fractionation and radiogenic isotope variation of Sr in geochemical samples

T. WAKABAYASHI, T. OHNO, Y. FUKUSHI, T. KOMIYA AND T. HIRATA

Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Japan (twakabayashi@geo.titech.ac.jp)

In this study, we have developed a novel method of precise isotopic analyses to investigate both mass dependent isotopic fractionation and radiogenic isotopic variation of Sr using MC-ICP-MS. Isobaric interferences and matrix elements were chemically eliminated by an extraction chromatography using Sr spec. resin. We examined Sr isotopic fractionation during the separation procedure. The result of the test demonstrated that Sr isotopes were measurably fractionated on the separation process. The cumulative Sr isotopic value of the eluent indicate that no detectable isotopic fractionation of Sr was found through a few percent loss of Sr during the chromatographic separation.

In order to examine the possible isotopic fractionation of Sr in nature, we analyzed Sr isotopic compositions of GSJ igneous rock standards (Basalt, JB-1a; Andesite, JA-2; Rhyolite, JR-1), GSJ carbonate mineral standards (limestone, JLS-1; Dolomite, JD-1; Coral, JC-1; Giant clam, JCt-1) and seawater samples. No Sr isotopic variation was found among the igneous rock standards, whereas the resulting δ88Sr of carbonate mineral standards showed lighter Sr isotopic composition than that of the seawater, suggesting that lighter Sr isotopes could preferentially co-precipitate with Ca as a carbonate mineral. The resulting δ88Sr of recent carbonate samples (JCp-1, JCt-1) were identical with that of seawater samples. These results imply that simultaneous determinations of mass-dependent isotopic fractionation and radiogenic isotope variation of Sr could become a new tool for geochemical research field.

Stable isotope geochemistry of Nd in various terestrial rocks

S. WAKAKI AND T. TANAKA

Dept. Earth and Environmental Sci., Nagoya Univ., Nagoya 464-8601, Japan. (wakaki@gcl.eeps.nagoya-u.ac.jp)

We have developed a precise Nd stable isotope measurement technique by the combination of TIMS and double spike method to examine the possible Nd stable isotopic variations in terrestrial and extraterrestrial materials. We will report our preliminary results of Nd stable isotope variations on 9 reagents and 8 rock samples including basalt, granite, rhyolite, calcite and dolomite. All the results are expressed as the relative deviations from the isotopic standard reagent JNd-1 in epsilon notation. The reproducibility of ε146Nd was estimated from the repeated analyses of the standard and is ± 0.3 (2SD, n=11).

Six igneous rock samples analyzed so far show no variation in Nd stable isotopic compositions instead of variations in their REE abundance pattern. The average ε146Nd is -0.2, which is slightly lower than that of JNd-1 but within the external 2SD range. Since isotope fractionation effects can be neglected in high-temperature equilibrium reactions, the average isotopic composition of the igneous rocks probably represents the bulk earth Nd isotopic composition. The GSJ reference rock sample JLS-1 (calcite) also has Nd isotopic composition indistinguishable from the igneous rocks.

The isotopic composition of the GSJ reference rock sample JD-1 (dolomite) is clearly different from the other samples ε146Nd = 2.1). Our observation confirmed the previous report using MC-ICP-MS (Ohno and Hirata, 2005). There are three possible scenarios to account for the heavy Nd isotopic enriched Nd in JD-1 dolomite. The first is that the isotope fractionation took place during the re-crystallization reaction of calcite (dolomite precursor), when most of the REEs have included into the calcite from seawater. The second is that the heavy Nd is inherited from the ancient seawater and no isotope fractionation have occurred during the REE concentration by the calcite re-crystallization reactions. The third is that Nd isotopes are fractionated during the dolomitization reaction of the precursor calcite. Since JD-1 and calcite from the same formation both have the seawater-like REE abundance pattern and similar REE concentrations indicating that the REEs of JD-1 are not affected by the dolomitization reaction (Miura et al. 2004), the third scenario is unlikely.
Late Archean molecular fossils from scientific drill cores record the antiquity of microbial diversity

JACOB R. WALDBAUMER, LAURA S. SHERMAN, DAWN Y. SUMNER AND ROGER E. SUMMONS

1Joint Program in Chemical Oceanography, Massachusetts Institute of Technology and Woods Hole Oceanographic Institution, Cambridge MA USA (jwal@mit.edu)
2Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, Cambridge MA USA (sherman3@mit.edu; rsummons@mit.edu)
3Department of Geology, University of California, Davis CA USA (summer@geology.ucdavis.edu)

The Agouron Griqualand Drilling Project has recovered a series of cores from the Neoarchean-Paleoproterozoic sedimentary cover of the Kaapvaal Craton, South Africa. With molecular fossil (biomarker) analysis in mind, this scientific drilling effort took measures from the outset to minimize the potential for organic contamination of the core material. We present the results of organic molecular biomarker analyses of sedimentary rocks from the Transvaal Supergroup, ca. 2.67 to 2.46Ga.

Bitumens from the Agouron cores consistently show syngeneric characteristics over more than 2500m of stratigraphy, despite the very low quantities of hydrocarbon extractable from the Transvaal rocks. These characteristics include high thermal maturity, absence of biomarkers from later-evolving organisms, correspondence between more- and less-matrix-associated bitumen pools, and sharply contrasting composition of overlying strata in the same core. Furthermore, comparisons of biomarker contents in stratigraphically correlated intervals from diverse lithofacies in two boreholes separated by 24km provide strong support their syngenetic nature.

The suite of molecular fossils identified in the late Archean bitumens includes hopanes attributable to bacteria, potentially including cyanobacteria and methanotrophs, and steranes of eukaryotic origin. The presence of fossils of steroids, whose synthesis requires molecular oxygen, suggests that aerobic processes (involving the production and consumption of O2) were underway by the late Archean. This molecular fossil record provides evidence for an origin of the three principal Domains of cellular life in the Archean Eon.

The 187Os/188Os of the convecting upper mantle: An update

RICHARD J. WALKER

Department of Geology, University of Maryland, College Park, MD, 20742 USA (rjwalker@geol.umd.edu)

What is the proportion of recycled oceanic crust that remains isolated within the mantle? Osmium isotopic data relevant to question have been accumulating for more than 40 years. Seminal papers that attempted to estimate the 187Os/188Os of the convecting upper mantle utilized data from Os alloys derived dominantly from upper mantle assemblages to conclude that the upper mantle evolved with a generally “chondritic” Re/Os. This conclusion is too vague to be used to good advantage with respect to oceanic crustal recycling and isolation, yet we have not advanced much beyond it.

Studies of abyssal peridotites, MORB and ophiolites have revealed considerable complexity in the Os isotopic evolution of the convecting upper mantle. For example, although the Os isotopic compositions of MORB and abyssal peridotites overlap, almost all MORB is more radiogenic than abyssal peridotites. Although some of the disparity may be tied to seawater-rock interactions, it is now clear that at least some MORB sources evolved with higher Re/Os ratios than are represented in most abyssal peridotites. Further, the 187Os/188Os of abyssal peridotites are quite variable. Some of these heterogeneities relate to long-term Re/Os variations in the mantle, not seawater alteration. Studies of ultramafic sections of ophiolites have provided complementary data to those from abyssal peridotites and MORB, but individual ophiolites are isotopically heterogeneous and ophiolite materials may not always record primary mantle compositions.

One of the most important recent observations regarding this topic is the documentation that even small domains within the convecting upper mantle develop and retain considerable Os isotopic heterogeneity. This is most clearly revealed in datasets for large numbers of Os-Ir-Ru alloy grains weathered from individual ophiolites, and also in suites of abyssal peridotites from discrete locations. Peridotites from the 6 Ma Taitao ophiolite (Chile) show correlations between melt depletion indicators, such as Mg# of olivines, and 187Os/188Os. This type of correlation has long been observed in samples from the subcontinental lithospheric mantle, but not directly for the convecting upper mantle. Collectively, these results suggest that some chemical heterogeneities related to melt extraction, present at the cm3 to km3 scale, were created and preserved in the upper mantle >1.5 Ga ago. This means that analysis of a limited number of samples from a given location (e.g. an ophiolite) may not yield a meaningful average composition. Based on consideration of the worldwide database for abyssal peridotites and ophiolites, the 187Os/188Os of the convecting upper mantle is ~0.125 to 0.126. This ratio, in comparison to current estimates for primitive upper mantle (>0.129) suggests that mafic slabs that are isolated from the convecting mantle may comprise 5 to 8% of its mass.
Insights into copper isotope fractionation during the oxidative phase transition of chalcocite, using time-resolved synchrotron X-Ray diffraction

A.J. WALL\textsuperscript{1}, P.J. HEANEY\textsuperscript{1}, R. MATHUR\textsuperscript{2} and J.E. POST\textsuperscript{3}

\textsuperscript{1}Center for Environmental Kinetics Analysis, Department of Geosciences, Pennsylvania State University, University Park, Pennsylvania, 16802 (awall@geosc.psu.edu, heaney@geosc.psu.edu)

\textsuperscript{2}Department of Geology, Juniata College, Huntingdon, Pennsylvania, 16652 (MATHUR@juniata.edu)

\textsuperscript{3}Department of Mineral Sciences, Smithsonian NMNH, Washington, D.C. 20013-7012 (POSTJ@si.edu)

The focus of this research is to understand Cu isotope fractionation associated with the oxidative dissolution of secondary copper minerals. As previously shown, chalcocite (Cu\textsubscript{2}S) transforms to covellite (CuS) with a series of intermediate phases by the oxidation of Cu\textsuperscript{+1} to Cu\textsuperscript{+2} and the loss of Cu from the mineral structure. Mathur et al. (2005) have demonstrated that the Cu isotope composition of the solids becomes lighter during this reaction. In this study, we have combined time-resolved X-ray diffraction with Cu isotope measurements to monitor changes to Cu-S mineral structures and the concomitant isotopic fractionation of Cu.

Pure, naturally occurring chalcocite powders were placed in flow-through capillary reaction cells and exposed to various concentrations of aqueous ferric sulfate for up to 2 hrs. Real-time diffraction data were collected at intervals of 2 min at beam line X7B, National Synchrotron Light Source, using a MAR345 imaging plate. The $\delta^{65}$Cu values of the leached Cu as well as the starting and final powders were measured using a Finnigan Neptune multi-collector inductively coupled plasma mass spectrometer.

The powder diffraction data revealed that chalcocite passes through a complex series of partially oxidized intermediate phases during its transformation to covellite using $10^{-2}$ M ferric sulfate. The untreated chalcocite powder had a $\delta^{65}$Cu value of 0.46±0.12‰ and the residual covellite had a $\delta^{65}$Cu value of 0.13±0.12‰. The $\delta^{65}$Cu value of the leachate sampled after 10 min. was 2.46±0.12‰. During the reaction $\delta^{65}$Cu values of the leachate decreased over time. The final leachate sample had $\delta^{65}$Cu values of -2.55±0.12‰. The most significant decrease in $\delta^{65}$Cu values of the leachate occurred during the transition of chalcocite to anilite and corresponded to the period of highest copper yield.

Towards an understanding of biosilicification mechanisms: Nucleation of amorphous silica on organic surfaces

A.F. WALLACE AND P.M. DOVE

Department of Geosciences, Virginia Tech, Blacksburg, VA 24060, USA (afw@vt.edu, dove@vt.edu)

Biochemical investigations have begun to yield information about structural and chemical properties of organic macromolecules involved in biosilicification processes. However, the mechanisms by which these molecules mediate biosilica formation remain unclear. Insights into how mineral formation occurs within living organisms can be gained by conducting experimental studies with simple model systems that emulate key features of biological systems. We employ a novel AFM-based approach to measure the dependence of amorphous silica nucleation kinetics on the chemical and structural nature of the underlying substrate.

The rate of silica nucleation was measured on COOH and mixed COOH/NH\textsubscript{3}\textsuperscript{+} surfaces, under conditions that simulate current views of the chemical environment within silica deposition vesicles of major diatom species (ambient temperature, pH = 5.0, NaCl = 0.1 mol/kg). Markedly faster rates were measured on mixed COOH/NH\textsubscript{3}\textsuperscript{+} surfaces than on either of the end-member films, suggesting that these two functional groups work in concert to promote the formation of silica at these interfaces. Differences between substrate-specific nucleation rates were determined to be controlled largely by kinetic factors rather than thermodynamic drivers. Further experiments with micro-patterned COOH and NH\textsubscript{3}\textsuperscript{-} terminated surfaces also showed that the initial stage of silica deposition occurred at the COOH/NH\textsubscript{3}\textsuperscript{+} interface. Although silica nucleation was not initially observed on purely aminated surfaces, the introduction of orthophosphate triggered the deposition of silica on these surfaces as well.

These results give insight into how silica mineralization may be controlled by organisms like diatoms. Molecules that have been identified as part of the silification mechanism either posses regions of locally concentrated positive and negative charge (silaffins), or require the presence of specific counterions such as phosphate to control silica deposition (polyamines). Phosphate anion has been previously implicated as having a probable role in controlling the self-assembly of these macromolecules into a template for silica deposition. Sites on the organic matrix that have phosphate and amine moieties in close proximity are likely to be points of initial silica deposition. These sites are also probable contact points between the constituent macromolecules in the matrix; hence, deposition of silica in these locations likely serves to cement the molecular elements of the organic matrix together.
Ascent, degassing, crystallization and eruption of H$_2$O-rich mafic arc magma: A melt inclusion perspective

PAUL WALLACE$^1$, EMILY JOHNSON$^1$, NATHALIE VIGOUROUX$^2$ and HUGO DELGADO GRANADOS$^3$

$^1$University of Oregon, Eugene, Oregon, U.S.A.
$^2$Simon Fraser Univ., Burnaby, British Columbia, Canada
$^3$Inst. de Geofísica, UNAM, Ciudad Universitaria, México

Mafic cinder cones are common in subduction-related volcanic arcs. Such cones exhibit a wide range of eruptive styles and are often violently explosive, but the mechanisms driving explosive cinder cone eruptions are still poorly understood, as is the nature of their underlying plumbing systems. Melt inclusions in phenocrysts from tephra deposits provide a record of ascent, degassing and crystallization processes beneath these cones and show evidence for temporal changes in plumbing systems that mirror changes in eruptive style and magma composition.

We have analyzed major elements and volatiles in olivine-hosted melt inclusions from 14 cinder cones in the central and western Trans-Mexican Volcanic Belt (TMVB), including the historic eruptions of Paricutin and Jorullo. Melt inclusions from each cone have highly variable H$_2$O (typically <1 wt% to maximum values of 4 to 5.5 wt%) and CO$_2$ (<50 to 5000 ppm), corresponding to crystallization pressures of <100 bars to ~5 kbars. This indicates that olivine crystallized from variably degassed melts over a range of depths extending from the mid-crust to very shallow levels. The highest CO$_2$ contents (~5000 ppm) are found in potassic minettes and basanites from the western TMVB, whereas values ≤500 ppm are typical of calc-alkaline basalts and basaltic andesites. Modeling of major element variations and comparison to phase equilibria demonstrate that olivine crystallization was driven by H$_2$O loss from melts during ascent. Olivine-melt geothermometry suggests temperatures of 1100-1200°C for these melts at depth. However, such geothermometers must be applied with caution because degassing-induced crystallization during ascent occurs increasingly below the equilibrium liquidus temperature as the melts ascend.

A puzzling feature of the inclusion data is that CO$_2$ does not decrease as rapidly with degassing as predicted by degassing models. A likely explanation involves open-system degassing in which relatively CO$_2$-rich vapor fluxes upwards through the conduit from degassing magma at greater depths. The high magmatic H$_2$O recorded by the inclusions is sufficient to drive explosive violent strombolian eruptions and produce vesicular ash and lapilli. Decreases in olivine crystallization depths over time at some cones reflect evolution of the conduit systems. During early stages, olivine crystallizes over a range of depths and is re-entrained by ascending batches of magma. In later stages, a dike-like storage region of degassed, crystallizing, and more differentiated magma forms at shallow depths beneath the cone.

Silicate weathering in anoxic marine sediments

Two 25 m long sediment cores were taken at the continental slope of Sakhalin. Pore fluids and solids were analyzed to determine the down-core changes in dissolved cations, total alkalinity and particulate metal concentrations. The pore fluids showed consistent enrichments in dissolved Mg, Na, K and alkalinity while the particulate Mg/Ti and Na/Ti ratios decreased with sediment depths. A numerical transport-reaction model was applied to derive rates of silicate weathering from both pore water and solid phase data. The rates derived from pore water data were as high as the rates derived from the independent solid phase data. The depth-integrated rates expressed in terms of CO$_2$ consumption per area and time are close to the average rate of silicate weathering on land. These results imply that silicate weathering in anoxic marine sediments may be as high as continental weathering rates. The pore water modeling further indicates low pH values (6.2 – 6.8) and high concentrations of total dissolved inorganic carbon (100 – 200 mM) in the deeper methanogenic section of the sediment cores. UV adsorption measurements suggest an increase in dissolved humic acid concentrations with sediment depth. Silicate weathering rates were low within the upper sulfate-bearing sediment section and strongly increased below the sulfate penetration depth. It thus seems that silicate weathering may be promoted by low pH values and high concentrations of dissolved inorganic and organic carbon in the methanogenic zone. Most of the silicate minerals deposited in the slope sediments were delivered by the Amur River. The Amur River Basin is characterized by low temperatures and permafrost conditions that may suppress the rates of continental weathering in the drainage area. Our results thus suggest that silicate weathering is shifted from the continental to the marine realm if continental weathering is inhibited by unfavorable climatic conditions and if the silicate minerals are deposited in anoxic marine sediments. This would imply that the negative feedback between silicate weathering and climatic conditions may not be as strong as commonly believed since silicate weathering is not limited to continental areas. Our results further imply that the sequestration of CO$_2$ in marine sediments could be a favorable option since CO$_2$ may be rapidly neutralized in marine sediments.
Methylated arsenic-sulfur compounds in ground water

D. WALLSCHLÄGER AND J. LONDON

Trent University, Peterborough, Canada
(dwallsch@trentu.ca, jacquelinelondon@trentu.ca)

Arsenic (As) speciation was determined by anion-exchange chromatography-inductively-coupled plasma-mass spectrometry (AEC-ICP-MS) in ground waters from a site impacted by methylated arsenic biocides. Aside from the expected four conventional As species arsenite, arsenate, monomethylarsenite (Me1As(V)), and dimethylarsenate (Me2As(V)), up to 9 additional As species were encountered. Among these, the five major species were the As(III) compound monomethylarsenite Me1As(III), and the four thio-substituted methylated As(V) compounds monomethylmonothioarsenate Me1As(V)-S1, monomethylidithioarsenate Me1As(V)-S2, dimethylmonothioarsenate Me2As(V)-S1 and dimethylidithioarseninate Me2As(V)-S2. All five compounds were identified by retention time matching to synthesized standards, and the last four identifications were additionally confirmed by electrospray-tandem mass spectrometry (ES-MS-MS) in collected AEC fractions. None of these As species have been identified in ambient waters before.

These novel As species not only occurred in most of the collected ground water samples, but usually also collectively constituted a major fraction of the total dissolved As concentration (TDAs) present. Average and maximum (in parentheses) relative concentrations measured (expressed in % of TDAs) were 5.3 (39.0) for Me1As(III), 10.2 (43.1) for Me1As(V)-S1, 2.1 (15.1) for Me1As(V)-S2, 3.1 (10.8) for Me2As(V)-S1 and 1.7 (9.0) for Me2As(V)-S2. The highest fractions of metabolites of the original biocides Me1As(V) and Me2As(V) were found in samples with intermediate TDAs concentrations, i.e. between the original emission site and the edge of the propagation plume, indicating that these novel metabolites play a role in the environmental transport and fate of the As biocides at this site. Although Me2As(V) and its metabolites were generally present at lower concentrations than Me1As(V) and its metabolites (as a result of the emission history), the fraction of dimethylated metabolites was higher on average than that of monomethylated metabolites, indicating that Me2As(V) is more reactive in the observed transformations than Me1As(V).

A preservation study of six selected samples over a period of 24 weeks showed that the novel As species were reasonably stable in unpreserved samples, but had a tendency to convert back to their original precursors, Me1As(V) or Me2As(V), respectively, over time. Cryofreezing on-site generally seemed to yield the best As speciation preservation, but unpreserved samples yielded comparable results. Acidification caused immediate and significant changes in As speciation, and must consequently be avoided for sites where these novel As species are or may be present.
How transition metals affect algal external carbonic anhydrase
B. Wang1, C.-Q. Liu1 and Y. Wu2

1State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, CAS, Guiyang 550002, China
(wangbaoli@vip.skleg.cn; liucongqiang@vip.skleg.cn)
2Institute of Agriculture Engineering, Jiangsu University, Zhenjiang 212013, China (yanyouwu@ujs.edu.cn)

Study aims
1) Effect of transition metals on the activity of external carbonic anhydrase (CAe) of alga C. reinhardtii; 2) The ways of transition metals affecting alga CAe.

Results and discussion
Our results are shown in the table below. The data have demonstrated that the extent of transition metals influencing CAe is different and the magnitude in which these transition metals affect CAe depends on the concentration. Transition metals influence the activity of CAe by two ways: (1) directly operating on CAe at cellular surface, (2) indirectly interfering in the metabolism of CAe in algal cell.

Significant difference # between metal-excessive (20µmol/L or 100µmol/L) and normal culture condition and *between "Before" and "After" (Tukey, P<0.05). "Before" is the relative activity of CAe from C. reinhardtii that was exposed to transition metals for 24 hrs before extracting; "After" is the relative activity of CAe that was exposed to transition metals after being extracted from C. reinhardtii.

Conclusions
Effect of transition metals on CAe is species-specific. Cu and Ni affect CAe by way (1); Zn by way (2); Cd by way (1) and (2); and Mn, Fe, and Co at least by way (1).

To harmonize the water resources system of Lake Taihu basin in China using circular economy notion
D. Wang1, J. Wu1, Y. Shi2 and Z. Gong3

1Department of Earth Sciences, Nanjing University, Nanjing, 210093, China (wangdong@nju.edu.cn; jcwu@nju.edu.cn)
2College of Geography and Marine Sciences, Nanjing University, Nanjing, 210093, China
3Taihu Basin Authority of Ministry of Water Resources, Shanghai, 200434, China

Lake Taihu basin is located at the south end of the Changjiang River Delta in China. In recent years GDP and finance incoming of this place is almost more than 10% of the total amount of the country, accounting only 0.4% for the areas and 3% for the population. It became one of the most developing and densely populated area. However, with the rapid economic development, the water resources system of Lake Taihu basin experiences a degenerate period from 1960. The water quality standard lowered 1 level every 10 years, and this is obviously more serious in recent years. How to control the degeneration in order to use water resources more scientifically and efficiently is drawing great attention among researchers both in China and overseas.

Figure 1: Variation over past 25 years of total nitrogen (TN) in Taihu Lake in China (unit: mg/L)

It is believed that, to restore the degenerated water resources system of Lake Taihu basin, circular economy notion must be used and insisted on. It relates to all kinds of measures such as law, administration, engineering, economy, science and technology, etc. Here only two of them are emphasized as following. (1) Integrated management of water resources. (2) Insisting on “3R Principle”, saving and using water scientifically.
Earliest geological record in North China Craton: 4079 Ma
Zircon U-Pb age

Evolution of early solid Earth is vital in the research of Precambrian geology. To date rocks older then 4.0 Ga have been only reported from Acasta gneisses in the Wopmay Orogeny of Canada, with a formation age of 4016 Ma representing the oldest crust record in North America, and detrital zircon with age from 4.1 to 4.4Ga are reported only from Jack Hill of the Yilgarn Craton (Compston and Pidgeon, 1986; Wilde et al, 2001) and South Tibet of China (Wen et al, 2006). It is worth to note, all these detrital zircons Older than 4.05 Ga are from Gondwanaland.

Here we report a zircon with LA-ICP-MS U-Pb age of 4079±5Ma, from the south margin of the North China Craton (NCC). The zircon is a fragment with size of 100×150 µm have clear core-mantle structure. It is xenocrystal zircon from a 456.4Ma andesite from Caotangou group, West Qinling belt along the south margin of NCC. Moreover, a variety of age is dated from the inherited xenocrystal zircons, including 3233Ma, 2788Ma, 2739Ma and 2714Ma (table 1). It is an age set earliest crustal record in North China Craton: 4079 Ma.

Solar wind Mg, Cr and Fe abundances in diamond-like carbon collector from Genesis mission

J. WANG1, L. R. NITTLER1 AND D. BURNETT2
1Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015, USA (jwang@dtm.ciw.edu)
2Geological and Planetary Sciences, Caltech, Pasadena, CA 91125, USA (burnett@gps.caltech.edu)

The chemical composition of the Sun provides the reference standard for a wide variety of astronomical, cosmochemical and geochemical studies. To better determine the solar composition, the Genesis spacecraft collected solar wind at the L1 point in space for 27 months from December 2001 to April 2004. Prior SIMS analyses of Genesis samples have found discrepant results for the Mg and Fe solar wind fluences from different collector materials (Burnett et al., 2007). We measured Mg, Cr and Fe abundances in a diamond-like carbon collector (sample 60062) using a CAMECA NanoSIMS 50L ion microprobe. A 4 nA -16kV O+ primary beam of about 2 µm in diameter was rastered at 25×25 µm2 on the sample surface. Positive secondary ions were extracted from the central 25% of the rastered area and measured with a double-focus multi-collector mass spectrometer. Masses 12C, 24Mg, 25Mg, 52Cr, 54Fe and 56Fe were measured simultaneously to a depth of about 500 nm from the surface. 25Mg and 54Fe implanted standards were measured before, after and in between sample analyses to quantify relative fluences. We analyzed 10 craters with one showing abnormally low 12C count rates and thus excluded. One crater showed significant surface contamination of Fe and no Fe data could be deduced. We found a Mg fluence of 4.3±0.26×1012 cm-2 and an Fe fluence of 2.39±0.15×1012 cm-2 for sample 60062. These are in good agreement with previous measurement of the same samples by ims-6f (Burnett et al., 2007). As seen before, the fluences derived from diamond-like C are higher than those from Si collectors; an explanation for this discrepancy is still lacking but the results from Si are preferred. We also collected 52Cr depth profiles. Since no Cr implant standard was available at the time of our analyses, we estimated a Cr fluence of 2.4×1013 using the relative Cr/Fe sensitivity factors in diamond of Wilson (1995). This is 4 times higher than the photosphere value (Asplund et al., 2005). However, surface contamination for this sample is apparently a contributing factor. Analyses of additional elements and collector materials will be conducted to get accurate data of the solar wind composition and to understand differences between different collectors.

The quarterly radiocarbon record in a coral from Daya Bay

N. WANG1,2, C.D. SHEN1, W.D. SUN1 AND P. DING1,2

1Key Laboratory of Isotope Geochronology and Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China (weidongsun@gig.ac.cn)
2Graduate University of Chinese Academy of Sciences, Beijing, 100049, China (bin@gig.ac.cn)

This study established 14C, Sr/Ca and Mg/Ca time series for a coral (Porites) from Daya Bay in the South China Sea, covering about 10 years from 1994 to 2004. About 12 samples/year were analyzed for Sr/Ca, Mg/Ca. By contrast, only 38 samples (~4 samples/year) were analyzed for Δ14C, because of larger amount of sample required. The Sr/Ca and Mg/Ca series display clear seasonal signals. There is also an abnormal segment (from 1996 to 1998) in the Sr/Ca and Mg/Ca records, probably reflecting an El Nino event. Seasonal variations of Δ14C were observed between 1999-2004 (Fig. 1). The Δ14C is higher in winter (low sea surface temperature, SST), which descends sharply in summer (high SST). Considering that summer is the upwelling season, the seasonal variations in Δ14C are probably due to the low 14C abundance in the upwelling coming from the deep marine. Consistent with Sr/Ca, Mg/Ca, the seasonal variations in Δ14C is not significant between 1996-1998, possible also due to the El Nino event.

Figure 1: The result of the Sr/Ca and Mg/Ca ratio and Δ14C record in the coral from the Daya Bay.

Mineral compositions and geochemical features of Sanhe bauxite deposit in western Guangxi province

QINGFEI WANG1,2, JUN DENG1,2, QINGJIE GONG1,2, QIZUAN ZHANG1,2, LI WAN1 AND BANGFEI GAO1,2

1State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (wqingfei@vip.sina.com; djun@cugb.edu.cn)
2Faculty of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China

The resources of accumulation-type bauxite deposits developed in Karst topography in the west of Guangxi province are abundant, and the area serves as an important bauxite base in China. The Sanhe bauxite deposit of accumulation-type is a representative one in western Guangxi province; we collected more than 20 pieces of ore samples to study the mineral compositions and geochemical features of the deposit. By slice observation, powder X-ray diffraction analysis, electron probe microanalyser (EPMA) and the major elements testing, we have determined the mineral compositions and contents: Diaspore about 68%, clay minerals (mainly kaolinite and chlorite) 14%, titania minerals (rutile or anatase) 9%, ferric oxide and ferric hydroxide minerals (mainly goethite and hematite) 6%, and gibbsite 3%. The major elements testing mainly by X-ray Fluorescence Spectrometer and the energy dispersive analysis of scanning electron microscopy show that the content of Al, Fe, Si, Ti goes down in turn; The ores mostly consist of Al2O3, Fe2O3, SiO2, TiO2 and H2O+, counting up for 98.51~99.55% of the total mass; the content of Al2O3 is 43.37~73.27% with the average of 54.75%, the value of Al2O3/SiO2 falls into 3.51~18.01, and there is a negative correlation between Al2O3 content and SiO2 content. The ores’ CIA indexes are all greater than 98%, indicating the maturity of ore’s chemical composition is relatively high. Based the counts of the elements via EPMA line analysis, using the method of moments of multifractal, the spatial changes of elements Al, Ti are analyzed; choosing weight -5 ≤ q ≤ 5, it can be seen that the width of multifractal spectrum of element Ti is 0.46, and 0.04 of Al, which shows that Ti element distribution is much more random than that of Al. The content ratios of Al2O3 ( or TiO2) to Zr, Hf, Nb and Ta in the ores are basically the same as those of the underlying limestone of Permian Maokou formation, which means the two are homologous. The gross content of ore rare-earth elements (ΣREE) varies a lot, light rare-earth elements (LREE) are enriched and the anomalous positive Ce is pronounced; all above demonstrate that the ore deposit has experienced an oxidized leaching process.
The composition and texture constrains on micro-porosities of dolomite reservoirs, Tarim Basin, NW China

X.L. WANG, W.X. HU, W.L. ZHANG AND J.T. ZHANG
Department of Earth Sciences, Nanjing University, Nanjing 210093, China (wangxiaolin@nju.org.cn)

Lower Paleozoic carbonates act as high quality reservoir rocks in the Tarim Basin, NW China. As they are mostly deeply buried up to ca. 5000 m, a long and complex diagenetic history must have happened. Consequently, the primary pore spaces of such carbonates were generally disappeared due to compaction and cementation. Thus, secondary porosities mainly caused by dissolution are important for petroleum accumulation as suggested by some authors. According to this research, the vuggy porosity is mainly resulted in diverse-dissolution between calcite and dolomite during burial. And the composition and texture of the dolomite have effective constrains on this process despite of the influence of geo fluids.

Based on the observation of cores and the analysis of logging data, the dissolved micro-porosities do not show an uniform occurrence. Specifically, it is well developed in the transition interval from limestone to dolomites of Lower Ordovician Yingshan Formation, where limestone, calcareous dolomite and dolomite are inter-bedded. It is common to observe intergrowth of the calcites and dolomite minerals, and the residue of calcite dissolution is obvious but the dolomites usually remain good rhomb crystals, which indicates that the calcite is much easier to be dissolved during burial than dolomite. And the dolomites act as framework to support the pores created by the calcite dissolution. Therefore, the composition of the carbonates has important influence on the formation of the porosities, and the calcareous dolomite could be good carbonate reservoir in the basin.

However, not all the calcareous dolomite could produce high porosity and permeability, and the carbonate texture must be also taken into account. By EPMA analysis and observation, the calcite minerals show different occurrences, some of which occur in the dolomite intercrystalline pores, and the others are scattered in the dolomite crystals. Then, the dolomites can be subdivided into three groups: intercrystalline filling type (type I), intracrystalline filling type (type II) and intra-and-intercrystalline filling type (type III). The calcite of type I is much easier to be dissolved than that scattered in the dolomite. It is suggested that the fluids could not easily dissolve the dolomite crystals so as to dissolve the calcite in them. As a result, the Type I and type III dolomites could become good reservoirs in this basin.

Rodinia mantle plume: New evidence from the ~825Ma komatiitic basalts in South China

X.C. WANG 1,2, X.H. Li1, W.X. Li1 and Z.X. Li 3
1Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China (xuancewang@gig.ac.cn; lixh@gig.ac.cn; liwx@gig.ac.cn)
2Graduate School of the Chinese Academy of Sciences, Beijing 100039, China
3Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia (Z.Li@exchange.curtin.edu.au)

Mantle plume or superplume activities have repeatedly been invoked as a cause for the breakup of the Neoproterozoic supercontinent Rodinia, with supportive evidence including radiating dyke swarms, globally-synchronous anorogenic igneous activities, large-scale lithospheric doming and unroofing, and geochemical signatures similar to recent plume-related magmatism. However, identification of the Precambrian mantle plumes has been difficult owing to modifications by younger geological processes, and thus the lack of more diagnostic plume-induced petrological records(high-temperature melts), such as picrites and/or komatiites has been a major argument against the Neoproterozoic South China plume model.

We present here geochronological and geochemical data from a komatiitic basalt suite of pillowed lavas in central South China. SHRIMP U-Pb dating of zircons from an evolved member of andesitic composition within this suite indicates that these lavas were erupted at 823 ± 6 Ma. All but a few highly-evolved, crust-contaminated basaltic rocks are characteristically high in MgO (10.2-17.5 %), Ni (183-661 ppm) and Cr (677-1672 ppm), low in TiO2 (0.5-0.7%), Al2O3 (10.6-12.7%) and FeO T (7.4-10.5%). By removing the effect of ~5% olivine crystallization, the Yiyang primary magma has typical komatiitic compositions with MgO ≈ 20%, FeO T ≈ 11%, SiO2 ≈ 47%, TiO2 ≈ 0.48%, Al2O3 ≈ 10%, Ni ≈ 800 ppm and Cr ≈ 1780 ppm. Such a high MgO content in the primary melts implies a melt temperature of >1500°C, suggesting that the Yiyang komatiitic basalts should have been generated by melting of an anomalously hot mantle source with potential temperature (Tp) being 260 ± 50°C higher than the ambient MORB-source mantle, similar to that of modern mantle plumes.

Our identification of the 823±6 Ma Yiyang komatiitic basalts, generated by ~825 Ma mantle plume, provides for the first solid petrological evidence to constrain the controversy of the tectonic provenance of Neoproterozoic volcanism and sedimentation within the South China Block (the combined Yangtze and Cathaysian Cratons) with direct bearing on Rodinia reconstruction models.
U-Pb zircon age of the metapelites and granitic gneisses from Nyalam High Himalayan Series and their significance to the early Palaeozoic tectonic evolution

YANBIN WANG
Beijing SHRIMP Center, Institute of Geology, Chinese Academy of Geological Sciences, China
(yanbinw@cags.net.cn)

The Nyalam High Himalayan Crystalline Series lies in Southern Tibet (roughly 28°N, 86°E) along the China-Nepal highway. These series include pelitic schists and gneisses, augen granitic gneisses, calcareous schists, marbles and quartzites that have been intruded by tourmaline-bearing leucogranites. There are not the isotope ages of the metapelites and the granitic gneisses from Nyalam High Himalayan Series in the Southern Tibet. The study of the zircon cathodoluminescence images from the metamorphic sedimentary rock show that there are complex textures. The dating results indicate Pan-African thermal events record in the zircon. A Pan-African periods deposition age (ca. 0.50 Ga) is inferred from the age of the metapelites. Zircon SHRIMP U-Pb dating yielded an age of 478.2±4.4 (2σ) Ma for the granitic gneisses.

U-Pb ages of detrital zircons show different peak (2.4 Ga, 1.6 Ga, 0.8 Ga and 0.50 Ga), suggesting that the detrital archive records the geological event history of its source region. The 0.5 Ga zircon grains with oscillatory zoning, uniform and concordant U-Pb systems, igneous Th-U ratios, are interpreted as primary magmatic zircons.

During the Pan-African periods, the northern part of India was affected by a Pan-African event. Numerous granitic intrusions dated at around 0.5 Ga are attributed to this event. The Pan-African event is marked by an unconformity between Ordovician continental conglomerates and the underlying Cambrian marine sediments. It is tempting to correlate the early Palaeozoic thermal event with the formation of the Gondwana supercontinent.

The protolith age of the High Himalayan metamorphic rocks is generally regarded to be Precambrian to early Palaeozoic. It seems plausible that the High Himalayan metamorphic rocks represent a minimum depositional age at ~0.5 Ga. 478 Ma granitic gneisses is assigned to an important orogenic event, the early Palaeozoic thermal event indicate that early Palaeozoic tectonism has played an important role in shaping the Himalayan orogen.

Evidences of Ghronology and Isotopic geochemistry of Bogda Rift Closure and Regional Uplift, Xinjiang

YIN-XI WANG1*, LIAN-XING GU2, ZUN-ZHONG ZHANG2, CHANG-ZHI WU2 and HUI-MING LI1

1Center of Modern Analysis (yxwang@nju.edu.cn), 2State Key Laboratory of Mineral Deposit Research, Nanjing University, Nanjing 21009, P.R. China

The Bogda Mountain, with Junggar basin on the north and Turpan-Hami basin on the southwest, is a part of the East Tianshan Mountains. The Dashtou-Shepikou area belong to the northern part of the eastern section of the Bogda orogen. Rhyolite of the Dashtou group gave a Rb-Sr age of 306.7±2.3Ma, and thus is suggested to have been produced at the uplifting stage following the closure of the Bogda rift. With ɛNd (t) of +5.30~6.40, (87Sr/86Sr)i of 0.703289~0.703496, (206Pb/204Pb)i of 15.524~15.567, 207Pb/204Pb), of 15.524~15.567 and (208Pb/204Pb), of 37.198~37.810, the rhyolite is comparable in Nd, Sr and Pb isotopes to the basalt and rhyolite of the Lower and Middle Carboniferous Qijiaoqiang formation that were formed during extension and subsidence of the Bogda intra-continental rift. Minor rhyolite accompanying a large amount of basalt in the Qijiaoqiang formation are thought to have been produced by fractional crystallisation of the basaltic magma, but a large quantity of rhyolite accompanied by very minor basaltic rocks precludes their formation by fractional crystallisation of basaltic magma. These data indicate that the rhyolite is similar in Nd-Sr-Pb isotopes to the rhyolite [1,2] that was formed by fractional crystallisation of the basaltic magma. The rhyolite of the Dashtou group is likely to have been derived from an underplated basaltic body by remelting of this body in response to mantle heating. Highly positive ɛNd (t), and negative ɛSr (t) (low 87Sr/86Sr initial ratio), and low Pb isotope ratios suggested that, like the pre-collision basalt of the Qijiaoqiang formation, the mantle magma underplated at the uplifting stage following the closure of the Bogda rift.

Iron (oxyhydr)oxides widely occur in earth’s surface environments, including soils, sediments and aquifers. Owing to their large specific area, these minerals can adsorb efficiently trace elements, as arsenic. Microorganisms are able to (trans)form iron minerals, directly by enzymatic oxidation or reduction and indirectly by complexation to organic compounds, and thus potentially play an important role in the cycling of iron and of associated trace elements. For example, bio-reduction of ferric (oxyhydr)oxides is known to be responsible for arsenic contamination of some important groundwater resources throughout the world.

We will present recent investigations of model systems relevant of arsenic behavior in anoxic soils and sediments. X-ray Absorption Spectroscopy (XAS) and transmission electron microscopy, are used to elucidate the molecular scale mechanisms of arsenic immobilization upon reduction of arsenic bearing iron oxyhydroxides. The results suggest that, in the presence of a sufficient amount of iron in the system, adsorption and co-precipitation reactions of both As(III) and As(V) with Fe(II)/(III) minerals may delay arsenic release in anoxic environments. Other processes, including the progressive leaching of iron, may thus influence arsenic mobility in these environments.

Pb-Sr-Nd Isotopic Composition of I-Type and S-Type Granites in Eastern Segment of East Tianshan Belt

Y.-X. WANG, L.-X. GU, Z.-Z. ZHANG AND H.-M. LI

Department of Earth Sciences, Nanjing University, Nanjing 21009, P.R.China (wyxn@sohu.com)

This paper reports the Pb-Sr-Nd isotopic composition of I-type and S-type granites in eastern segment of east Tianshan Belt, China. Systematical research on Pb-Pb, Rb-Sr and Sm-Nd isotopes and the crustal growth age were made on six granitic intrusions in the eastern segment of middle east Tianshan belt. Pingdingshan augen-gneissic monzonitic granite, Back hill gneissic granodiorite and Tianhudong gneissic granodiorite, with (206Pb/204Pb)\textsubscript{i} of 18.356 ~ 18.426, (207Pb/204Pb)\textsubscript{i} of 15.697 ~ 15.867 and (208Pb/204Pb)\textsubscript{i} of 38.623 ~ 38.817 ε\textsubscript{Nd (t)} of -3.7 ~ -7.8, (87Sr/86Sr)\textsubscript{i} of 0.712632 ~ 0.718410; T\textsubscript{Nd(DM)}=1.81 ~ 2.05 Ga; Shalongdong monzonite, with (206Pb/204Pb)\textsubscript{i} of 18.015 ~ 18.182, (207Pb/204Pb)\textsubscript{i} of 15.426 ~ 15.591 and (208Pb/204Pb)\textsubscript{i} of 37.67 ~ 37.824, ε\textsubscript{Nd (t)} of +2.4 ~ +2.7, (87Sr/86Sr)\textsubscript{i} of 0.703710 ~ 0.703853, T\textsubscript{Nd(DM)}=0.82 Ga; Weiya manzonitic granite(center zone) and Weiya manzonitic granite (internal zone), with (206Pb/204Pb)\textsubscript{i} of 18.181 ~ 18.293, (207Pb/204Pb)\textsubscript{i} of 15.492 ~ 15.612 and (208Pb/204Pb)\textsubscript{i} of 37.804 ~ 37.973, ε\textsubscript{Nd (t)} of -0.9 ~ -1.0, (87Sr/86Sr)\textsubscript{i} of 0.704733 ~ 0.704831; T\textsubscript{Nd(DM)}=0.3 79-0.380Ga. In combination with the geological evidence and other geochemical date, it is believed that the granites in eastern segment of middle east Tianshan belt are composed of granitoids of different ages, different genesis, and different source materials. Pingdingshan augen-gneissic monzonitic granite, Back hill gneissic granodiorite and Tianhudong gneissic granodiorite belong to S-type granites or a transformation type and are mainly autoch-paraautochthonous Syntectonic granites characterized by gneissic structure. Shalongdong monzonite belongs to I-type granites or syntactic type derived from a differentiated mantle magma assimilated and contaminated with crustal materials. Weiya manzonitic granites possibly belong to I/S-type granites or an intermediate type between I-type and S-type. The only difference in I-type and I/S-type is that the Weiya manzonitic granites have a higher crustal component to mantle component ratio than that of Shalongdong monzonite.

Nd-Sr-Pb Isotopic Geochemistry and Rb-Sr age for Late Cretaceous volcanic rocks in King George Island, Antarctica

YIN-XI WANG¹², HUI-MING LI¹, NIN-XI ZHAO³, JIE-DONG YANG¹ and YAN-BIN SHEN³

¹Center of Modern Analysis, State Key Laboratory of Mineral Deposit Research, Nanjing University, Nanjing 21009, P.R. China (yxwang@nju.edu.cn)
²School of Geographic and Oceanographic Sciences, Nanjing University, 210093, China
³Nanjing Institute of Geology and Palaeontology, Academia Sinica, Nanjing 210008, China

Introduction and Analytical Method

The samples used in this study were all collected from the Half Three Point Formation of the Fildes Peninsula, King George Island, Antarctica and were attributed to the Upper Cretaceous formation. Analysis of Nd, Sr and Pb isotope compositions were performed on an automated multi-channel mass spectrometer VG 354 at Center of Modern Analysis, Nanjing University. \(87\text{Sr}/86\text{Sr} = 0.710224 \pm 0.00062 (2\sigma)\) for NBS987 standard. \(43\text{Nd}/144\text{Nd} = 0.512465 \pm 0.00012 (2\sigma)\) for BCR-1 standard. \(206\text{Pb}/204\text{Pb}=16.939\pm0.010, 207\text{Pb}/204\text{Pb}=15.489\pm0.029\) (n=20).

Discussion of Results and Conclusion

Fitting together of Rb-Sr isochron dating of the tuffite samples measured result: \(t=71.33\pm0.3\text{Ma}, \ 87\text{Sr}/86\text{Sr} = 0.70314\pm10 (2\sigma)\). Thus, the age date is reliable, which indicate the stratigraphic age of the volcanic sedimentary rock from the Half Three Point Formation, coinciding with that of date indicated spore pollen [1]. It is further proved that the activity of the volcanic eruption in Fields Peninsula began at least in the Late Cretaceous and not in the Tertiary age. With \(\varepsilon_{\text{Nd}}(t)\) of +5.53 ± 6.15, \(\left(40\text{Sr}/86\text{Sr}\right)_{\text{i}} \approx 0.703139 \approx 0.703148, \ (206\text{Pb}/204\text{Pb})_{\text{i}} \approx 18.028 \approx 18.316, \ (207\text{Pb}/204\text{Pb})_{\text{i}} \approx 15.329 \approx 15.462\) and \(208\text{Pb}/204\text{Pb}_{\text{i}} \approx 37.091 \approx 37.612\), the tuffites are comparable in Nd, Sr and Pb isotopes to the basalt of the Lower and Middle Carboniferous Qijiaojing formation [2] and some mid oceanic ridge basalt ratio, and these matters were chiefly derived from the depleted mantle.

Putting diffusive Re-Equilibration to work: Determination of entrapment pressures of olivine-hosted melt inclusions

ZHENG RONG WANG, GLENN GAETANI AND NOBU SHIMIZU

Woods Hole Oceanographic Institution (zwang@whoi.edu; ggaetani@whoi.edu; nshimizu@whoi.edu)

Silicate melts entrapped in olivine phenocrysts provide snapshots of melt generation, transport and mixing processes. The range of compositional and isotopic variability they preserve far exceeds that in erupted lavas, demonstrating partial melting is near-fractional and the upper mantle is heterogeneous. However, the conditions at which these diverse melts are aggregated to produce basaltic lavas remain an open question. Here we present a new method for determining the entrapment pressures of olivine-hosted melt inclusions and, thereby, constrain the conditions at which mantle melts aggregate prior to eruption. Application of this approach to melt inclusions from the Western Reykjanes Peninsula indicates that they formed at pressures of 2-4 kbars.

Entrapment pressures are determined by first heating inclusion-bearing olivines at the estimated liquidus temperature of the host lava for several days to produce local equilibrium between the inclusion and adjacent crystal. The major element composition of structurally intact inclusions and the adjacent olivine are then determined by electron microprobe. These compositions and the furnace temperature are used to solve for pressure using a new model for the partitioning of Fe and Mg between olivine and silicate melt, calibrated using both new experiments and those from the literature.

This approach has been applied to olivine-hosted melt inclusions from a picritic lava erupted on the Western Reykjanes Peninsula of Iceland. These inclusions have \(K_{2}O/TiO_{2}\) ratios of 0.1405±0.0003 to 0.2545±0.0014, demonstrating that each represents a distinct melt, and that all are different from the host lava \((K_{2}O/TiO_{2} = 0.024)\). Our calculations indicate that these inclusions were entrapped at pressures of 2-4 kbar, so that aggregation of these diverse melts was a late-stage process that occurred at crustal conditions.
Measurement of $^{226}$Ra using a RaDeCC and its application for tracing submarine groundwater discharge

H. WASKA$^1$, S. KIM$^2$, D. W. HWANG$^3$ AND G. KIM$^4$

School of Earth and Environmental Sciences/RIO, Seoul National University, Korea ($^1$hwaska@snu.ac.kr, $^2$ss4eva@snu.ac.kr, $^3$dwhwang@snu.ac.kr, $^4$gkim@snu.ac.kr)

A delayed coincidence counter (RaDeCC), which previously had been developed to determine ultra-low levels of $^{223}$Ra and $^{224}$Ra in seawater (Moore and Arnold, 1996), was used in a new way to measure $^{226}$Ra. Using a high speed Ra extraction system, Ra was pre-concentrated from a large volume of seawater (> 100 L) onto MnO$_2$-coated fibre. After the measurement of $^{223}$Ra and $^{224}$Ra with the RaDeCC, we show in this study that the $^{226}$Ra activity in the same sample can be successfully determined using the RaDeCC’s ability to record alpha decay of its daughters as total counts. In order to have enough ingrowth time of $^{222}$Rn, the column containing the MnO$_2$-fiber is hermetically sealed for a few days. The ingrown $^{222}$Rn is circulated through the RaDeCC air-loop system for ten minutes followed by shutting down of the pump and closure of the scintillation cell. Counting may be completed within a few hours for $^{226}$Ra in normal seawaters. With a standard calibration, the results from this method were in good agreement with the data obtained from another verified method using a radon-in-air monitor (RAD-7). In addition to this development, we present $^{226}$Ra data from Gamak Bay (South Sea of Korea), which has been acquired with the new RaDeCC method. A mass balance model for $^{226}$Ra in the bay reveals that the input of SGD in the shallow area (< 5 m water depth) was about 1.2-1.9 x 10$^7$ m$^3$ day$^{-1}$ in spring and summer 2006, which was two orders of magnitude higher than the total stream discharge (0.27–0.30 x 10$^5$ m$^3$ d$^{-1}$) during the study period.

No matrix-like rims on CR chondrules

JOHN T. WASSON AND ALAN E. RUBIN

University of California, Los Angeles, CA 90095-1567, USA. (jtwasson@ucla.edu; aerubin@ucla.edu)

In the past it was widely held that chondrules are surrounded by compact matrix-like rims that formed in the solar nebula [1]; the most dramatic evidence was presented by Metzler et al. [2] for rims on CM chondrules. These thick rims are envisioned to have formed one grain at a time [3]. However, simulations and physical modelling show that the accretion of small (≤1 μm) grains produces structures with high porosities of >80%, far higher than observed (~14%) in the fine matrix of chondrites or in the purported matrix-like rims [4]. Trigo-Rodriguez et al. [5] presented evidence and arguments supporting the alternative interpretation, that CM matrix (~35 vol%) was compacted by asteroidal impacts rather than in the nebula, and that the rims surrounding most chondrules were the result of enhanced compaction near incompressible objects such as chondrules. In BSE images these compacted "rims" are darker than surrounding matrix.

A problem with studying matrix in CM chondrites is that they have experienced extensive aqueous alteration. On the other hand, in some primitive chondrites of type 3.0 or 3.1 that have experienced little aqueous alteration there is very little matrix making its chemical study and the petrographic comparison of matrix and possible rims very difficult. We have therefore focused our study on the CR chondrites, which have large amounts (~32 vol%) of matrix and large intact chondrules but have experienced much less aqueous alteration than CM chondrites. In our section of CR LAP02342 most chondrules show no textural evidence of being surrounded by rims. Potential rims are small in thickness and irregular.

Models of the formation of radially symmetric rims in the nebula require them to form one grain at a time [3] and thus be compositionally homogeneous. We have surveyed random spots in the matrix and compared them to regions near chondrules (i.e., possible rims). There is a relatively large degree of variation in matrix composition, and this carries over to the rims as well. In some cases matrix on opposite sides of a chondrule showed resolvable differences in composition, inconsistent with symmetric formation. If rim formation was not occurring at the CR-chondrite formation locations, it is unlikely that rims formed around chondrules at other locations.

The role of organic ligands in Fe isotope fractionation during dissolution of hornblende

L.E. Wasylenki1, A.D. Anbar1,2 and S.L. Brantley3

1School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA 85287-1404
2Dept. of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1604
3Dept. of Geological Sciences, Pennsylvania State University, University Park PA USA 16802

Dissolved Fe in some rivers is isotopically light by ~ 1 %o (δ56/54Fe) compared to average crustal Fe [1,2]. Fe isotopes are thus fractionated by one or more processes during weathering of crustal rocks, resulting in preferential transport of light isotopes of Fe toward the oceans and retention of heavy isotopes in weathering residues. Our ability to understand the Fe isotope budget of the crust-ocean-biosphere system, past and present, depends critically on understanding how isotope effects originate during weathering of major Fe-bearing crustal minerals.

An experimental study of hornblende dissolution by Brantley et al. [3] suggests that Fe-binding ligands play an important role not only in promoting dissolution of Fe-bearing silicate minerals, but in fractionating Fe isotopes. In those experiments, which were 4-6 days long, hornblende dissolved in the presence of acetic, oxalic, or citric acid or a siderophore molecule, desferrioxamine B. Fe-release rates correlated with Fe-binding affinity. In addition, the results suggested a relationship between Fe-binding affinity and the Fe isotope composition of the Fe released into the solvent medium. Brantley et al. hypothesized that fractionation occurs during incongruent dissolution of hornblende and that the isotope effect should decrease over time as Fe concentration in the leached layer approaches steady state.

To test this hypothesis, we have extended these experiments from 4-6 days to 70 days. We see a continuation of the relationship between Fe-release rates and Fe-binding affinity up to 22 days, beyond which precipitation of Fe (oxyhydr)oxides obscures the effect. Isotopic analyses of the solvent media up to 22 days will reveal whether the isotope effect indeed diminishes as dissolution progresses toward a steady-state leached layer. Whether this happens or not is important for constraining the mechanism of isotope fractionation. Understanding this mechanism is key to predicting how isotope effects in natural weathering environments influence the Fe isotope budget of natural waters. In addition, if siderophores leave a distinct isotopic fingerprint on weathering residues, as suggested by our preliminary work, it may be possible to detect where and when such molecules were produced in the past.

Non-heterogenous oxygen isotopic distribution in coral microstructures

T. Watanabe, K. Sowa, N. Sakamoto and Y. Yurimoto

Dept. Natural History Sciences, Graduate School of Science, Hokkaido University (nabe@mail.sci.hokudai.ac.jp)

Massive corals have been widely used as proxies for past changes in sea surface temperature (SST) of the tropical and subtropical oceans because the oxygen isotopic and strontium/calcium (Sr/Ca) ratios of their aragonitic skeletons are believed to vary as a function of the temperature of the ambient seawater. However, recent microanalytical studies using secondary ion mass spectrometry (SIMS) have revealed large chemical heterogeneities for Sr/Ca and oxygen isotopic ratios in coral skeleton, which cannot be explained by temperature variation (e.g. Meibom et al., 2004, Rollin-Bard, et al., 2003).

We report the micro-scale image of oxygen isotopic distribution within the two basic building blocks of the coral skeleton; centres of calcification (COC) and fibers. With Hokudai isotope microscope (Cameca ims 1270 + SCAPS), obtained image for relative 83O/86O ratio in the microstructure of coral Porites ,which is the most widely used species for paleoclimatic studies, shows small variation in COC and few isotopic difference between COC and fibers at least within ~1 %. This result is inconsistent with the large oxygen isotope heterogeneities previously reported (Rollin-Bard, et al., 2003, Meibom et al., 2006), although their spot analysis could not capture full image of oxygen isotopic composition in COC. These recent works suggested that coral biomineralization processes are governed strongly by biological control (Meibom et al., 2006) or rapid environmental changes (Rollin-Bard, et al., 2003) occurred in ultra structure level. Therefore, it implied that such heterogeneities must mask significantly geochemical signal for reconstructing past temperature changes. However, our result indicates that in the case of coral Porites, such dynamic process seem not to be happened, or even happened in some degree, oxygen isotopic ratio in coral skeletons could be still robust paleoclimatic proxy for tropical SST, which play important role for understanding earth climate system. Further investigations using these microanalytical technique with ion probe can provide important informations for establishing new biomineralization model and help constrain the degree to which temperature and/or biological processes affect the composition of skeleton in corals, as well as biogenetic carbonates formed by other marine organisms.

The presence of mass-independently-fractionated sulfur isotopes (MIF-S) in pre-2.45 Ga sedimentary rocks, but the general absence in post-2.45 Ga rocks, have been linked to atmospheric oxygen evolution [1, 2]. However, recent studies have revealed that: (1) Archean sedimentary rocks with no MIF-S signatures are common, particularly during the mid-Archean era [3, 4]; (2) the magnitude of MIF-S may vary greatly within short (<10 m) stratigraphic intervals (e.g., 2.5 Ga Mt. McRae Fm) [5]; (3) Antarctic snow that accumulated during violent (stratospheric) volcanic eruptions trapped sedimentary rocks with MIF-S are more common in organic sulfates with small but distinct MIF-S [6]; (4) Archean sedimentary rocks with MIF-S are more common in organic carbon-rich black shales with hydrothermal alteration effects [7]; and (6) H2S that generated from the thermochemical Pyrites in a Jurassic ammonite show small but distinct MIF-S than in organic carbon-poor sandstones/carbonates [3]; (5) carbon-rich black shales with hydrothermal alteration effects [6]; Baroni M. Detrital zircon ages of metamorphic and sedimentary rocks from the Maya block (Middle America)

B. Weber¹, V.A. Valencia² and U.C. Martens³

¹Departamento de Geología, CICESE, Ensenada, BC, México (bweber@cicese.mx)
²Department of Geosciences, University of Arizona, Tucson AZ, USA (victorv@geo.arizona.edu)
³Department of Geological & Environmental Sciences, Stanford University, Stanford, CA, USA (umartens@stanford.edu)

The pre-Mesozoic basement of the Maya block is exposed in the Maya Mountains of Belize and in the Chiapas Massif Complex (CMC) of SE Mexico. In the CMC medium- to high-grade metasedimentary rocks occur as isolated domains in predominantly metaigneous rocks. The CMC was affected by a Late Permian tectonothermal event, culminating in partial anatexis and the intrusion of the Chiapas batholith. This strong overprint has obscured the origin of the metasedimentary precursors and hindered correlations with other basement units.

Our in-situ U-Pb dating by LA-MC-ICPMS and SHRIMP is focused on detrital zircon cores from CMC metasediments and detrital zircons from Paleozoic strata exposed in the Maya block. This allowed unraveling the provenance of the CMC, which is summarized in the Figure below. The early Paleozoic sedimentary rocks from Belize were shed mostly from a Grenville orogen and from a ~1.5 Ga old source (Rondonia, SW Amazonia). Pan-African zircons are characteristic for the Carboniferous-Permian sequence (Santa Rosa Formation) in which zircons of mid-Proterozoic ages are less abundant. This dichotomy can be observed in a similar way for the detrital zircon cores of metasediments from the CMC and, hence, both sedimentary units were involved in the late Permian orogeny of the CMC.

Formalization of copper sulfide nanoparticles in a flooded soil: Potential for colloid-facilitated transport of contaminants

F.-A. Weber¹, A. Voegelin¹, R. Kaegi² and R. Kretzschmar¹

¹Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (faw@env.ethz.ch)
²Particle Laboratory, EAWAG, Dübendorf, Switzerland

The role of colloids in facilitating the transport of strongly sorbing contaminants has been demonstrated under oxic conditions [1], but little is known about their importance in reduced environments. In microcosm experiments, we have studied in situ formation of biogenic sulfide minerals during flooding of a heavy metal contaminated soil. We especially investigated the precipitation of sulfide nanoparticles forming in the pore water upon soil reduction and evaluated their effect on the mobility of contaminants (Cu, Cd, Pb), combining electron microscopy, X-ray absorption fine structure (XAFS) spectroscopy, and wet-chemical analyses.

Results

In the bulk soil, 25% of the initially organic matter bound Cu(II) was transformed into Cu(I) sulfide minerals within just 7 days of flooding, controlling dissolved Cu to <0.4 µM. In the colloidal phase, we concomitantly observed the formation of up to 20 µM of Cu sulfide particles, comprising (i) nanoparticles with diameters <30 nm; and (ii) ~200 nm-hollow Cu sulfide structures associated with free living bacteria. Both types were apparently mobile in the reduced soil and carried substantial quantities of Cd and Pb, dominating their pore water speciation. We attribute the distinct properties of the nanoparticles compared to the hollow structures to different mechanisms of formation involving homogeneous nucleation [2, 3] and bacterially-induced biomineralization [4], respectively. Parallel to an increase in pore water ionic strength during soil reduction, both types of colloids were slowly removed from solution by deposition [5], following an apparent first-order kinetics.

Conclusion

We demonstrate that the formation of mobile Cu sulfide colloids drastically enhanced Cu, Cd, and Pb mobility in a flooded soil, albeit concomitant sequestration in immobile sulfide minerals. Our results thus point to a potentially important pathway for the translocation of class B metals from contaminated floodplain soils to adjacent surface and groundwater bodies.

⁵Universidad Nacional de Colombia, calle 65 No. 78-28, Facultad de Minas, (gzapata@unalmed.edu.co)

P-T-t evolution of Cretaceous high-pressure rocks found as fragments in a Tertiary conglomerate from the Guajira Peninsula of Colombia, record the complex multistage history of the southern-margin subduction and collision zone of the Caribbean plate and Northern South America. The metamorphic rocks include metamafites (kyanite eclogites) and metasedimentary rocks (garnet-kyanite schists, glaucophane-bearing garnet gneisses and garnet-bearing chloritoid gneisses), that represent both oceanic and continental protoliths trapped in an accretionary wedge. Early Eocene granitoids as well as gabbros and serpentinites are also common in this conglomerate.

Mineral chemistry and textural evidence show two phases of prograde syn-tectonic metamorphic growth, and peak metamorphic conditions where calculated at 770°C and minimum pressures of 17 kbars. Some of these high pressure rocks have reequilibrated completely at amphibolite-facies conditions.

The earlier prograde phases are related to the subduction-collision event in the oceanic-continental margin, and the beginning of exhumation, whereas the later amphibolite facies overprint suggests that the exhumation rates possibly diminished, probably as a consequence of shifting towards a more oblique convergent margin.

Geochemical variability in deep-sea sediments of the Eastern Equatorial Pacific: Foundation for orbital-based chronology since the Late Miocene
M. E. WEBER ¹, C. ROLF ² AND W. RICKEN ³
¹Institute for Geology and Mineralogy, University of Cologne, Germany (michael.weber@uni-koeln.de)
²GGA-Institute, Grubenhagen, Einbeck, Germany (c.rolf@gga-hannover.de)
³Institute for Geology and Mineralogy, University of Cologne, Germany (wricken@uni-koeln.de)

Goals
The goal of this study is to provide an orbital-based chronology for sediments from the Peru Basin, eastern equatorial Pacific (EEP), that allows for the reconstruction of the deep-sea response to major oceanographic changes since the Upper Miocene. We present carbonate, opal, and XRF element data measured on samples and obtained non-destructively on 26 sediment sites. Chronology is based on magnetic polarity changes, biostratigraphy, stable oxygen isotopes, and tuning the carbonate and opal proxy records to orbital insolation. Accordingly, we obtained age models with 21-kyr control points.

Evolution since the Upper Miocene
The youngest core covers the last 1.3 Ma and the oldest core reaches back until the Upper Miocene (7.74 Ma), with sedimentation rates of 2 to 0.1 cm/kyr, respectively. A stacked carbonate record of all 26 sites minimizes local influences and provides the regional information that is necessary for large-scale climate considerations.

Accordingly, a pronounced carbonate maximum at 6.8 to 6.4 Ma is most likely associated with ‘the biogenic bloom’. Until 4.6 Ma, there is a long-term decrease with internal 400-kyr eccentricity cycles, probably amplified by pulsations of the Antarctic ice sheet and linked to the final narrowing of the Isthmus of Panama. Very low amplitudes in the 400-kyr component between 4.5 and 3.4 Ma indicate the isolation of the EEP from the Atlantic (Caribbean) due to the final closure of the Isthmus, and the time required to reorganize circulation. At 2.7 Ma, carbonate contents began to increase with a peak at 2.4 Ma. This time probably marked the first substantial glaciation of the northern hemisphere as a preservation and/or productivity spike in the EEP, followed by a gradual decrease until the Pliocene/Pleistocene boundary, a period that yields a major environmental change from oxic to suboxic conditions, indicative for a distinctive decrease in deepwater oxygen content. This change is accompanied by a 0.7-myr hiatus. During the Pleistocene, the 100-kyr amplitude of the stack started to increase at 1.3 Ma, suggesting that the response to the 100-kyr eccentricity cycle might have evolved in low latitudes and migrated to higher latitudes at 0.9-0.8 Ma. In conclusion, geochemical variability is strictly orbital controlled and traces all major oceanographic changes in the EEP.
Experimental constraints on fluorine and chlorine partitioning in the pseudosystem apatite-silicate melt-fluid(s) and applications to magmatic degassing

J.D. WEBSTER

Department of Earth and Planetary Sciences, American Museum of Natural History, Central Park West at 79th Street, New York, NY 10024-5192, (jdw@amnh.org)

Hydrothermal experiments were conducted to determine the partitioning of Cl between rhyolitic to rhyodacitic melts, apatite, and aqueous fluid(s) and the partitioning of F between apatite and these melts at 200 MPa and 900-924° C. The number of fluid phases in the experiments is unknown; a single fluid and/or vapor plus saline liquid may have been stable. The partitioning behavior of Cl between apatite and melt is non-Nernstian and is a complex function of melt composition. Values of \( D_{Cl}^{apat/melt} \) (i.e., the wt. fraction of Cl in apatite/Cl in melt) vary from 0.5 – 3.8 and are largest when the Cl concentrations of the melt are at or near the Cl-saturation value of the melt. The Cl-saturation concentrations of silicate melts are lowest in evolved, silica-rich melts, so with elevated Cl concentrations in a system and with all else equal, the maximum values of \( D_{Cl}^{apat/melt} \) occur with relatively felsic melts. In contrast, values of \( D_{F}^{apat/melt} \) range from 16-39 for these felsic melts, and they are as much as an order of magnitude greater than those applying to basaltic melts at 200 MPa and 1066-1150° C. The concentration of Cl in the fluid(s) is a simple and linear function of the Cl concentration of apatite. Values of \( (D_{Cl}^{fluid/apat}) \) for these experiments range from 15 – 44, and are nearly an order of magnitude greater than those for 200 MPa experiments involving basaltic melts at 1066-1150° C.

In order to determine the F and Cl contents and interpret volatile behavior in magmas, the experimental data have been applied to the halogen concentrations of apatite grains from chemically evolved rocks of Augustine volcano, Alaska; Krakatau volcano, Indonesia; Mt. Pinatubo, Philippines; Mt. St. Helens, Washington; Mt. Mazama, Oregon; Lascar volcano, Chile; Santorini volcano, Greece, and the Bishop Tuff, California. The F concentrations of these magmas estimated from apatite-melt equilibria range from 0.05–0.13 wt.% and are generally equivalent to the concentrations of F determined in corresponding melt inclusions. In contrast, the Cl concentrations of the magmas estimated from apatite-melt equilibria greatly exceed those determined in the melt inclusions from all of these volcanic systems except for the Bishop Tuff where the agreement is good. This discrepancy in estimated Cl concentrations of melt could result from several processes, including that apatite chemistry represents an earlier stage of magma evolution – prior to the sequestration of Cl by coexisting magmatic fluid(s).

Microbial activity associated with asphalt volcanism at the Campeche Knolls, Gulf of Mexico

GUNTER WEGENER\(^1,2\), M. BOWLES\(^3\), J. FELDEN\(^1\), FRANK WENZHOEFER\(^1\), F. SCHUBOTZ\(^2\), KU HINRICHS\(^2\), M. ZABEL\(^2\), G. BOHRMANN\(^2\) and A. BOETIUS\(^1\)

\(^2\)Research Center Ocean Margins, Bremen, Germany, (schubotz@uni-bremen.de, bohrmann@uni-bremen.de)

\(^3\)Department of Marine Sciences, University of Georgia Athens, Georgia, USA

The Campeche Knolls are characterized by active oil and methane seepage, and spectacular asphalt flows covering the seafloor. We studied the biogeochemistry of this extreme environment at 3000 m water depth during METEOR cruise M67/2 with ROV QUEST.

The asphalt flows on Chapopote, one of the Campeche knolls, show a variety of surface patterns including densely populated areas hosting deep water corals, chemosynthetic bivalves and giant tubeworms, wide flat zones covered by bacterial mats and some grazers, and regions devoid of any visible life.

Here we will present the first in situ measurements of oxygen consumption, sulfate reduction and methane turnover associated with asphalt volcanism. A central question is the source of energy to the abundant life at the asphalt flows. We found indications of high methane and sulfide fluxes, as well as extremely high oxygen consumption rates associated with the asphalt flows and will discuss the proportions of microbial and chemical processes associated with these fluxes.
Evolution of a maturing arc system: The west-central Isthmus of Panama

W. WEGNER 1, G. WÖRNER 1, R.S. HARMON 2, K. SIMON 1 AND B.S. SINGER 3

1 Geowissenschaftliches Zentrum Göttingen, Abt. Geochemie, Universität Göttingen, D-37077 Göttingen, Germany (w_wegner@yahoo.de, gwoerne@gwdg.de)
2 Environmental Science Division, Army Research Office, Research Triangle Park, NC 27709 USA (russell.harmon@us.army.mil)
3 Department of Geology & Geophysics, University of Wisconsin, Madison, WI 53706 USA (bsinger@geology.wisc.edu)

Geochemical data from the Cordillera de Panama documents the evolution magmatism and oceanic plate interactions over the past 90 Ma. Three geochemical associations are observed on the basis of trace element characteristics and ages: (i) Oceanic basement of the Caribbean Large Igneous Province (CLIP) displaying either flat trace element patterns or OIB signatures, CLIP rocks with an arc signature are rare. (ii) The Chagres Igneous Complex (66-45 Ma, Ar-Ar mineral ages) and (iii) a series of younger, Late Cretaceous to Early Tertiary mafic complexes with arc-tholeiitic trace element signatures (variably enriched in Cs, Ba, Rb, K, Sr). LILE/HFSE ratios display arc-type patterns, suggesting an origin from subduction below a CLIP oceanic plateau. Miocene (20-5 Ma) andesites from discrete volcanic centers across the Cordillera de Panama display a progressive enrichment from a tholeiitic to a more uniform medium-K arc character. This type of arc magmatism ceases around 5 Ma, followed by adakite volcanism (<2 Ma), which represents the youngest magmatism in Panama.

This evolution in magma sources through time can be interpreted in terms of a 2-stage process. 1. An early arc source that likely involved (i) enriched Galapagos mantle (plume or lithosphere) and (ii) typically depleted asthensphere. 2. The composition of the mantle wedge became progressively more homogeneous through time, either due to mixing of the two sources or by replenishment with undepleted mantle from the back arc. One possible cause for initiating this change in mantle sources could be tectonic re-arrangement after the break-up of the Farrallon plate around 28 Ma.

In-situ X-ray synchrotron high-pressure measurements of magnetite

M. WEHBER, C. LATHE, F.R. SCHILLING
GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (michael.wehber@desy.de)

Introduction
Magnetite is a ferrimagnetic inverse spinel where the tetrahedral positions are occupied by Fe$^{3+}$ and the octahedral sites contain equal amounts of Fe$^{2+}$ and Fe$^{3+}$. It occurs in the earth crust and the upper mantle and is also an important material in industrial applications such as data storage.

Experimental methods
For our experiments, magnetite-powder was mixed with vaseline to obtain hydrostatic pressure and sodium chloride was added to act as an internal pressure standard. This mixture was filled into a boron-resin cube. The measurements were carried out at the multi-anvil press MAX80 at the HSYLAB in Hamburg using “white” synchrotron beam. The pressure was increased stepwise up to 4.5 GPa.

The data were evaluated with the Rietveld-method using the GSAS / Expgui-software suite to obtain the cell parameters of the magnetite and the pressure standard.

Results
With increasing pressure the volume of the unit-cell decreases. At higher pressures the slope declines slowly. Further evaluation of the data will derive the bulk modulus of magnetite using the 3rd order Birch-Murnaghan equation of state.

Seasonal changes in seawater pH from Boron isotope systematics in a Porites coral from the Northern South China Sea
G.J. Wei1,2  G. Mortimer2  M.T. McCulloch2  AND  W.F. Deng1
1Key Laboratory of Isotope Geochronology and Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, 510640, China (gjwei@gig.ac.cn; wfdeng@gig.ac.cn )
2Research School of Earth Sciences, The Australian National University, Canberra, ACT0200, Australia (Graham.Mortimer@anu.edu.au; Malcolm.McCulloch@anu.edu.au )

We report seasonal changes in seawater pH using boron isotopic variations in high and low-density bands from a Porites lutea coral from Sanya, in the northern South China Sea. Boron isotopes in coral act as a proxy for seawater pH and were investigated using the method of positive TIMS with 309Cs2BO2/308Cs2BO2 species being measured and the results expressed as δ11B relative to NBS SRM 951. The internal precision is better than 0.2 ‰ (2σ) and the external precision indicated by repeated measurement of a working coral standard is ~0.4 ‰ (2σ), which is about 2-3 times better than that by negative TIMS method, corresponding to an overall uncertainty of less than ±0.03 pH units.

The results indicate that winter seawater pH values, represented by δ11B in high-density bands, range from 7.31 to 8.15, and from 7.87 to 8.17 for summer pH values determined from the low-density bands. The pH values in winters are generally lower than in summers, which is consistent with increased uptake of CO2 in seawater during cooler seasons due to increased solubility.

There is generally an increasing trend for seawater pH values in this region from 1992 to 1995, with pH values changing from ~7.8 to ~8.17, which appears to coincide with reduced salinity caused by increased precipitation. This may indicate more alkali (higher pH) input from the runoff into the reef, in which the seawater is significantly influenced by highly modified urban inputs from the Sanya region.

Bacterial tetraether membrane lipids in soils and their application in palaeoenvironmental studies
Johan W.H. Weijers, Stefan Schouten and Jaap S. Sinninghe Damsté
Royal Netherlands Institute for Sea Research (NIOZ), P.O. BOX 59, 1790 AB Den Burg, Texel, the Netherlands (jweijers@nioz.nl)

Branched Glycerol Dialkyl Glycerol Tetraethers (GDGTs) are membrane lipids synthesized by ostensibly anaerobic bacteria that thrive in soils and peat bogs (Weijers et al., 2006). Multiple types of branched GDGTs exist, differing in the amount of methyl branches and cyclopentanyl moieties in their carbon chains. Analysis of branched GDGTs in >150 soils indicated that soil bacteria use these differences to adapt their cell membrane to ambient temperature and soil pH conditions, which is necessary to keep the membrane in an optimal liquid crystalline state (Weijers et al., 2007a).

Upon soil erosion, branched GDGTs are transported by rivers to the marine environment. In conjunction with bulk geochemical proxies, the relative abundance of branched GDGTs in a marine sediment core located near the Congo River outflow showed that soil organic matter input varied over the last deglaciation by up to a factor 5. In addition, the degrees of methylation and cyclisation of the branched GDGTs were used to reconstruct a Congo Basin integrated soil pH and temperature record. These records reveal a gradual deglacial warming of 4°C in tropical Africa and a co-variation of soil pH with African humidity over this time interval (Weijers 2007b). This latter result might be explained by enhanced soil leaching processes with increased precipitation and vice versa.

The structure of the Hawaiian plume conduit from high-precision isotopic studies of Mauna Loa lavas

DOMINIQUE WÉIS1, J. MICHAEL RHODES2 AND MICHAEL O. GARCÍA3

1PCIGR, Earth and Ocean Sciences, University of British Columbia, 6339 Stores Road, Vancouver BC, V6T-1Z4 Canada (dweis@eos.ubc.ca)
2Dept. of Geosciences, University of Massachusetts, Amherst, MA 01003, USA
3Dept. of Geology-Geophysics, University of Hawaii, Honolulu, HI 96822, USA

The Earth’s two largest volcanoes are located adjacent to each other and astride the long-lived Hawaiian mantle plume. Mauna Loa is thought to sample the plume core; Mauna Kea, a less central part. The shield stage of Mauna Kea was well sampled (3200 m, 600 kyr) and geochemically characterized by HSDP2. Here we present results from a systematic high-precision isotopic study of a comparable portion, potentially up to 500 kyr, of Mauna Loa’s shield history.

Older Mauna Loa lavas (>60 ka), sampled along the submarine southwest rift zone, including the Mile High-Section, do not define Pb-Pb isotope lines. For the younger lavas (<60 ka), the slopes of the Pb-Pb lines increase with age. In contrast, older HSDP2 Mauna Kea basalts form Pb-Pb lines, where slopes decrease with age [1, 2]. In both volcanoes, the older lavas have higher \(^{3}He/^{4}He\) [3]. The older Mauna Loa lavas (high \(^{208}Pb* / ^{206}Pb*\), lower \(^{87}Sr / ^{86}Sr\) and \(^{143}Nd / ^{144}Nd\) and higher \(Nb/Y\)) also define separate binary isotope trends compared to the younger lavas, on the less enriched side of the trends defined by Koolau (i.e. recycled oceanic crust and sediment component). This indicates the presence of another component in the source of older Mauna Loa lavas.

Our large-scale isotopic study of Mauna Loa shield basalts confirms the apparent bilateral asymmetry of the plume conduit, originally based on distinctly higher \(^{208}Pb / ^{204}Pb\) for a given \(^{206}Pb / ^{204}Pb\) [4, 5]. The Mauna Loa source is also systematically more heterogeneous in all isotopic systems by a factor of 1.5 than the Mauna Kea source. This is maintained throughout the long magmatic history of these volcanoes. Yet older lavas from both Mauna Kea and Mauna Loa sample a more heterogeneous plume source (Loihi-like?) than younger shield lavas. Implications for the structure of the Hawaiian plume conduit, the mantle source and geophysical constraints will be discussed.

Low-grade zeolite facies
metamorphism in gneisses of the
Simano nappe (Arvigo, Val Calanca,
Grisons, Switzerland)

T. WEISENBERGER AND K. BUCHER
University of Freiburg, Germany,
(tobias.weisenberger@minpet.uni-freiburg.de)

Banded biotite gneisses intercalated with coarse light
coloured two mica gneisses and less frequently with
calcsilicate lenses are mined as building stones at Arvigo. The
rock series belongs to the upper Simano nappe of the
crystalline Penninic basement. The Arvigo quarry became
famous for a large number of Alpine fissure minerals, which
occur in extensional fractures and cavities of the granitic
gneisses. Fissures and gashes formed by semi-brittle
deformation of granitic gneisses, which were generated during
exhumation and uplift of the Alpine orogen. These fractures
and cavities were filled with fluids and new minerals
crystallized in the open space.

The Arvigo fissures contain the assemblage epidote,
prehnite and various species of zeolites. In general epidote is
overgrown by prehnite and zeolites. The specific zeolite
mineral formed in the fissures depends of the temperature
(Fig. 1). In the Arvigo fissures the following zeolites
precipitated from the fluid with decreasing temperature,
in agreement with the predicted sequence on figure 1
(300°-100°C): scolecite, laumontite, heulandite, chabazite and
stilbite.

Se isotopic variations in black shales
of the Yutangba Se deposit, China

H.J. WEN1,2 AND J. CARIGNAN2
1SKLODG, Institute of Geochemistry, Chinese Academy of
Sciences, Guiyang, 550002, China
(wenhj1302@plastic-gyig.ac.cn)
2CRPG-CNRS, 15, Rue Notre-Dame des Pauvres, B.P. 20,
54501, Vandoeuvre-lès-Nancy Cedex, France
(carignan@crpg.cnrs-nancy.fr)

The Yutangba Se deposit is the only sedimentary-type Se
deposit known in the world to date. Se is present in relatively
high abundance in both host rocks and ores, with
concentrations of up to 1.3% on average in the enriched zones.
Our preliminary study showed that about 66% Se occurs as
nanograins of elemental Se (Se0) embedded in kerogen. Three
hypotheses are proposed to explain the presence of Se0: 1) sea
water Se was reduced by a high productivity of marine
plankton, which died rapidly, and were scavenged to the sea
floor to form Se-rich carbonaceous rocks; 2) larger Se crystals
are related to combustion of stone coal (Se oxidation); 3)
redox processes related to water table fluctuations, resulting in
Se oxidation-reduction reactions (Wen and Carignan, 2006).

Se isotopic measurements on Se-rich rocks provided large
variations of δ82/76SeNIST, which varied from -12.77‰ to
4.93‰ for a total range of 17.7‰. This is the largest Se
isotopic variation found so far in natural terrestrial samples.
One of the high-Se carbonaceous shale samples yielded the
most depleted composition, with a δ82/76SeNIST of -12.77‰. On
the other hand, Hagiwara (2000) reported that
bioaccumulation of Se by plankton do not lead to large
isotopic fractionation, generally about 1-2‰ between
available dissolved oxidised species and biologically reduced
Se. In addition, no significant isotopic fractionation is
observed during oxidation reactions of Se, as reported by
Johnson (2004). Obviously, the “redox model” is favoured to
explain the Se isotopic variations in the Yutangba black
shales. Above or in the close vicinity of the water table
(oxidizing conditions area), Se2 in rocks and ores is readily
oxidized to 0, +4, or +6 valences, without isotopic
fractionation. Then, Se+4 and Se+6 mobilised in oxidising
solutions may be readily reduced again to zero (or partly -2)
valence, as the water migrates and eventually encounters
lower redox potential. At the scale of the deposit, repeated
reduction reactions should induce significant Se isotopic
variations (Johnson 2004).

The extreme isotopic variation measured in the black
shales of the Yutangba Se deposit strongly supports the high
potential of Se isotopes as a powerful redox tracer.

Distribution of mineral potassium in the Luochuan loess section, China

RAO WENBO1 AND LUO TAIYI2

1Institute of Isotope Hydrology, Hohai University, China
(raowenbo@hotmail.com)
2Institute of Geochemistry, CAS, China
(luotaiyi@vip.gyig.ac.cn)

Mineral potassium (K) is the dominant part of potassium in the loess and paleosols, mainly residing in feldspar and mica. We report here variation in mineral potassium contents of the Luochuan loess section during the past 130ka (Table 1).

Table 1: Mineral K content and magnetic susceptibility (MS)

<table>
<thead>
<tr>
<th>Strat. (the number of samples)</th>
<th>Mineral K (%)</th>
<th>MS (SI)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Range  Mean</td>
<td>Range  Mean</td>

<td>1.45-1.72 1.65</td>
<td>53.6-233.3 180.3</td>
</tr>
</tbody>
</table>

Mineral potassium content varies within the range of 1.42-1.72% with the average of 1.59% in the Luochuan section during the last 130ka, and is slightly higher in the paleosol S1 than in the loess L1. In addition, the distribution curve of mineral potassium in the Malan Loess section (L1) exhibits three small fluctuations between low and high values. Mineral potassium is low in the loess L1,LL2, high in the weak pedogenic loess L1,SS1, and then low in the loess L1,LL2.

S0 and S1 were developed during the post-glacial period and the last interglacial period, respectively. L1 formed during the last glacial period, composed of three parts (L1,LL1, L1,SS1 and L1,LL2). L1,LL1 formed during the last stade of the last glacial period, L1,SS1 were developed during the interstade of the last glacial period and L1,LL2 formed during the early stade of the last glacial period. So, mineral potassium content oscillates regularly with climate change. Climate change probably resulted in leaching of diffluent elements (Ca and Na), but relatively enrichment of mineral potassium of the Luochuan loess section.

Moreover, the fluctuation of mineral potassium is similar to that of magnetic susceptibility in the Luochuan loess section during the past 130ka. Both have also a good correlation (r=0.81). MS has been considered to be a classical proxy indicator of variations in the summer monsoon strength [1]. Therefore, variation in mineral potassium contents can also reflect the East Asian summer monsoon evolution.

Biogeochemistry of the volcanic acidic waters at the Andean Volcan Copahue (Argentina)

KATRIN WENDT-POTTHOFF1, GUSTAVO BAFFICO2 AND MATTHIAS KOSCHORRECK3

1Helmholtz Centre for Environmental Research – UFZ, Department of Lake Research, Brueckstr. 3a, 39114 Magdeburg, Germany, (katrin.wendt-potthoff@ufz.de, matthias.koschorreck@ufz.de)
2Centro Regional Universitario Bariloche, Universidad Nacional del Comahue, Argentina, (gbaffico@crub.uncoma.edu.ar)

The naturally acidic water system near the active Volcan Copahue consists of the Copahue Crater Lake, the Upper Rio Agrio which flows into Lake Caviahue, and the Lower Rio Agrio below Lake Caviahue. The crater lake and most of the Upper Rio Agrio are extremely acidic (pH ≈0-1.6) with oxidizing conditions and poor colonization, mostly by well-known acidophilic bacteria and algae. In the lower part of the system before inflow into Lake Caviahue, microbial biomass, oxygen penetration and oxygen consumption in the sediments were similar to non-extreme aquatic habitats [1]. Lake Caviahue has a pH similar to acidic pit lakes (pH 2.2 – 2.7), but lower iron and higher phosphorus concentrations [2]. Sedimentation of algae is higher than in acidic pit lakes due to different algal communities and volcanic ash input. This results in better degradable organic carbon compounds in the sediments compared to pit lakes. Microbrial sulfate reduction proceeds in Lake Caviahue sediments at pH<3 [3], and methanogenesis occurs in deeper layers below 25 cm. Below Lake Caviahue, the Lower Rio Agrio is gradually diluted and neutralized by tributaries, thereby shifting from a chemotrophic system dominated by Fe-S-Al biogeochemistry to an organotrophic system dominated by heterotrophic processes. Epilithic biofilms are an important habitat throughout, and we assumed that respiration would increase with increasing pH. In contrast to this, we obtained a minimum curve for biomass, respiration and photosynthesis with lowest values at a site with massive mineral precipitations. This indicates that physical stress is a more important regulatory factor for the bioocoenosis than pH. We also observed considerable interannual variations in physicochemical conditions and high diurnal fluctuations of temperature and discharge in this part of the river. These fluctuations may represent a stronger stress for the biota than more acidic but stable conditions.

Interactions between inorganic ions, natural organic matter and iron oxides: Effects of particle size and charge distribution

LIPING WENG, WILLEM H. VAN RIEMSDIJK AND TJISSE HIEMSTRA

Department of Soil Quality, Wageningen University, P.O. Box 8005, 6700 EC, Wageningen, The Netherlands. (liping.weng@wur.nl, willem.vanriemsdijk@wur.nl, tjisse.hiemstra@wur.nl)

Both the humic acid (HA) and fulvic acid (FA) fraction of natural organic matter adsorb strongly to iron (hydr)oxide minerals such as goethite. The current study shows that the charge of HA in the compact part at the oxide-water interface needs to be partially separated from the electrolyte ion pairs in space. This separation can be attributed to the large size of the HA particles that limits their close access to the surface. In addition, the calculations also indicate that the positive ionic strength dependency of HA adsorption can be explained by the conformational change of HA particles with ionic strength.

Electrostatic interaction is an important mechanism by which adsorbed organic matter particles influence adsorption of inorganic ions to oxide surface. The charge distribution of both the adsorbed organic particles and inorganic ions influence their interaction. The stronger interactions between Ca and FA than between Cu and FA can be explained by the larger amount of positive charge that is located at the d-plane of goethite surface in the case of calcium. The charge distribution is thus a major factor in the proper prediction of the interactions of charged species at the metal (hydr)oxide surface.

Cenozoic extension in the Pearl River Delta region (South China): Evidence from structural geology and apatite fission track thermochronology

SHEN WENLUE1, CHAN LUNG SANG1 AND MANUEL PUBELLIER2

1Department of Earth Sciences, the University of Hong Kong, Hong Kong;
2CNRS-UMR 8538, Laboratorie de Géologie, Ecole Normale Superieure, 24, rue Lhomond, F-75231 Paris Cedex 05, France.

The Pearl River Delta (PRD) region is located in the coastal South China Block (SCB) which was rifted in the late Mesozoic-Cenozoic time. New morphotectonic and structural studies reveal a polyphased extension in the PRD region, including one phase of extension in the NNW-SEE direction, consistent with but predating the opening of the South China Sea, and one phase in the ENE-WSW direction, which introduced NW-striking normal faults and probably a differential uplift of the basement in this area. Apatite fission track (AFT) analysis were applied for 14 samples, including granite, paleozoic rocks and Mesozoic red beds. 9 samples yield apparent ages varying from from 14Ma to 36Ma with an average confined track length of ~14µm showing a distribution of unimodal frequency, roughly contemporary to the sea floor spreading of the South China Sea, indicating a rapid exhumation of the basement as a passive margin. These ages are much younger than the published AFT ages (43–68Ma) for the western basement, indicating a differential exhumation process probably due to the polyphased extension in the coastal SCB. The very young results (<3Ma) are interpreted as neotectonic influence, since some of the samples were collected near the active fault zones in this area.

OH/F local environment in metamict titanite by $^1$H and $^{19}$F MAS NMR spectroscopy

J. M. Wennekamp$^1$, M. Fechtelkord$^1$ and L.A. Groat$^2$

$^1$Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität-Bochum, Universitätsstraße 150, 44780 Bochum, Germany (Johannes.Wennekamp@ruhr-uni-bochum.de)

$^2$Department of Earth and Ocean Sciences, The University of British Columbia, 6339 Stores Road, Vancouver, BC, V6T 1Z4, Canada

Titanite is a common accessory mineral in igneous and metamorphic rocks. The ideal formula is CaTi(SiO$_4$)O, but there can be extensive substitution at both cation and anion sites. Calcium may be replaced by Na, REEs, Y, U, and Th. To maintain electroneutrality there are also substitutions at the site of the (O) anion that is not bonded to Si. Thus (OH)$^-$ and F can replace O$_2^-$ in significant amounts, coupling with the cation substitutions to satisfy the overall constraint of electroneutrality. The radionuclides U and Th are responsible for alpha-decay events which mainly result in atomic displacements which cause increasing damage to the crystalline structure (metamictization; Ewing et al. 1987). The study of metamictization could help to find nuclear waste deposits since the metamicts have experienced a long-term damage by radionuclide decays.

We have examined a series of chemically and structurally well-characterized titanite samples by $^1$H and $^{19}$F MAS NMR spectroscopy to investigate the local structural environment of OH and F inside the structure as a function of the structural distortion caused by metamictization. Titanite samples with a varying degree of alpha-decay damage were selected for the experimental study. Most of the samples are from Norway and they have previously been characterized using IR spectroscopy, electron microprobe, powder X-ray diffraction, HRTEM, EXAFS-XANES spectroscopy and $^{29}$Si MAS NMR spectroscopy (Hawthorne et al. 1991).

Our preliminary results show that the amount of OH increases with the degree of alpha-decay damage. Both $^{19}$F and $^1$H MAS NMR show that the increasing amorphization results in significant NMR line broadening.

Spin transition in magnesiowüstite in Earth’s lower mantle

R.M.M. Wentzcovitch

Minnesota Supercomputing Institute and Department of Chemical Engineering and Materials Science, University of Minnesota, 421 Washington Ave SE, Minneapolis MN 55455, USA (wentzcov@cems.umn.edu)

Iron in the major lower mantle (LM) minerals undergoes a high spin (HS) to low spin (LS) transition at relevant pressures (23–135 GPa). Previous failures of standard first principles approaches to describe this phenomenon have hindered its investigation and the clarification of important consequences. Using a rotationally invariant formulation of LDA+$U$ we report a successful study of this transition in low solute concentration magnesiowüstite, Mg$_{1-x}$Fe$_x$O, ($x<0.2$), the second most abundant LM phase. We show that the HS-LS transition goes through an insulating (semiconducting) intermediate mixed spins (MS) state without discontinuous changes in properties, as seen experimentally. We show that the HS state crosses over smoothly to the LS state passing through an insulating MS state where properties change continuously. We address the change in elastic properties across this transition and its significance for the interpretation of seismic data.

Work done in collaboration with T. Tsuchiya, C. R. S. da Silva, and J. F. Justo F., and Z. Wu. Research supported by NSF/EAR 013533, 0230319, 0635990, and NSF/ITR 0428774 (VLab).
Spatio-temporal variability in diffuse hydrothermal vent fluids – Implications on biogeochemical processes

F. WENZHÖFER, H. ROY AND J. FELDEN
Max Planck Institute for Marine Microbiology, Bremen, Germany, (fwenzhoe@mpi-bremen.de)

The emission of hydrothermal fluids into the ambient seawater leads to steep physico-chemical gradients which can strongly vary over space and time. The greatly varying chemical conditions and the often very steep chemical gradients, generate a wide range of geochemical niches and potential energy sources for (micro-)organisms. An understanding of variability of vent fluids is a prerequisite for understanding the distribution and activity patterns of organisms and thus the interplay between biotic and abiotic process at hydrothermal habitats. To measure at the scale relevant for the vent organisms, high resolution in situ measurements are required to precisely characterize gradients of temperature, O$_2$, pH, sulfide and hydrogen. From these measurements microhabitat structures can be identified and they provide invaluable information on how hydrothermal habitats evolve and how vent organisms maintain their energy requirements.

Here we report on studies investigating the physico-chemical gradients of diffuse vent fluids at the Logatchev vent field (14°45’N). In situ microsensor measurements of O$_2$, H$_2$S, T and H$_2$ were used to investigate the links between the geochemical energy supply from hydrothermal fluids and hydrothermal vent communities. Microsensor time records show a highly fluctuating signal over time. At occasions where warmer fluids pour out electrode signals of H$_2$S and H$_2$ increased while O$_2$ electrodes showed a distinct reduction. This shows that beside methane also sulfide and hydrogen are available as an energy source for both free-living and symbiotic sulfur-oxidizing bacteria. Also, the maximum signal change varied spatially within the same mussel field on a distance of a few decimeters.

This work is carried out in the framework of the German DFG-Priority Program SPP1144 “From mantle to ocean”.

Major, minor and trace element analyses with XRF using synthetic standards

JÜRGEN WESS
(juergen.wess@panalytical.com)

X-ray fluorescence spectrometry is used extensively for geochemical analyses. Simple sample preparation, high accuracy and precision, and a good to excellent detection limits across large parts of the periodic table are the principal reasons for this choice.

Major, minor and trace element analyses are possible with respect to the task of the examination.

Accurate quantification requires accurate spectrally clean net peak intensities, accurate corrections for inter-element matrix effects and good standards either for wide range oxide major and minor concentrations as well for trace element analyses.

For major and minor concentrations a fused bead sample preparation is recommended for various reasons. Together with a set of synthetic standards (in collaboration with the British Geological Survey) 21 elements can be covered up to very high concentrations. Based on advanced FP algorithms a very good accuracy and precision can be achieved from ores, soils to technical minerals.

For accurate quantification of traces close to their detection limits a different approach is needed. Using, carefully designed, interference free, pressed powder standards, accurate background intensities are determined. Spectral line overlap factors, for both peak and backgrounds are iteratively calculated. Further corrections for tube spectral impurities are possible. Calibrated based on the corrections of mass absorption coefficients no major concentrations have to be known.

The combination of advanced algorithms with superior standards makes the analyses of traces a routine type of work.
Uranium “stable” isotope fractionation in nature: A potential paleo redox- and biotracer?

S. WEYER1, A.D. ANBAR2, A. GERDES1, G.L. ARNOLD2, G. GORDEN3, J McMANUS3 AND E.A. BOYLE4

1University of Frankfurt, (stefan.weyer@em.uni-frankfurt.de)
2Arizona State University, (anbar@asu.edu)
3Oregon State University, (mcmanus@coas.oregonstate.edu)
4MIT, (eaboyle@mit.edu)

We investigated variations of the $^{238}\text{U}/^{235}\text{U}$ isotope ratio in natural samples with MC-ICP-MS. A mixed $^{238}\text{U}/^{235}\text{U}$ isotopic tracer (double spike) was added prior to chemical separation of U from the sample matrix to correct for isotope fractionation during sample purification and instrumental mass bias [1, 2]. The uranium isotope ratios were measured relative to the international U standard U950a and are reported as $\delta^{238}\text{U}$.

The total range observed from the isotopically lightest to the heaviest sample was 1.3‰, exceeding by far the analytical precision of our method ($\approx 0.06$‰ for $^{235}\text{U}$, 2SD). The lightest U isotope compositions were observed for two Banded Iron Formations (Lake Superior and Central India) which have $\delta^{238}\text{U}$ of -0.71‰ and -0.88‰, respectively. The heaviest $\delta^{238}\text{U}$ were observed for two Unit II sediments from the Black Sea (+0.25 and +0.44‰, respectively). The U isotope composition of seawater ($\delta^{238}\text{U} = -0.41$‰) is only slightly fractionated relative to the major U source and sinks of U from the oceans (continental crust and suboxic margin sediments, $\delta^{238}\text{U} \approx -0.15$‰ to -0.40‰).

However, we observed significant isotope fractionation during (1) incorporation of U into manganese crusts and (2) U removal into black shales. In the first case we hypothesize that adsorption leads to an enrichment of light U isotopes ($\delta^{238}\text{U} = -0.52$‰ to -0.62‰), as is the case for Mo and Tl isotopes [3, 4]. In the second case reduction of soluble UVI to insoluble UIV might result in the observed heavy U isotope compositions of black shales compared to seawater. U burial in black shales also results in a correlation of U isotopes with U concentrations and TOC values. The latter might suggest that microbial reduction is involved in fractionating U-isotopes [2].

The range and direction of our observed U isotope variations agree with theoretical considerations [5] which predict U equilibrium isotope fractionation between the species $U^{VI}$ and $U^{IV}$. Our results indicate that U isotopes may be a promising tracer for paleo-redox-conditions and microbial reduction.

What the evolution of soil profiles tell us about weathering rates

ART F. WHITE, MARJORIE SCHULTZ, ALEX BLUM AND DAVISON VIVIT

U. S. Geological Survey, Menlo Park, CA, 94125, USA

A soil chronosequence developed along coastal California exhibited, with increasing time (65 to 226 kyrs), progressively deeper and more intensively weathered depth profiles. Weathering reactions involve the relative rapid, non-stoichiometric release of Na, Ca and Sr from plagioclase and the slower release of K, Rb and Ba from K-feldspar.

The spatial geometry of the weathering profiles, describing the relationship between plagioclase and K-feldspar concentrations and depth, evolves with time at Santa Cruz and is interpreted in terms of weathering mechanisms and rates. Profile linearity over the intermediate range in residual feldspar concentrations is approximated by the relationship

$$R = \left( \frac{1}{b_s} \right) \cdot \frac{m_{sat}}{S_v}$$

where R, the weathering rate, $b_s$ is the weathering gradient or slope, $S_v$ the volumetric surface area and $\omega$, the velocity at which the weathering front moves downward through the regolith. The non-linear regions of the mineral profiles, at low and high residual concentrations are described, using a spread sheet-base profile calculator, by relating R to exponential functions describing mineral surface/volume ratios and to the approach to thermodynamic saturation. A faster plagioclase weathering velocity, $\omega$, compared to K-feldspar, reflects greater thermodynamic solubility (500x). Fluid fluxes, based on weathering profiles agree closely with independent estimates using CI mass balances ($q_h = 0.07$ to 0.17 m yr$^{-1}$).

Under saturation-controlled and transported-limited weathering, the rate becomes defined as,

$$R = \left[ \frac{q_S}{b_s} \right] \cdot \frac{m_{sat}}{M_{total}} \cdot S_v$$

an expression containing no explicit kinetic term but defined by measurable terms, i.e., the ratio of fluid flux to mineral gradients in the profile and the ratio of feldspar solubility $m_{sat}$ to the protolith mass $M_{total}$. The above approaches yield plagioclase weathering rates at Santa Cruz of $R = 0.5$ to 1.4 x $10^{-11}$ moles m$^{-2}$ s$^{-1}$ that agree closely to those reported for other weathering environments of comparable climate and age.
Reading the high-grade metamorphic record
R. W. WHITE
Institute for Geoscience, University of Mainz, Mainz, Germany (rwhite@uni-mainz.de)

The minerals textures and structures preserved in metamorphic rocks represent an incomplete and encoded record of their evolution during orogenesis. This record, reflecting the pressure–temperature–deformation history of the crust and a range of important crustal processes, is a primary source of information for unravelling the tectonic evolution of crustal rocks. Shortcomings in our ability to read the record preserved in rocks, in the form of their mineral assemblages and mineral textures, is a limiting factor in understanding these processes. With increasingly sophisticated methods being employed in geochronological studies, the potential for understanding the timescales of metamorphic evolution and the rates at which metamorphic processes operate may be realized. However, our success at this will depend very much on our ability to provide a sophisticated and robust metamorphic framework in which to interpret geochronological data.

Improvements in our understanding of high-grade metamorphism are ongoing, with mineral equilibria modeling emerging as a powerful approach to understanding the evolution of metamorphic rocks and metamorphic processes. Of key importance is understanding the P-T evolution of rocks via effectively reading the mineral assemblages and reaction textures, as well as being able to understand open system processes such as melt loss.

Applying mineral equilibria modeling in geologically-realistic chemical systems, as well as newly-developed methods for calculating chemical potential gradients and volumes of equilibration in rocks allow us to better understand the P-T evolution and spatial organization of minerals in rocks. Forward modeling methods such as calculated pseudosections allow observations to be interpreted within a predictive framework and likely mineral assemblage evolutions deduced. The interpretation of geochronology within this framework will allow tighter constraints to be placed on rates of metamorphic evolution.

Are ‘constant’ trace element ratios in oceanic basalts really constant?
WILLIAM M. WHITE
Dept. of Earth & Atmospheric Sciences, Cornell University, Ithaca, NY 14853 USA (wmw4@cornell.edu)

Pb/Ce and Nb/U ratios differ dramatically between the continental crust and the mantle. Furthermore, these ratios appear to be approximately uniform in mid-ocean ridge (MORB) and oceanic island (OIB) basalts. Nb/Ta and Zr/Hf ratios are expected to be nearly constant in both crust and mantle because of the highly similar behavior of the elements involved. This study re-examined question of how constant these ratios are using data from the GEOROC and PetDB databases as well as recent data from the literature. In particular, the study addressed the question of whether statistically significant differences existed between OIB and MORB generally, and among oceanic island chains. Data from GEOROC and PetDB were first filtered to exclude differentiated lavas, samples that were significantly weathered, and poor quality analyses. After filtering, roughly 200 MORB and 1500-2000 OIB values remained, depending on the ratio.

Overall, mean values of Pb/Ce, U/Nb, Nb/Ta, and Zr/Hf for MORB and OIB are indeed similar. Because of this, I used a statistical approach, the Student-t test, to determine if real and statistically significant differences existed. This approach reveals that MORB have statistically significant (95% confidence level) lower Zr/Hf and Nb/U ratios than OIB (39.3 vs 41.5 and 44.8 vs 48.5). Differences in Pb/Ce and Nb/Ta were not statistically significant. The Hawaiian volcanoes have mean trace element ratios close to the overall mean for OIB (partly a consequence of the Hawaiian data representing close to half of all OIB data). However, some other island chains do show statistically significant differences in ratios from Hawaii and the OIB mean. The Canaries, Cape Verdes, Easter Is. and St. Helena have the significantly low Pb/Ce (0.026 to 0.029 compared to 0.036 for Hawaii). The Canaries, Cape Verdes have high Nb/U (49 to 62, compared to the mean of 48.8 for Hawaii), while the Society Is., St. Helena, the Mascarene Is., and Tristan da Cunha have low values (46.7 to 32.32). Mean Nb/Ta of oceanic island chains range from 13.71 to 17.01 compared to 15.24 for Hawaii and 15.49 for MORB. At the extremes, the variations are statistically significant. Zr/Hf ratios vary from 38.63 to 43.6, and at the extremes these differences are significant. Variation in Pb/Ce and Nb/U thus allow for some, albeit limited recycling of continental crust into the mantle, specifically into mantle plume sources, Both Zr/Hf and Ta/Nb in oceanic basalts are systematically different from chondritic values, hence this Earth has differentiated with respect to these ratios.
Stable isotope microanalysis – A SIMS perspective

MARTIN J. WHITEHOUSE
Swedish Museum of Natural History, Box 50007, SE104-05 Stockholm, Sweden. (martin.whitehouse@nrm.se)

Modern micro-sampling methods invariably reveal greater isotope heterogeneity than bulk sampling methods, a general rule being that the smaller the scale of observation, the more variation is seen. The challenge to most in situ methods is to measure accurate isotope composition variations at the highest possible precision and, preferably, with minimum sample consumption in order to preserve material for other methods. This presentation will review the state-of-the-art in secondary ion mass spectrometer (SIMS) measurement of both traditional and non-traditional stable isotopes, with particular emphasis on what can be achieved with the current generation of multicolonlector-equipped, high mass resolution instruments (e.g. Cameca IMS1270/80).

A key element in driving down analytical precision to a commonly achievable level of ca. 0.1-0.2 ‰ (RSD) is the ability to measure large (preferably >2 x 10^6 cps) secondary ion signals simultaneously using low noise Faraday detectors and amplifiers. Such large signals are readily obtained for the most abundant isotopes of major elements in specific targets and permit most analyses to be performed in only a few minutes, thus limiting sample consumption. Studies of S isotope variations in sulphides by SIMS now achieve <0.2 ‰ precision on both δ^{34}S and δ^{33}S, the latter revealing non-mass-dependent variations that, for example, have been successfully used to investigate ancient atmosphere evolution. Measurement of δ^{18}O in zircon is now a major element of many crustal evolution studies and an essential complement to in situ U-Pb geochronological and trace element studies, while δ^{18}O measurements in other silicates (e.g. garnet) are critical for evaluating metamorphic fluid evolution. The minor isotope of oxygen, δ^{17}O, while of little interest for terrestrial studies is important in cosmochemistry. At the typical signal level obtained for δ^{18}O studies using Faraday detectors, δ^{17}O is too small to measure with reasonable precision but may still be measured simultaneously using an electron multiplier, although introduction of EM’s into such measurement will be accompanied by gain drift which must be monitored and corrected, and requires substantially longer count times to achieve reasonable precision.

Recent development of in situ Fe isotope measurement by SIMS, using multiple Faraday detectors, highlights the potential of the method for such non-traditional stable isotopes, for example revealing hitherto unknown small scale heterogeneity of Fe isotopes in magnetite from banded iron formations. As with all SIMS stable isotope measurements, appropriate matrix matching of standards is critically important for accuracy and highlights the continuing need for collaboration between SIMS analysts and practitioners of other analytical techniques.

Novel functions of siderophores in Azotobacter vinelandii

THOMAS WICHARD, JEAN-PHILIPPE BELLENGER AND ANNE M.L. KRAEPIEL
Princeton University, Princeton Environmental Institute, Guyot Hall, Princeton NJ 08544, USA (twichard@princeton.edu)

The asymbiotic N2-fixing soil bacterium Azotobacter vinelandii requires the metals Mo and Fe for diazotrophic growth. It acquires Fe by excreting small organic ligands (siderophores) that bind iron and increase its availability. But recent evidence suggests that the catechol siderophores of A. vinelandii also affect the bioavailability of other metals, and particularly of the oxoanions molybdate, vanadate, and tungstate. Here, we investigate the various functions of these catechols using a combined approach of short-term uptake-experiments and HPLC analytics.

Results

High (toxic) concentrations of tungstate induce the release of large amounts of tris(catechol) siderophore protochelin in the growth medium. The excretion of protochelin is modulated in such a way that there is just enough protochelin to bind all the WO_4^{2-} in the medium. Further, we show that the formation of W-protochelin suppresses W uptake by the cells, demonstrating that protochelin is used for W detoxification in A. vinelandii. A similar study shows that protochelin (and possibly the bis(catechol) azotochelin) are also used for vanadate detoxification.

At very low (limiting) Mo concentrations, protochelin is also present in the growth medium, and it is released preferentially to other catechol compounds. In this case, using short term uptake experiments with ^98Mo, we show that Mo-protochelin (unlike W-protochelin) is available to the bacteria, indicating that protochelin is a metallophore used not only for Fe but also for Mo acquisition in these bacteria.

Conclusion

The catechol compounds excreted by A. vinelandii, previously believed to be dedicated to iron acquisition, are multiple functional tools used for the acquisition and/or detoxification of various metals (Fe, Mo, V, W). From a broader perspective, the elucidation of the mechanisms used by N_2 fixers to acquire and detoxify metals may lead to a better understanding of the nitrogen cycle, as metals, and particularly Mo, now appear as potential controls on nitrogen fixation in terrestrial ecosystems.

A Holocene strontium isotope record of palaeosalinity for the Littorina Sea stage of the Baltic Sea

A. WIDERRUND1 AND P. S. ANDERSSON2
1Division of Applied Geology, Luleå University of Technology, SE-971 87 Luleå, Sweden (Anders.Widerlund@ltu.se)
2Laboratory for Isotope Geology, Swedish Museum of Natural History, Box 50007, SE-104 05, Stockholm, Sweden (Per.Andersson@nrm.se)

The Holocene history of the Baltic Sea is characterized by a complex interplay between deglaciation dynamics and isotropic/eustatic relative sea-level changes. The resulting salinity variations experienced during the development of the Baltic Sea have been discussed extensively since the late 19th century, but are still incompletely understood. Here we present a study of Baltic palaosalinity variations based on the 87Sr/86Sr isotope record of 14C-dated sub-fossil shells of blue mussels (Mytilus edulis) found in raised-beach sediments from the Littorina Sea stage of the Baltic Sea (~8000–3000 cal BP). Scanning electron microscope images of the shells show no signs of secondary calcite overgrowths. This suggests that the sub-fossil shells are well-preserved, and that the 87Sr/86Sr ratio in the carbonate shells should reflect the isotopic composition of dissolved Sr in Baltic Sea water at the time of mussel growth. The distribution of dissolved Sr in the Baltic Sea is controlled by conservative mixing between seawater and river water, and proxy salinities are calculated using a mixing model where the concentration and isotopic composition of dissolved Sr in present-day seawater and river water are known.

The Sr isotopic composition in shell carbonate and present-day seawater was determined using a Thermo–Finnigan® Triton multiple collector mass spectrometer (TIMS). Replicate determinations of 87Sr/86Sr isotope ratios in modern shells, and comparison with measured present-day salinities indicate a relative precision and accuracy of better than ± 5 % for the proxy salinities. With this precision and accuracy, the present-day salinity differences between the major Baltic sub-basins can be detected. During the time interval 6800–3100 cal BP, the surface-water salinity in the Bothnian Bay increased from 7 to 9, while that in the Bothnian Sea increased from 7 to 13. These palaeosalinities are considerably higher than the present-day surface-water salinities in these two sub-basins of the Baltic Sea (2–3 and 5–6, respectively), and suggest that the Littorina Sea stage palaeosalinity of the Bothnian Bay was similar to that of the present-day Baltic Proper (6–8). The observed difference in palaeosalinity between the Bothnian Bay and the Bothnian Sea (7–9 vs. 7–13) suggests that deep-water-exchange between these two basins was restricted by a sill also during the Littorina Sea stage, despite the 30–90 m larger water depth at that time.

Isotopic tracers of lithospheric recycling

E. WIDOM
Department of Geology, Miami University, Oxford, Ohio, 45056, USA (widome@miami.edu)

Recycling between the Earth’s crustal and mantle reservoirs is a fundamental consequence of plate tectonics, and there is compelling evidence for recent recycling of oceanic crust and sediment at subduction zones from both geochemical and seismic data. The chemical and isotopic signatures of oceanic basalt provide a window into the spatial and temporal variations of the composition of the Earth’s mantle that have resulted from past recycling. Radiogenic Pb and Os isotopic compositions of ocean island basalts have long been held as evidence for significant fractions of ancient recycled oceanic crust in OIB mantle sources, and radiogenic Sr signatures have generally been attributed to recycled sediment. However, despite decades of investigations and an arsenal of radiogenic isotope systems, unambiguously identifying the nature of potential recycled components and uniquely distinguishing crustal recycling from alternative mantle enrichment processes has proven difficult. Recycled crustal materials will, after subduction and aging in the mantle, bear only limited resemblance to the original crustal “inputs” in their radiogenic isotope signatures due to changes in parent:daughter element ratios during subduction zone dewatering and variable durations of post-subduction aging.

Recent studies, though, have shown that light stable isotopes such as O and Li may have great potential as diagnostic tracers of recycled crustal material in oceanic mantle sources. Strong fractionations of light isotopes occur only in low-temperature (near-surface) conditions, with minimal fractionation at magmatic temperatures and no time dependence. Isotopic variations of O and Li in OIB outside of the relatively restricted MORB mantle range can provide strong support for a role of recycled lithospheric material in OIB mantle sources, as long as the influence of shallow magmatic processes can be ruled out. Low O isotope signatures in many OIB, including some with highly radiogenic Sr, appear to preclude a significant role of recycled sediment but are consistent with recycling of lower oceanic crust or serpentinized mantle lithosphere. Surprisingly, though, there is a growing database of heavy Li isotope signatures in OIB that, based on our current understanding of Li behavior, is not easily explained by recycled oceanic crust in OIB mantle sources. Instead, incorporation of subduction modified mantle wedge or serpentinitized lithospheric mantle could be important components of some OIB sources. The ages of such mantle can potentially be constrained based on Re-Os and Lu-Hf isotope systematics, both of which are relatively resistant to overprinting by metasomatic fluids and can serve tracers of aged melt-depleted mantle.
Quantifying the SIMS structural matrix effect

M. WIDENBECK
GeoForschungsZentrum Potsdam, 14473 Potsdam, Germany (michawi@gfz-potsdam.de)

Background
Determining absolute concentrations of trace elements by secondary ion mass spectrometry requires the use of one or more reference samples which are “matrix matched” to the material being analyzed. It is commonly posited that both the degree of crystallinity and the major element composition of a reference material influence its secondary ion yields, thereby affecting the determined relative sensitivity factors. This abstract reports on a project which quantifies the role played by sample crystallinity: the SIMS structural matrix effect.

Method
High purity disks of synthetic α-quartz and amorphous SiO₂ were purchased commercially. Special attention was given to obtaining samples with an optical polish with the surface roughness ≤10 nm. Both sample types underwent accelerator ion implantation in which the crystalline and amorphous samples were implanted during the same run, thereby assuring that both materials received identical ion fluxes (1e+14 ions/cm²). Separate Quartz-glass pairs were implanted with ¹⁰B, ²⁷Al and ⁴⁷Ti individually and the applied accelerating voltage was adjusted for each element so as to produce a maximum implant density at a depth below surface of ~200 nm.

Results
The results from single analyses on implanted pairs produced very similar depth profiles. The ratios of M⁺ to ³⁰Si⁺ at peak concentration were similar in both the crystalline and amorphous samples (see table). These results have yet to be assessed for second order issues including ion channeling during implantation, target knock-on during SIMS analysis and sample intrinsic background.

<table>
<thead>
<tr>
<th>Implant species</th>
<th>Quartz peak (M⁺/³⁰Si⁺)</th>
<th>SiO₂ glass peak (M⁺/³⁰Si⁺)</th>
</tr>
</thead>
<tbody>
<tr>
<td>¹⁰B</td>
<td>3.6e-3</td>
<td>3.8e-3</td>
</tr>
<tr>
<td>²⁷Al</td>
<td>3.8e-2</td>
<td>3.1e-2</td>
</tr>
<tr>
<td>⁴⁷Ti</td>
<td>2.8e-2</td>
<td>2.7e-2</td>
</tr>
</tbody>
</table>

Discussion
These preliminary results demonstrate that, at least in the case of SiO₂, the structurally induced SIMS matrix effect for crystal-glass pairs with identical major element compositions is <20% for all of elements reported here. This conclusion is important because it suggests that the use of a chemically matched but amorphous reference material for SIMS mineral analyses would introduce a systematic error of only 10 to 20 percent.

How can we trace Fe isotope fractionation by weathering in soils?

J.G. WIEDERHOLD¹,², B. BOURDON³ and R. KRETZSCHMAR¹

¹Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (wiederhold@env.ethz.ch)
²Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, Switzerland

Stable Fe isotopes are fractionated during biogeochemical transformations of Fe in nature. Precise Fe isotope ratio measurements collected by several research groups using mainly MC-ICPMS have generated a substantial data set, which allows assessing natural Fe isotope variations and gaining insight into the underlying fractionation mechanisms. These studies have revealed both kinetic and equilibrium Fe isotope fractionations in laboratory systems and natural environments including soils. Hence, Fe isotopes represent a potential tool to trace past and present Fe cycling.

Iron occurs in soils in many different forms, and its transformations play an important role in weathering and soil formation. The oxidation of ferrous to ferric iron is one of the first steps in the weathering of primary silicate minerals under atmospheric conditions, which ultimately leads to the breakdown of the mineral structure. In contrast to other elements, Fe is usually not leached out of the system under oxic conditions, but precipitates immediately in the form of ferric (oxyhydr)oxide minerals. Thus, oxic weathering mainly produces in-situ re-distributions of Fe between different pools. Chemical extraction procedures are widely applied to separate specific Fe pools from soils. However, the success of these methods strongly depends on the mineralogy of the sample material, and they need to be calibrated carefully to obtain meaningful Fe pools and to avoid isotope fractionation artifacts. Therefore, we have tested whether grain size separation through physical methods might represent a suitable alternative approach to separate weathering products and residues in soils for Fe isotope analysis.

We will present Fe isotope data from an oxic Cambisol weathering horizon (Bw) on Aare granite (Switzerland). In this soil, weathering products (secondary Fe (oxyhydr)oxides) are enriched in the clay size fraction (<2 μm), whereas weathering residues (primary silicate minerals) are enriched in the sand size fraction (>63 μm). We performed and evaluated both physical and chemical separation methods in order to trace Fe isotope fractionation during weathering. The clay size fraction was found to be enriched in light Fe isotopes by more than -0.5‰ (reported as δ⁵⁷Fe) compared to the bulk digestion, whereas the sand size fraction was found to be enriched in heavy Fe isotopes by +0.2‰. An elemental and isotopic mass balance for Fe is consistent with a re-distribution of Fe within a closed system.

Our results show clear evidence for Fe isotope fractionation during weathering in soils causing enrichments of light Fe isotopes in weathering products and of heavy Fe isotopes in weathering residues. Potential fractionation mechanisms and implications for the interpretation and application of Fe isotope signatures in soils will be discussed.
The use of atomic force microscopy to study crack tips in glass

SHELDON M. WIEDERHORN\textsuperscript{1}, JEAN-PIERRE GUIN\textsuperscript{2} AND THEO FETT\textsuperscript{3}

\textsuperscript{1}National Institute of Standards and Technology, Gaithersburg, MD 20899-8520
\textsuperscript{2}University of Rennes I, Rennes, France
\textsuperscript{3}Universitat Karlsruhe, D-76131 Karlsruhe

Sub critical crack growth is the primary cause of failure in glasses, brittle ceramics and minerals when these materials are forced to sustain mechanical loads for long periods of time. Recently, a number of investigators have turned to the use of atomic force microscopy to characterize crack motion in glass. The technique has been used to study crack motion to velocities as low as $1 \times 10^{-13}$ m/s. It has also been used to characterize the roughness and fractal dimensions of fracture surfaces. By comparing opposing fracture surfaces, permanent displacements are shown to develop between fracture surfaces as a consequence of corrosion during the fracture process. In this talk we examine fracture surfaces of glass specimens that have been subjected to stresses at or below the static fatigue limit. Opposing fracture surfaces matched to an accuracy of better than 0.3 nm normal to the fracture plane and 5 nm within the fracture plane. Displacements between the upper and lower fracture surfaces that developed after a critical holding time were independent of distance from the crack tip, but increased with holding time, approaching an upper limit of about 25 nm for very long times. Despite the surface displacement, cracks tips appeared to be sharp. No evidence of plastic deformation near the crack tip was found. Results are discussed in terms of a hydronium ion - alkali ion exchange along the crack surfaces and corrosion of the glass surface near the crack tip by hydroxyl ions.

Hydrogen anomalies at seismogenic depths of the San Andreas Fault

THOMAS WIERSBG & JÖRG ERZINGER
GFZ Potsdam, Telegrafenberg, 14473 Potsdam, Germany (wiers@gfz-potsdam.de, erz@gfz-potsdam.de)

During drilling of the SAFOD Main Hole (San Andreas Fault Observatory at Depth), up to several percent of hydrogen were identified in drill mud gas. Hydrogen enters the well particularly in two fractured zones around the fault center, whereas apparently no hydrogen is present in the fault core in ~3100-3425 m bore hole depth.

In the fractured zone on the Pacific plate (~2700-2900 m bore hole depth), hydrogen correlates mainly with CO$_2$ and radon, whereas in the fracture zone on the North American plate (below ~3550 m bore hole depth), hydrogen concurrently appears also with hydrocarbons.

The H/D values of hydrogen in drill mud gas range from –618‰ to –708‰ SMOW. Deuterium fractionation between water and hydrogen would imply hydrogen genesis at relatively low temperatures that makes a deep hydrogen source unlikely. Moreover, we can widely rule out artificial hydrogen from drilling, hydrogen from serpenitization reaction, as well as radiolytic and organic hydrogen.

Several laboratory studies have shown in the past that freshly generated silicate mineral and quartz surfaces can catalyse the synthesis of hydrogen from water. Such reactive mineral surfaces could be generated in the rupture zone around a fault core, however, no experiments on fault zone rocks from seismogenic depths have been carried out yet. Thus, we have performed experiments on the mechno-chemical gas synthesis on SAFOD drill cuttings from seismogenic depth of the SAF, which mainly consist of clay, shale and sandstone. First results reveal an increase in gas after ball-milling the rock samples in a vaccum-tight mill. We will furthermore show results from experiments at varying conditions to verify if indeed mechno-chemical processes could account for hydrogen occurrences at the SAF.
Influences of thermal degradation on lipid composition of crop plant biomass

G.L.B. WIESENBERG1,2 AND L. SCHWARK2

1Department for Agroecosystem Research, University of Bayreuth, 95440 Bayreuth, Germany (guido.wiesenberg@uni-bayreuth.de)
2Department for Geology and Mineralogy, University of Cologne, Zuelpicher Str. 49a, 50674 Cologne, Germany (lorenz.schwark@uni-koeln.de)

Lipids are main components of fresh crop plant biomass. Only low amounts of those lipids are able to be incorporated and stabilized in soils due to e.g. the removal of biomass upon harvest or immediate remineralization. Incorporation pathways of lipids from plant biomass towards soil organic matter have been intensively studied throughout the past decades. However, it still remains unknown how the lipid composition of plant biomass is modified by thermal degradation, e.g. during burning. Within this study, we will show the effect of thermal degradation of maize and rye straw at several temperatures based on the lipid composition.

Maize and rye-straw were degraded thermally at temperatures of 300°C, 400°C and 500°C. Free lipids were extracted using ASE and thereafter separated into five fractions (aliphatic and aromatic hydrocarbons, low polar components including alcohols and ketones, acids and a high molecular weight and high polarity fraction) via a sequential chromatographic clean-up using SPE and MPLC. Deuterated molecular weight and high polarity fraction) via a sequential chromatographic clean-up using SPE and MPLC. Deuterated standards were added to the lipid fractions. Identifications and quantification were performed using a GC-MS after optional derivatisation.

The thermal degradation even at low temperatures (300-400°C) resulted in a reduction of the amounts of most lipid components, while the proportions of aromatic hydrocarbons were observed to increase. This was related to the incomplete combustion of the plant biomass forming new components at low temperatures. Especially at a temperature of 400°C large amounts of 3-6-ring PAHs including their alkylated counterparts were formed. At higher temperatures (500°C) more effective combustion resulted in lower concentrations of detectable aromatic hydrocarbons.

In contrast to predictable PAH formation, surprising results were obtained for the behaviour of carboxylic acid fractions. Similar to the other straight-chain lipids, the amounts of carboxylic acids decreased significantly with increasing temperature. But in contrast to other lipids like alkanes and alcohols, selected acids were still observable at 500°C. At 300°C preferentially straight-chain, branched, and unsaturated short-chain acids became relatively diminished in comparison to long-chain homologues. Conversially, higher relative proportions of short-chain acids were obtained upon combustion at 500°C. We postulate that these short-chain acids may have been extracted from organic components like black carbon, newly synthesised during the degradation process, which is subject of ongoing studies.

Constraining magmatic differentiation at Teide/Pico Viejo and associated rift zones, Tenerife, Canary Islands

S. WIESMAIER1, V. R. TROLL1, G. L. HART2, J. C. CARRACEDO3 AND J. A. WOLFF2

1Dept. of Geology, Trinity College Dublin (wiesmais@tcd.ie)
2School of Earth and Environmental Sciences, Washington State University, Pullman, WA, USA
3Estacion Vulcanologica de Canarias, Inst. Productos Naturales (CSIC), 38206 La Laguna, Tenerife

To unravel magma chamber processes and eruption triggers at the central volcanic complex Pico Teide/Pico Viejo (TPV) and its adjacent rift zones on Tenerife, we investigated 52 samples for their Sr isotope composition in feldspar phenocrysts. Processes such as magma mixing and contamination can be masked in whole-rock analyses, which merely represent the integrated average of all component parts involved (crystals, liquid, xenoliths). As feldspar crystals record prolonged crystallisation histories, we employ a micro-analytical approach to resolve magmatic processes. LA-MC-ICPMS represents the best means to a) yield a stratigraphy of Sr isotope ratios over core-to-rim profiles of single phenocrysts, i.e. a ‘timeline’ of the magma’s isotopic evolution and b) to carry out a large number of analyses in a relatively short time.

$^{87}$Sr/$^{86}$Sr has been analysed in plagioclase phenocrysts of the most recent eruptive products on Tenerife that built the TPV-complex and effused from the rift zones to the NW and NE over the last 35,000 yrs [1]. No correlation between $^{87}$Sr/$^{86}$Sr and An content has been detected in feldspars of these deposits, in concordance with the results from other localities such as Merapi or Krakatau [2; 3].

Crystal populations are found to be very heterogeneous amongst the sample suite and also within single samples [cf. 4]. The latter may range from no significant variation in $^{87}$Sr/$^{86}$Sr and An in some crystals to significant rises and subsequent falls of $^{87}$Sr/$^{86}$Sr independent of associated An variations in others.

A wide array of processes including FC, AFC and magma mixing is suggested to influence the evolution of TPV and rift zone lavas, demonstrating a complex interplay of differentiation processes within the TPV plumbing system.

No evidence of diffusive homogenisation of carbon isotopes in Yakutian diamonds

D.F. WIGGERS DE VRIES¹, G.R. DAVIES¹, G.P. BULANOVA² and D.G. PEARSON³

¹Vrije Universiteit, Amsterdam, NL (daphne.wiggers.de.vries@falw.vu.nl, gareth.davies@falw.vu.nl)
²University of Bristol, UK (galina.bulanova@hotmail.com)
³Durham University, UK (d.g.pearson@durham.ac.uk)

C-N isotopes of diamonds are potentially useful in establishing the source and temporal evolution of C-bearing fluids in the mantle. Complex growth forms revealed by CL images indicate that many diamonds grew under varying conditions. However, using C-N isotopes to probe the evolutionary history recorded in successive growth bands is only of use if there is no diffusive equilibration at the µm scale. Little information is available about carbon diffusion. Harte et al. (1999) suggested that diffusion potentially homogenises C in diamonds due to their long residence in the mantle. Hauri et al. (2002) and Bulanova et al. (2002), however, argued that diffusion was insufficient to equilibrate C in Yakutian diamonds at the 50 µm scale.

Here we report SIMS data with high spatial resolution (<30 µm, spot size 20 µm) on traverses across <110> plates of Yakutian diamonds. Most diamonds, of both P- and E-type paragenesis, have δ¹³C between -8‰ and -2‰ close to that of ambient asthenospheric mantle. Variation in δ¹³C in excess of 1‰ is found between successive growth bands in 5 of the 11 stones studied to date, indicating a punctuated growth history (SIMS reproducibility ±0.2‰). Diamond 1703 from Mir records a remarkable 10‰ difference in δ¹³C between the octahedral core and rim. A traverse conducted at a 40° angle to the contact established that there is no resolvable diffusive exchange between the successive growth bands at 30 µm scale. We therefore conclude that C isotope diffusion is non-existent at the 30 µm scale and that δ¹³C variations in successive growth bands do record information about the composition of the C-bearing fluids that formed diamonds. SIMS N isotope data from the Yakutian samples is underway to characterise the coupled C-N isotope variations of these crystals.

Insights into enzymatic reduction of metal-oxides from single-molecule tunneling studies of multiheme cytochromes

NICHOLAS S. WIGGINTON¹, KEVIN M. ROSSO², LIANG SHI², BRIAN H. LOWER² and MICHAEL F. HOCHELLA, JR.¹

¹Department of Geosciences, Virginia Tech, Blacksburg, VA 24061 USA (wigginton@vt.edu)
²Environmental Molecular Sciences Laboratory, Chemical Sciences Division, and Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA 99352 USA

We have performed recent experiments that aim to elucidate the molecular mechanisms of enzymatic bacterial metal reduction by studying purified multiheme cytochromes (OmcA, MtrC) from Shewanella oneidensis MR-1 with single-molecule electron tunneling spectroscopy. Enzyme-mediated direct electron transfer (ET) between metal-reducing bacteria and mineral surfaces is a prominent environmental redox process that directly and indirectly influences subsurface geochemistry. By developing a means to chemically adsorb cytochromes to a solid surface, tunneling spectroscopy showed distinctly different conductance for OmcA and MtrC (Wigginton et al., 2007) indicative of two different surface-directed electron tunneling mechanisms for these proteins (Wigginton et al., submitted). The data suggest that one or more heme groups in MtrC participate in ET, and therefore MtrC may be tuned to a specific redox potential for biological function. In contrast, OmcA may function as a non-specific multi-pathway reductant of mineral surfaces because the tunneling spectra suggest that superexchange ET is the predominant mechanism. We are further scrutinizing this difference by using a novel configuration for biomolecule scanning tunneling microscopy (STM) to determine if MtrC and OmcA show different distant-dependent tunneling behavior. This configuration uses an insulated Au STM tip functionalized with cytochromes to systematically vary the separation distance between the cytochromes and a hematite surface. These experiments, performed as a function of solution chemistry, are also designed to provide specific information on the effects of pH, ionic strength, and electrolyte compositions on ET efficiency.

Biotite polytypes versus occurrence in granite body, Karkonosze, Poland

A. WILAMOWSKI
Institute of Geological Sciences PAS, Twarda 51/55, 00-818 Warszawa, Poland (awilamow@twarda.pan.pl)

Correlation between the polytypic compositions of biotites and their occurrence in the granite body was studied in the eastern part of the Karkonosze granite massif, SW Poland. Polytypic composition was expressed as the per cent ratio of 2M1 polytype in the mixture with the 1M (and 3T) polytypes, and was assessed based on powder diffraction patterns. The oblique texture method was used to enhance intensities of the diagnostic reflections: T14 of 2M1 and T12 of 1M.

The ratio of 2M1 decreases in the sequence: schlieren-free parts of granite, schlieren-rich parts, and schlieren themselves. Assuming that schlieren form as biotite segregations against rigid walls of country rocks during ascension of plastic magma, the magma chamber environment favours crystallization of 2M1, and the marginal parts of intrusion favour crystallization of 1M.

Biotite crystals occurring as inclusions in central parts of feldspar phenocrysts show a high ratio of 2M1 up to 43%. Biotites forming inclusions at the rims of feldspar phenocrysts have similar polytypic compositions as the main pool of biotites in the rock, and are about 25% 2M1. Assuming that the onset of crystallization of feldspar phenocrysts took place in the environment of the initial stage of magma crystallization, and that the tiny biotite crystals occurring in the central parts of feldspar phenocrysts preserved their original polytypic composition, this environment would promote the formation of the 2M1 polytype. This interpretation is in accordance with results of earlier studies (Wilamowski, 2002).

Biotites from mafic microgranular enclaves (MME) show 2M1 ratios of about only 6%, which is the lowest value recorded in the studied pool of samples. The polytypic composition of biotites from MME is either original, or established after incorporation of the enclaves. In the latter case recrystallization of biotites would occur under thermal influence of the granite magma. Indeed, the oval shapes of enclaves suggest their intensive thermal reworking. Also, the feldspar phenocrysts from granite magma often penetrate inside the MME proving the plastic state of the enclaves, which favours recrystallization processes.

Positive correlation of 2M1 with Ti content, and negative correlation with octahedral Al, are observed. Correlations between the polytypic compositions of biotites and the oxygen isotope compositions are expected. The oxygen isotope studies are in progress.

This study was supported by the research project of the Ministry of Science and Higher Education no 2 P04D 058 27.

Revisiting the oldest rocks in China

S.A WILDE1, D.Y. LIU2, Y.S. WAN2 AND J.S WU2
1TIGeR, Applied Geology, Curtin University, Perth, Australia (s.wilde@curtin.edu.au)
2Beijing SHRIMP Center, Chinese Academy of Geological Sciences, Beijing China (liudunyi@bjshrimp.cn)

Background

It has been known for over fifteen years that the Anshan region of the North China Craton contains the oldest rocks in China, extending back to 3811 Ma (Liu et al., 1992). Although these rocks are some of the most ancient preserved examples of continental crust on Earth, they occupy only a small portion of the craton, cropping out over an area of <20 km². We re-examined the Anshan area to determine if (i) the extent of ancient zircons is more widespread than originally defined, (ii) components older than 3.8 Ga are present, and (iii) Hf isotopic data can provide evidence of crustal evolution back to 4 Ga or beyond.

Results

Our results establish that rocks ~3.8 Ga in age are present in three areas close to Anshan City: in the Baijiafen, Dongshan and Shengoushi complexes. A mylonitized trondhjemite in the Baijiafen quarry has a SHRIMP zircon 207Pb/206Pb age of 3800±5 Ma, identical to earlier results from the area. Importantly, biotite schist from this quarry records an age of 3811±4 Ma, making this the oldest known supracrustal rock in the North China Craton. Trondhjemite collected adjacent to the site in the Dongshan complex that recorded an age of 3811±4 Ma, yielded younger zircons defining a crystallization age of 3680±19 Ma, indicating the complexity of magmatic relations in this area. A trondhjemite from the Shengoushi complex has a 207Pb/206Pb age of 3777±13 Ma, making this the third area in the district recording ages of ~3.8 Ga. The Hf data indicate that some zircons from all three complexes have depleted mantle model ages that extend back to 4.0 Ga. However, no rocks of this age have been identified and the data reveal that it is unlikely that considerably older components are present in the North China Craton.

Advection and redox processes as controls on minor elements in groundwater influenced by irrigation and surface-water exchange

R. A. WILDMAN, JR. 1, J. G. HERING 2, AND J. L. DOMAGALSKI 3

1 California Institute of Technology, Caltech MC 138-78, Pasadena, CA 91125, USA (wildman@caltech.edu)
2 Eawag, Überlandstrasse 133, 8600 Dübendorf, Switzerland (janet.hering@eawag.ch)
3 United States Geological Survey, Placer Hall, 6000 J Street, Sacramento, CA 95819-6129, USA (joed@usgs.gov)

An understanding of the groundwater chemistry and transport of minor inorganic constituents must begin with the major processes of the hydrologic system. This research compares the influences of groundwater advection and redox chemistry on trace elements in a heavily irrigated agricultural hydrologic system.

Three times during 2004, samples were collected from both a groundwater transect that flows to the Merced River (California, USA) and from riverbed wells at the approximate point of flowpath discharge. Previous work (1, 2) has quantitatively described groundwater advection and denitrification in this groundwater system. Samples for this study were analyzed for a suite of dissolved elements by Inductively-Coupled Plasma Mass Spectrometry. Results are considered in the context of the U.S. Geological Survey National Water-Quality Assessment Program.

Concentrations of dissolved elements were statistically analyzed. Bromine, assumed to be a conservative tracer of advection, and manganese, an indicator of reducing conditions, were used as predictor variables. Strontium, barium, uranium, and phosphorus were relevant response variables. Principal component analyses and linear regression analyses indicate that advection dominates groundwater chemistry beneath the Merced River. Seasonal variation appears to influence whether groundwater composition is influenced by either hyporheic exchange from river surface water or groundwater supplied by the surrounding farmland. When the influence of advection is removed, redox chemistry becomes significant.

Stable sulfur and carbon isotopes of pore-water and solid-phase compounds in sediments of the Chapopote Asphalt Volcano, southern Gulf of Mexico

1 Alfred Wegener Institute for Polar and Marine Research, Am Handelsfahnen 12, 27570 Bremerhaven, Germany (thorsten.wilhelm@awi.de, sabine.kasten@awi.de)
2 Max Planck Institute for Marine Microbiology, Celsiusstrasse 1, 28359 Bremen, Germany (vbrucher@mpi-bremen.de)
3 Department of Geosciences, University of Bremen, Klagenfurter Str., 28359 Bremen, Germany (tpape@uni-bremen.de, schubotz@uni-bremen.de, khinrichs@uni-bremen.de)

During R/V Meteor cruise M67 2a/b (March-April 2006) to the Asphalt Volcanoes of the southern Gulf of Mexico two gravity cores were retrieved from the central depression of the Chapopote Knoll which contained viscous oil/asphalt a few meters below the sediment surface. Also several push cores were taken with the remotely operated vehicle (ROV) QUEST at sites where oil/asphalt reached closely below the sediment surface. From these cores solid-phase and pore-water samples were taken for on-board and subsequent shore-based analyses. Together with a core taken from a background site which is not influenced by asphalt/oil seepage these sediment and pore water samples are currently subject to detailed analyses of (1) the stable sulfur isotopic composition of both dissolved (sulfate and sulfide) and solid-phase (iron monosulfides, pyrite) sulfur compounds, and (2) the composition and stable carbon isotopic signatures of hydrocarbon gases.

The major aims of these investigations are to identify whether and to which extent the upward migration of oil, asphalt and gas (1) stimulates biogeochemical processes and turn-over rates, and (2) influences the stable sulfur isotopic composition of both dissolved and solid phase sulfur compounds. Furthermore, we seek to determine the potential of these – possibly unusual – stable sulfur isotopic signals of solid-phase sulfides to reconstruct hydrocarbon seepage in older geological records and to elucidate how the composition and the stable carbon isotopic composition of the hydrocarbon gases are altered by the action of typical chemosynthetic communities thriving at these sites. The values of δ34S of pore water and solid phase sulphide and furthermore of δ13C of the pore water methane give a first indication for high bacterial activity.
Sulfur speciation in quenched melts by Micro-XANES – The nature of S(IV+) in glasses

M. WILKE 1, P.J. JUGO 2, R.E. BOTCHARNIKOV 3 AND J. SUSINI 4

1Universitaet Potsdam, Karl-Liebknecht-Str. 24, 14476 Potsdam-Golm, Germany; (max@geo.uni-potsdam.de)
2Laurentian University Sudbury, ON P3E 2C6, Canada
3Leibniz Universitaet Hannover, 30167 Hannover, Germany
4ESRF Grenoble, F-38043 Grenoble Cedex, France

Although Sulfur occurs only as a trace element in magmatic systems its behavior is directly related to a variety of important geological processes (e.g. formation of ore deposits, global cooling by S-rich explosive volcanism). The solubility of sulfur depends strongly on its oxidation state that may vary from S2− to S6+, and thus shows strong dependence on the oxygen fugacity in the system. XANES measurements at the S K-edge provide unique information on the sulfur species present. The fine structure at the S K-edge is dominated by localised 1s-2p transitions, which are strongly dependent on the electronic configuration of S [1]. Spectra were recorded at the ESRF ID 21 micro-focus beamline using a combination of broad and focused beams (200 µm and 0.8 µm diameter). We determined the S speciation in glasses in a variety of naturally occurring composition synthesized at 1 GPa, 1100 to 1350 °C (dry conditions) and at 200 MPa and 1050°C (5 wt% dissolved H2O). Of special interest was the detection of a S4+ species at intermediate redox conditions, i.e. the transition from S2− to S6+, as found by [2] in natural samples. The presence of such an intermediate species has important consequences on the thermodynamic treatment of sulfur equilibria in magmas. Synthetic samples were equilibrated at various oxygen fugacities and sulfur saturated conditions. In addition, disequilibrium samples were made, resulting in a continuous transition from S2− to S6+ from the rim to the center of the samples. The presence of S4+ was observed only in a few oxidized samples. However, our experiments show that the S4+ is related to beam damage induced by the electron-microprobe analysis, which preceded the XANES analysis. Furthermore, time-dependent XANES measurements indicate strongly that S4+ is also formed during the acquisition of the XANES spectra, which is particularly the case when using the focused beam. Due to this effect the S species in the disequilibrium samples were not analysed by collecting the complete XANES. Instead, scans across the samples were performed by resonant excitation at the energy position of each species. These profiles gave no indication for the presence of S4+. Finally, we have used the intensities of the respective resonances for S2− and S6+ to determine the sulfur oxidation state in the glasses as a function of the oxygen fugacity during the synthesis.

Controls on microbial activity and compositional alteration of crude oil during in reservoir biodegradation

H. WILKES 1, A. VIETH 1, R. ELIAS 1 AND R. RABUS 2

1GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany (wilkes@gfz-potsdam.de; vieth@gfz-potsdam.de; elias@gfz-potsdam.de)
2Institute for Chemistry and Biology of the Marine Environment, University of Oldenburg, D-26111 Oldenburg, Germany (ralf.a.rabus@uni-oldenburg.de)

Biodegradation of crude oil and natural gas in petroleum reservoirs is of great economic relevance and plays an important role in the biogeochemical carbon cycle. Petroleum reservoirs are an outstanding habitat of the deep subterranean biosphere where hydrocarbons – the main constituents of crude oil and natural gas – are present in abundance to function as potential microbial carbon and energy sources. The effects of biodegradation on oil and gas composition are well-documented while only little is known about the underlying processes. It is, however, clear that geologic environments with significant accumulations of hydrocarbons, particularly petroleum reservoirs, are mostly anoxic. Limitations of microbial activity in petroleum reservoirs are poorly understood and are subject of ongoing investigations. Temperature is generally regarded as being very important with a threshold for biodegradation of approximately 80°C. Little is known about the availability of electron acceptors and nutrients.

This contribution will present new approaches to better assess and understand processes associated with hydrocarbon degradation in subsurface reservoirs by employing advanced analytical techniques (petroleum and stable isotope geochemistry). Model experiments with individual hydrocarbons as pure substrates or crude oil as a complex mixture of substrates provide insight into substrate specificities of numerous pure cultures of denitrifying and sulphate-reducing hydrocarbon-utilising bacteria. On this basis it can be shown that different patterns of hydrocarbon degradation in different oil fields most likely reflect differences in the respective microbial consortia. A new concept explaining observed patterns of compositional alteration will be suggested, which is based on the hypothesis that bioavailability of individual petroleum constituents is a crucial control of microbial activity. This is supported by the patterns of stable isotope fractionation associated with the oxidation of light hydrocarbons which allow the conclusion that diffusive transport of hydrocarbons exerts a main control on biodegradation rates, bioavailability of substrates and thus on microbial activity in a reservoir. Our results from various petroleum systems have strong implications with respect to the validity of the conventional perception of biodegradation as a process removing different compound classes sequentially resulting in more or less similar patterns of compositional alteration in any biodegraded oil reservoir.
Late Pleistocene and Early Holocene variability in organic matter sources in Lake El’gygytgyn, NE Siberia

K.M.K. Wilkie, S. T. Petsch, and J. Brigham-Grette
Dept. of Geosciences, University of Massachusetts, Amherst, MA, USA (kwilkie@geo.umass.edu)

Lake El’gygytgyn is a 3.6 Ma old impact crater lake located in central Chukota, NE Siberia and has now become the major focus of multi-disciplinary drilling programs to study the climate history of the Arctic. Sediment cores recovered as pilot work from the central part of the lake in 1998 and 2003, comprise the last ~250 ka BP and thus probably represent the longest continuous terrestrial record of Arctic climate change. The results of this research will contribute to protocols for multinational teams of scientists to investigate more than 400 m of sediment expected to record climate change over the past 3.6 Ma.

Organic biomarkers representing four lipid classes (saturated hydrocarbons, ketones, alcohols and sterols, and free fatty acids) were isolated from selected depths in the core. Depths represent extreme environmental conditions (e.g. Early Holocene warmth and cold and dry conditions of the Last Glacial Maximum, LGM) determined from previous bulk sedimentary and inorganic geochemistry (Melles et al., 2007; Minyuk et al., 2007). The suite of n-alkanes recovered reflect a combination of autochthonous production and terrestrial plant input. Indices such as OEP and TAR consistently point to enhanced delivery of terrestrial OM during warm, wet conditions. In contrast, cold phases show diminished terrestrial input compared to aquatic production, likely controlled by perennial ice cover and water column stratification. Additionally, a suite of complex branched alkanes are observed within the LGM samples, yet their identification and source remain to be determined. A wide suite of sterols were also identified including cholesterol, cholestanol, stigmasterol and sigmasterol, consistent with Hanisch et al., 2004. Differences are observed between the LGM and interglacial intervals among low molecular weight alcohols, such as n-alcohols, and higher molecular weight sterols and other cyclic and acyclic isoprenoids. These preliminary results suggest complex interactions between OM sources and productivity, seasonal ice cover and regional climate.

Subduction erosion of lower continental crust: A mechanism to produce chemical mantle heterogeneities

M. Willbold1 and A. Stracke2

1University of Bristol, Department of Earth Sciences, Bristol, BS7 1RJ, United Kingdom
2ETH Zürich, Institut für Isotopengeologie, Clausiusstr. 25, 8092 Zürich, Switzerland

Sr-Nd-Pb-Hf-Os isotope and trace elements data suggest that the lower continental crust (LCC) may be part of the so-called enriched mantle (EM) sources (Kamenetsky 2001; Escrig, 2004; Hanan, 2004; Lustrino, 2005; Willbold, 2006). The mechanism(s) that transport LCC material into the mantle, however, remain enigmatic. Delamination and foundering of LCC during continental break-up are the mechanisms suggested most often, but may only lead to shallow-level contamination of upper mantle sources (Escrig., 2004; Hanan, 2004). Moreover, isotopic and trace element constraints on EM-type ocean island basalts require upper and lower crustal material to be mixed with ancient subduction-modified oceanic lithosphere previous to incorporation of the recycled material in OIB sources (Willbold, 2006). Subcontinental lithosphere is chemically buoyant and lower crustal signatures are generally not accompanied by the characteristic Hf and Os signatures expected for the subcontinental lithosphere. These observations provide a major obstacle for delamination processes. Erosion and subsequent subduction of overlying lower arc-crust at erosive plate margins (Clift, 2004; von Huene, 2004), on the other hand, is a suitable and straightforward physical mechanism for creating blends of the lower and upper continental crust (i.e., as sediments) and for recycling them, together with the subducted oceanic lithosphere, into the deeper mantle. Subduction erosion may thus be one of the principal mechanisms involved in generating EM sources and may also have important implications for the compositional evolution of the Earth’s mantle-crust system in general.

Massive H2S release to surface waters at the Precambrian-Cambrian (PC-C) boundary: Evidence from Mo isotopes

MARTIN WILLE1, THOMAS F. NÄGLER1, STEFAN SCHRÖDER2, BERND LEHMANN3 AND JAN D. KRAMERS1
1Institute for Geological Sciences, University of Bern, Switzerland, (wille@geo.unibe.ch)
2Department of Geology, University of Johannesburg, South Africa
3Institute of Mineralogy, Technical university of Clausthal, Germany, (lehmann@min.tu-clausthal.de)

The geological and geochemical circumstances which have caused a decline in abundance and diversity of the soft-body Ediacara fauna at the end of the Precambrian followed by the “Cambrian explosion”, is still a question of debate. Several triggers and associated kill mechanism could have been responsible for the sharp extinction at the PC-C boundary. Besides a bolide impact, flood basalt eruptions and methane release, shallow water euxinia caused by upwelling of euxinic bottom waters could provide an explanation for this biotic crisis. Further it is known that changing redox conditions like an increase in atmospheric oxygen concentrations could have played a key role for the Cambrian explosion. It was proposed that during the late Neoproterozoic period, elevated free oxygen concentrations could have triggered the evolution of eukaryotic organisms (Fike et al. 2006). Therefore it seems to be reasonable, that changing redox conditions could have also been responsible for the evolutionary changes in early Cambrian times.

To check this hypotheses we present Mo isotope signatures in black shales from two sample sets (Ara group, Oman and Yangsee Platform, China) which were deposited at and shortly after the PC-C boundary.

At the first view, the overall Mo isotopic signature of the early Cambrian black shales from Oman and China are similar to the signature found in Mesoproterozoic shales (Arnold et al. 2004). Canfield (1998) proposed that the Paleoproterozoic and Mesoproterozoic ocean was strongly chemically stratified with sulfidic deep deep waters and modestly oxygenated surface waters. Our new early Cambrian data support the idea that this stratification might have continued until the end of the Proterozoic.

On a closer inspection, a transient Mo isotopic signal following immediately after the PC-C boundary in both sample sets indicates a short but intense global non-steady state situation. Combined with the extreme Mo enrichment, found in the Chinese sulfide marker bed at the PC-C boundary, this signal can not be explained with recent Mo scavenging mechanism known from recent oceans. We put forward the working hypothesis of an upwelling of euxinic bottom water masses of an chemically stratified ocean as explanation for this Mo anomalies. This scenario not only explains the transient isotopic signal and the metal enrichment found at the PC-C boundary in several localities, it can also be responsible for the sudden extinction of the Ediacarian fauna caused by H2S poisoning.

Low-latitude calibrations of terrestrial cosmogenic nuclide production rates

A. J. WILLIAMS, R. PIK AND P. G. BURNARD
CRPG-CNRS, 15 rue Notre Dame des Pauvres, 54501 Vandoeuvre-les-Nancy, France (alicejw@crpg.cnrs-nancy.fr; rpi@crpg.cnrs-nancy.fr; peteb@crpg.cnrs-nancy.fr)

The scaling factors used for correcting production rates of terrestrial cosmogenic nuclides (TCN) for the effects of atmospheric absorption and the geomagnetic field on the cosmic ray flux, remain the largest source of uncertainty in determinations of surface exposure ages and erosion rates using the TCN technique. In the framework of the CRONUS-EU Marie Curie research training network, established to refine scaling factors and production rates, we have targeted basaltic lava flows at low latitude (where the effects of the geomagnetic field are assumed to be greatest) for natural calibration of cosmogenic 3He, 21Ne and 36Cl production rates. Sampling conducted over altitude transects permits quantification of atmospheric effects.

The first locality sampled was 6000m-high Mt. Kilimanjaro, Tanzania (03°S). Young (50 ka?) olivine- and pyroxene-bearing flows were sampled in an "elevation window" defined by the upper limit of rainforest and the lower limit of Quaternary glacial activity. Additional samples were collected from older (c. 500 ka?) cones at low elevation in nearby localities and, for relative calibrations of TCN production rates (e.g. 3He/36Cl), from glaciated surfaces at high elevations. Initial results yield cosmogenic 3He concentrations of 6.56 ± 0.21 x 107 at/g (2750 m) to 11.06 ± 0.46 x 107 at/g (3300 m), consistent with exposure ages of c. 150 ka for these contemporary flows if calculated using published production rates and scaling factors. Negligible variation in measurements of multiple samples (< 5% uncertainty) supports preservation of original flow-top features and the absence of post-eruptive erosion or burial of flows. Independent age determinations of these samples using Ar/Ar dating are on-going.

Recent investigation has moved to the Afar region of Ethiopia (12°N). Preliminary sampling has entailed collection of multiple samples over a 350 m altitude transect of a single flow on Beddi volcano in the Dabbahu rift-segment. The initial cosmogenic 3He measurements will assess our ability to perform high-sensitivity altitude calibrations.

Along with localities targeted by other teams in the CRONUS-EU network (Ascension Is. 07°N, Univ. Edinburgh and Cape Verde Is., 14°N, Univ. Glasgow) the Kilimanjaro and Ethiopia localities comprise the lowest latitude calibrations performed to date.
Fractionation of Fe and O isotopes in the mantle: Implications for the origins of eclogites and the source regions of mantle plumes

H.M. Williams1,2, S.G. Nielsen1,2, C. Renac3, C.A. McCammon4, W.L. Griffin1 and S.Y. O’Reilly1

1GEMOC, Macquarie University, Australia
2Dept of Earth Sciences, Oxford University, UK
3Dept de Géologie de l’Université Jean Monnet, France
4Bayerisches Geoinstitut, Universität Bayreuth, Germany

Oxygen isotopes are widely utilised as tracers of subducted and recycled oceanic crust in the convecting mantle and in the source regions of mantle plumes. This assumes that the δ18O values reported for some ocean island basalts (OIB) and eclogites reflect the involvement of oceanic crust hydrothermally altered at low and high temperatures, respectively, in their genesis.

We have measured Fe and O isotopes in garnet and clinopyroxene mineral separates from 6 eclogite xenoliths from the Kaalvallei and Bellsbank kimberlites, South Africa. Iron isotope compositions (δ57/54FeIRMM-14) for garnet and clinopyroxene range from -0.64±0.08 (2 SD) to 0.61±0.08‰ and -0.21±0.08 to 0.57±0.06‰, respectively. Calculated bulk-rock δ57/54Fe ranges from -0.58±0.12 to 0.28±0.1‰. Garnet and clinopyroxene δ18O ranges from 3.8±0.2 (2SD) to 5.1±0.2‰ and 4.6±0.2 to 5.9±0.2‰, respectively. Calculated bulk-rock δ18O varies from 4.6±0.3 to 5.2±0.3‰. Mineral and bulk-rock δ57/54Fe values correlate positively with δ18O, implying that these isotopic signatures were produced by the same underlying mechanism.

One possibility is that the eclogites are derived from oceanic crust with a low δ18O signature produced by high-temperature alteration, which also creates the δ57/54Fe-δ18O trend. However, Fe isotopes only appear to be significantly fractionated during low temperature alteration when Fe is lost from the oceanic crust [1]. Iron isotopes are also unlikely to be fractionated by high temperature alteration as the Fe concentrations in these lithologies are unchanged from their precursors and the low Fe concentrations in hydrothermal fluids would limit isotopic exchange reactions.

It is therefore likely that the δ57/54Fe-δ18O correlations are produced in the sub-continental lithospheric mantle (SCLM) by melting and metasomatic processes. Previous studies have shown that Fe isotopes can be fractionated in the mantle by processes such as partial melting [2]. If the measured variations in δ57/54Fe and δ18O can indeed be produced in the SCLM, the implication is that the low (<5.2‰) δ18O values of some OIB and eclogites cannot necessarily be interpreted in terms of subducted oceanic crust components.

Interpreting soil profiles developed on loess using a GCM and a watershed weathering model

Jennifer Williams1,2, David Pollard3, Yves Godderis2, Joel Bandstra3, Jacques Schott2 and Susan Brantley1,3

1Department of Geosciences, Pennsylvania State University, University Park, PA 16802 (jwilliam@geosc.psu.edu)
2LMTG, CNRS-Observatoire Midi-Pyrénées, Toulouse, France
3Center for Environmental Kinetics Analysis, Earth and Environmental Systems Institute, Pennsylvania State University, University Park, PA 16802

Indicators tracking the global climate warming since the last glacial maximum in continental environments are still sparse, and display a non-uniform geographic distribution. A North-South transect in the Mississippi river valley provides a natural environment to explore the climate changes along this transect since 13 ky BP, through the interpretations of pedon scale chemical weathering as applied to a regional landscape. The studied modern soils are interpreted to have developed on loess with pedogenesis commencing between 13 – 10 14C ky BP. Mineralogical analysis of a sample subset are being compared to XRF elemental analysis to define weathering profiles across the temperature and precipitation gradient.

In order to understand the profiles we have observed and their relationship with the climatic evolution along the transect, we have used the GENESIS global climate model to predict soil temperature and moisture fluxes along the transect as a function of time. We then used these model outputs to drive the WITCH model to calculate weathering profiles. The WITCH model relies upon laboratory kinetic rate laws, rationalized within the framework of Transition State Theory (TST), to describe mineral weathering (dissolution/precipitation) in natural environments. Additionally, the model accounts for soil CO2 levels at varying depths and biogenic influences derived from the uptake or release of elements by vegetation. We compare observed soil profiles to soil profiles calculated by WITCH to learn about the effects of temperature and precipitation on weathering over the last 13 ky.
Growth of the South American convergent margin (lat. 31°-36°S) during Late Paleozoic times: A U-Pb and Hf-isotope study of detrital zircons from a fossil accretionary system

A.P. WILLNER1,2, A. GERDES1 AND H.-J. MASSONNE1
1Institut für Mineralogie & Kristallchemie, Univ. Stuttgart, Azenbergstr. 18, D-70174 Stuttgart
2Institut für Geowissenschaften, Mineralogie, J.W. Goethe Universität, D-60438 Frankfurt
3Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität, D-44780 Bochum

Laser ablation ICP-MS U-Pb and Lu-Hf isotope studies of detrital zircon from different levels of the Chilean coastal accretionary system and the collisional Guarguaráz Complex W of the exotic Argentine Precordillera terrane delineate the growth pattern of southern South America during Paleozoic times: Zircons in the latter area mainly display a broad U-Pb age cluster at 0.98-1.50 Ga similar to the variation in sediments of the Argentine Precordillera, which were subducted at its western suture. By contrast, the age pattern of detrital zircons from the Late Paleozoic Chilean accretionary prism shows a mixed provenance, i.e. from the Argentine Precordillera as well as from the NW-Argentine basement to the east of it. Here, an additional age cluster of 0.39-0.58 Ga is typical for the variation of zircons grown during the Pampean and Famatinian orogenies in NW-Argentina. Minor ages of 0.60-0.98 Ga may represent the youngest zircon ages from the Precordillera and/or from the Brasiliano orogen. A second major age cluster at 1.0-1.4 Ga is consistent with a mixed signature of recycled zircons from the Precordillera and from the NW-Argentine basement. Minor age clusters between 1.50 and 3.20 Ga suggest multiple recycling of material derived from cratons in the interior of Gondwana.

Whereas metagreywackes of the coastal accretionary system at 35°S were deposited at a stable margin prior to the onset of subduction, youngest euhedral zircons (295-360 Ma) in metagreywackes at 31°S derived from a concomitant magmatic arc and were incorporated into basally accreted as well as forearc basin sediments. Initial Hf-isotope composition of around 150 representative zircons from the different age groups reveal that the respective protoliths originated from recycled sources with variable crustal residence time as well as directly from juvenile, mantle-derived melts.

Tracing terrestrial and cosmic dust with helium isotopes

GISELA WINCKLER
Lamont-Doherty Earth Observatory, Columbia University, 61 Route 9W, Palisades, NY 10964, (winckler@ldeo.columbia.edu)

Noble gases have made significant contributions in paleoclimate studies over the past decades. Recent studies indicate that helium analyzed in key climate archives, such as marine sediments and ice, is dominated by interplanetary dust particles rich in implanted solar wind and terrigenous dust rich in radiogenic helium.

Because the helium isotopic composition of these two endmembers differs by about 4 orders of magnitude, helium isotopes, particularly their combination, are powerful proxies to monitor the flux of cosmic and continental dust.

Here, I present case studies from different sampling archives with an emphasis on Helium-4 as a novel tool for the study of eolian dust transport, dust provenance, environmental conditions of the dust source region and resulting implications for the interpretation of the paleoclimatic record.
Structure of grain boundaries in silicate materials (olivine and K-feldspar) applying focused ion beam (FIB) specimen preparation and TEM

RICHARD WIRTH AND KATHARINA HARTMANN

GeoForschungszentrum Potsdam, Experimental Geochemistry, Telegrafenberg, D14473 Potsdam, (wirth@gfz-potsdam.de; hartmann@gfz-potsdam.de)

Our present knowledge on structure and behaviour of grain boundaries in silicates is still moderate compared to grain boundaries in metals and oxide materials. Various properties of silicates might be significantly influenced by the presence of grain boundaries and the grain boundary atomic structure. Structural grain boundary models derived from investigations on metals and oxides are frequently applied to silicates. Is such an assumption justified? There are similarities in the grain boundary structure. Melt films are observed along olivine grain- and olivine-pyroxene phase boundaries (Wirth, 1996). They are similar to amorphous films along interfaces in Si₃N₄ material (Kleebe et al., 1993).

However, there are also differences in the grain boundary structure. Based on the visibility of dislocation contrast in the TEM, the transition of low-angle to high-angle grain boundaries is suggested to be in the range of 10 – 15° of misorientation between the adjacent grains. Is this rule applicable to silicate grain boundaries? TEM grain boundary investigations on forsterite bicrystals synthesized by direct bonding question that transition range of 10 – 15°. In a recent paper by Heinemann et al. (2005) it was demonstrated that even at 21° misorientation of two adjacent forsterite grains, arrays of individual dislocations were observed. This observation suggests a different grain boundary structure from that of metals. In silicate grain boundaries charge compensation is a crucial requirement in contrast to grain boundaries in metals and therefore, a different grain boundary structure in silicates should be expected.

The abundances of nominally chalcophile trace elements in the main minerals of upper mantle rocks

G. WITT-EICKSCHEN¹, H. PALME¹, H. ST. C. O’NEILL², AND C.M. ALLEN²

¹Institut für Geologie und Mineralogie, Universität Köln, Germany (Gudrun.Witt-Eickschen@uni-koeln.de)
²RSES, ANU, Canberra, Australia (hugh.oneill@anu.edu.au)

Knowledge about the behaviour of the nominally chalcophile trace elements As, In, Sn and Cd in the Earth’s mantle is important to understand accretion, core formation, or the Earth evolution models. The abundances of these elements in the main minerals of upper mantle rocks are unknown. We present the required data, estimate inter-crystalline partition coefficients and Earth mantle abundances for these elements and demonstrate the lithophile nature of In, Sn and Cd in the upper mantle.

The trace element abundances in the minerals were measured in situ by LA-ICP-MS on polished thin sections of 20 spinel lherzolite and clinopyroxene-bearing harzburgite xenoliths hosted in alkali basalts from worldwide intra-plate volcanic fields. The xenoliths cover a large range of equilibration temperatures (from 850 to 1250°C) and are well-equilibrated with respect to major elements and lithophile and siderophile trace elements (e.g. REE, Sc, HFSE, Co, Ni). Most of the samples are free of visible sulfides except for the xenoliths from Kilbourne Hole carrying up to 0.1 % modal Fe-Ni-Cu-sulfides.

The main host phases for the elements In, Sn and Cd are clinopyroxene (13-58 ppb In; 48-527 ppb Sn; 37-149 ppb Cd) and if present, amphibole (49-58 ppb In; 248-649 ppb Sn; 53-89 ppb Cd). The contents in the sulfides are so low (sulfide/clinopyroxene ratio < 5) that the contribution of sulfides to the bulk rock abundances of these elements is negligible. In contrast, Arsenic is to a larger extent stored in sulfide (sulfide/clinopyroxene ratio > 100). All elements show systematic partitioning trends among the main minerals as function of temperature providing evidence that inter- and intracrystalline chemical equilibrium between the coexisting phases of the peridotites is achieved. The effect of increasing temperature is to redistribute the elements from clinopyroxene into orthopyroxene and even olivine. A very good coherence in the Dcpx/opx of In, As, Se and V suggests that these elements partition into the same pyroxene site (M1) and share the same oxidation state (i.e., 3+).

The whole rocks element abundances were calculated by combining the contents in the minerals and the modal compositions of the peridotites in order to circumvent the problems of recent contaminations of the element budgets (e.g. by the transporting host basalt). The xenoliths define linear trends of bulk rock In, Cd and Sn with CaO respectively Yb. Using a primitive mantle value of 3.65 wt% CaO the correlations yield Earth mantle abundances of 18 ppb In, 35 ppb Cd and 92 ppb Sn, whose implication for the history of the Early Earth will be discussed.
Geochemical travertine records – Insights from µ-EDXRF and µ-XRD

A. Wittenberg¹, M. Kraml¹, C. Berthold²,
R. van Geldern³, V. Kato⁴ AND D. Delvaux⁵

¹BGR, Hannover, (a.wittenberg@bgr.de, m.kraml@bgr.de)
²IfG, Tübingen, (christoph.berthold@uni-tuebingen.de)
³GGA-Institut, Hannover, (r.geldern@gga-hannover.de)
⁴GSMD, Entebbe, (kato_vicent@hotmail.com)
⁵RMCA, Tervuren, (damien.delvaux@africamuseum.be)

Natural travertines are deposited by hot springs (thermogene origin) or by low-temperature fluids (meteogene origin). Samples were chosen from a suite of travertines collected in Uganda and Tanzania along the western branch of the East African rift system. The travertine deposits are related to sites with hydrothermal activity, which are being investigated for their suitability of geothermal energy use within the BGR GEOTHERM programme. Travertines preserve a valuable record of paleo-fluid composition. Due to their inhomogeneity (thin layering) bulk analytical methods are in most cases not sufficient to unravel the small scale chemical and mineralogical changes. Hence, a combination of in situ methods with high spatial resolution (µ-EDXRF and µ-XRD) was applied. µ-EDXRF allows element mapping with a spatial resolution of 100µm by an assumed detection limit of 50 to 100µg/g for each element (>30 elements can be detected simultaneously). Locally precise measurements with a BRUKER D8-GADDS microdiffractometer allow a rapid phase analysis with a spot size down to 50µm. Such high resolution in situ analyses of mineralogical and chemical compositions are essential for reliable genetic interpretations. Due to their non-destructive and contact-less nature they are leading to a refined procedure to take sub-samples for further detailed investigations (e.g. stable isotope analysis to distinguish between meteogene and thermogene travertines).

Archetypal Archean lithosphere from West Greenland implicates shallow melting at >3.0Ga

N. Wittig¹, M. Webb¹, D.G. Pearson¹,
G.M. Nowell¹, S. M. Jensen¹ AND K. K. Sand³

¹Department of Earth Sciences, Durham University, South Road, Durham, DH1 3LE, UK,
(nadine.wittig@durham.ac.uk)

³Geological Survey of Denmark and Greenland, Øster Voldgade 10, 1350 Copenhagen, DK

We present whole rock major, trace and Re-Os isotope systematics of garnet and spinel-facies peridotite xenoliths (n = 50) sampled across the North Atlantic Craton (~700km, NAC), West Greenland at c. 600 and 200 Ma. NAC whole rock peridotites have low Al/Si (0.002 to 0.06) and high Mg/Si (1.43 to 1.61), making them distinct from Kaapvaal and Siberian cratonic lithosphere. Furthermore, at a given MgO the NAC peridotites extend to distinctly lower Al₂O₃ compared with East Greenlandic lithosphere. Samples from the Kangerlussuaq and Sarfartoq regions (northern margin NAC) appear to be compositionally more heterogeneous; extending to both more fertile and more depleted Al₂O₃ and Mg# in comparison to samples from Pyramidfjeld (southern margin NAC). Low Sc and Al₂O₃ systematics of all samples can be reconciled with approximately 25-40% melt extraction at shallow garnet-facies conditions (~4GPa). V abundances in conjunction with Sc and Al₂O₃ indicate that relatively low fO₂ prevailed during the last melt extraction, although subtle differences exist in samples from the northern and southern NAC.

Whole rock Os isotope data shows considerable variation in NAC samples, with the most unradiogenic γOs (e.g. -14.2) corresponding to T_RD model ages > 3.0Ga. Harzburgites and dunites from the southern NAC indicate Mesozoic Re disturbances, possibly due to the kimberlite activity. The T_RD model age probability distribution of these samples shows relevant peaks at 1.8 Ga and 2.3 Ga possibly relating the lithosphere to orogenies and crustal formation events that affected the Archean basement of this area. Notably, preliminary olivine Os isotope systematics point to a significantly older formation of the lithosphere (~2.5Ga) and Os disturbance on the whole rock scale.

Melting conditions and distinct Mg/Si and Al/Si systematics of the Archean NAC peridotites indicate that archetypal Archean lithosphere formed in a relatively shallow, anhydrous setting. Furthermore, this data suggests that the orthopyroxene-rich Kaapvaal and Siberian lithosphere records secondary Si enrichment, thereby eliminating these continental roots as classic examples of Archean melting environments. Further lines of investigation will include resampling of the NAC, profiling of whole rock and constituent minerals for Os isotopes; lithophile and siderophile trace element systematics together with HF-Nd-Sr-Pb isotope determination measurements of pyroxenes.
Modeling cosmogenic nuclide accumulation in the upper Amazon basin

H. WITTMANN1*, F. VON BLANCKENBURG1, J.-L. GUYOT2, AND P. W. KUBIK3

1Institut für Mineralogie, Universität Hannover, Callinstr. 3, 30167 Hannover, Germany
2Institut de Recherche pour le Développement, IRD, UR 154 LMTG, Casilla 18, Lima, Peru
3PSI/ Institute of Particle Physics, ETH Hönggerberg, 8093 Zürich, Switzerland

To date, cosmogenic nuclides in detrital material have been used to determine denudation rates, but determination of cosmogenic nuclide accumulation during sediment storage in large depositional basins has received little attention. We have designed a cosmogenic nuclide-based accumulation model for depositional regimes along a river as it actively migrates across its floodplain. The feasibility of the model was tested in the Beni catchment in Bolivia, a large (~70,000 km²) Andean foreland basin draining the northern Bolivian Andes. On its way to the Amazon the river traverses through ~50,000 km² of floodplain, thereby depositing ~100 Mt of sediment per yr. The storage of sediment debouched from the source areas has been studied in great detail in terms of migration rate, sediment exchange between floodplain and channel, and therefore of sediment residence time scales11.

To resolve irradiation of sediment during transport and storage in the floodplain, the input of material from source areas was characterized cosmogenically. Samples from the High Andes, Andean foothills, and Cratonic shields give mean SLHL-scaled 10Be concentrations of 5*10^4, 1*10^5, and 4*10^5 ats/g, respectively, which correspond to mean denudation rates of 0.14, 0.5, and 0.02 mm/yr for these three areas. However, cosmogenic nuclide measurements on bedload from the active Beni channel (n=20; mean SLHL-scaled concentration of 3.7*10^4 ats/g) show neither significant accumulation nor decrease of nuclides.

Our accumulation model assumes erosion of sediment from river cut banks due to lateral migration, and an admixture of sediment conveyed directly from the previous reach. Sediment deposition is simulated by forming point bars from portions of the mixed material. Model parameters are most sensitive to initial concentration of the erosion products, channel migration velocity, channel remobilisation depth, and the relative magnitude of upstream sediment discharge to that of floodplain reworking. The model indeed predicts no significant gain in nuclide concentration from floodplain sediment remobilization for Beni river conditions. Therefore, even for a source area with erosion rates as high as the Andes, the cosmogenic erosion rate signal is preserved throughout residence in the depositional zone of the basin.

Oxygen Fugacity in the Laboratory and in Terrestrial Systems

E.WOERMANN1, G.C. ULMER2, G.ERIKSSON3 AND S.K. SAXENA4

1Inst.f.Kristallographie, RWTH, D-52056 Aachen, Germany, (woermann@xtal.rwth-aachen.de)
2Geology Dept., Temple University, Philadelphia, Pa., 19122, (gulmer@temple.edu)
3GTT-Technologies, D-52134 Herzogenrath, Germany, (ge@gtt-technologies.de)
4CeMEC, University Park, Miami, Fl., 33199, (saxenas@flu.edu)

Several different synthetic phase assemblages – so called oxygen buffers – were devised by Eugster, 1957 in order to adjust defined oxygen fugacities in laboratories for experimental petrology at given temperatures and pressures. The “oxygen buffers” – and the corresponding acronyms – soon became popular and are now applied universally also to express fO2 levels in natural systems where, however, a correlation with the phase assemblages of the originally defined buffers is not evident. A typical example is presented by the numerous analyses of basalts with oxygen fugacities of QFM (see Ulmer et al., 2007).

From the fact that the fO2-data of the majority of basalts worldwide are arranged in a narrow belt along QFM (see Basaltic Volcanism Study Project, 1981) it is concluded that their redox state must be buffered. What may the properties and the quality of the buffers involved be? It must be realized that

- an oxygen buffer is a phase assemblage containing a certain element in different oxidation states. The entire periodic system was scanned and elements capable of coexisting in various oxidation states were marked.
- any buffer assemblage may react with any other one until one phase from buffer assemblage is quantitatively consumed and the latter buffer is thus annihilated. Eventually thus only one complete buffer assemblage can survive and will thus be dominating.

From the conditions cited above it is concluded that only the reaction: 2 H2O = 2 H2 + O2 may provide the required buffer. By thermodynamic calculations the oxygen fugacity of dissociating pure water close to QFM is confirmed for temperatures above 800 K, kinetically above the closing temperature of a reaction between basaltic magma and water, i.e. for conditions prevailing for the eruption of MORBs.

The correlation between the oxidation state of a rock and the activity of water during its formation may be extended to further systems. Thus the fact that analyses of Nakhlites were showing an oxidation state close to QFM indicates that during their formation on Mars water must have been involved – although at present neither water nor hydrous components in Mars minerals directly seem to support this conclusion.

Model crustal fluids at high P and T: Implications for aluminum transport

A. Wohlers and C. E. Manning

Department of Earth and Space Sciences, University of California at Los Angeles (UCLA), Los Angeles, U.S.A.

wohlers@ucla.edu, manning@ess.ucla.edu

Fluid-rock interaction associated with metamorphism and magmatism causes mass transfer in the Earth’s crust. To understand metasomatism in model crust at high P and T, we investigated the solubilities of K-feldspar (K-fsp), muscovite (ms) and corundum (co) in H2O at 700 °C and 10 kbar. Starting materials of natural microcline, single corundum crystals, reagent KSi3O8.5 (KS3) and specpure H2O were reacted in a piston-cylinder apparatus. Fluid compositions were determined by weight loss of K-fsp and co and phase-equilibrium bracketing methods. K-feldspar and ms dissolve incongruently at the investigated pressure. With increase of 0.021 to 0.45 m KS3, Al increased from 0.012 to 0.170 m and coexisting mineral assemblage changed from co, through ms, to K-fsp. Our results locate two invariant points: I1, co + ms + fluid (0.082 m Al, 1.32 m KS3) and I2, K-fsp + ms + fluid (0.16 m Al, 2.69 m KS3). Total solubility of Al and SiO2 in the presence of dissolved K is considerably higher than in pure H2O at the same P and T, and SiO2 solubility in the presence of K-fsp is at least 0.83 mol/kg H2O, which is higher than the SiO2 in H2O in equilibrium with quartz at the same P and T (0.68 molal).

Preliminary experiments at quartz saturation at the same P and T provide the pH buffering assemblages K-fsp + ms + qtz (J1) and ky + ms + qtz (J2) and give nearly identical results. Fluid composition at J2 is 0.07 m Al and 0.098 m KS3, and at J1 is approximately 0.173 m Al and 0.264 m KS3. The results imply that the presence or absence of quartz does not effect the Al solubility for the investigated mineral assemblages. The fluids of the experiments are models of aqueous solutions equilibrated with common crustal bulk compositions such as metapelite and peraluminous and metaluminous granite. The results show that the dissolved Al content in the fluid increases as the bulk rock Al declines; i.e., a fluid in equilibrium with a model metaluminous granite has a higher Al content than one in equilibrium with a model metapelite. The high measured Al concentrations in H2O-rich fluids indicate that substantial Al transfer may occur at deep-crustal metamorphic conditions, even at low water-rock ratios. The enhanced Al solubility is a strong indication for Al-K and Al-K-Si complexing.

Influence of fO2 on the precipitation of Fe-poor sulfide minerals

Cora C. Wohlgemuth-Ueberwasser1, Chris Ballhaus2 and Jasper Berndt1

1Institut für Mineralogie, Universität Münster, Corrensstr. 24, 48149 Münster, Germany, (ueberwas@uni-muenster.de)
2Mineralogisches Institut und Museum, Universität Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany

The Skaergaard Intrusion (East Greenland) differs from other layered intrusions in that it contains disseminated, stratiform Pd-Au mineralizations. In comparison with the classic disseminated sulfide-PGE horizons such as the Merensky reef in the Bushveld Complex or the J-M reef at Stillwater, the Platinoiva reef occurs at a much higher, chemically more evolved stratigraphic level in the cumulate pile in magnetite-quartz-rich cumulates. Sulfide mineralogy dominated by metal-rich Cu sulfides like bornite, and the noble metals associated with the sulfide are Pd and Au, mostly as alloys with (Cu,Fe)(Au,Pd,Pt). Typical Fe-Ni-dominated sulfides like pyrrhotite or pentlandite are absent.

Several processes have been discussed to explain Cu-enriched, Fe-depleted Pd-Au-enriched sulfide horizons: 1) fractional crystallization of (Fe,Ni)1-xS monosulfide leading to Cu enrichment in the derivative sulfide melt, 2) modification of Fe-Ni-sulfides by infiltration of Cu-enriched postmagmatic fluids, and 3) sulfide oxidation.

To simulate sulfide oxidation experimentally, we add to an (FeNiCu)1-xS monosulfide composition varying amounts of hematite and equilibrate these mixtures in welded evacuated SiO2 glass capsules at temperatures ranging from 1050 (superliquidus) to 700°C (subsolidus). Hematite reacts with the FeS component of the sulfides according to 2 FeS + 2 Fe2O3 = 6 FeO + S2, raising fS2 and sequestering FeO to the sulfide melt. In the subsolidus region, the reaction is 6 FeS + 24 Fe2O3 = 18 Fe3O4 + 3 S2, raising fS2 and stabilizing magnetite. The sequence of oxidation of sulfide species follows broadly the electromotive series, first FeS, then NiS, and finally Cu2S and CuS, eventually producing Cu-rich sulfides like bornite that coexist with metallic Cu, as observed in the Platinoiva reef. Microprobe analyses of the first experiments at 1050°C revealed a successive increase in oxygen (O2) content in the sulfur melt at the expense of S2 from < 0.5 wt.% (detection limit) to 7 ± 1 wt.% O2 in charges with > 30 wt% hematite. Iron also increases with increasing O2 content in the melt, suggesting that oxygen dissolves in the sulfide melt principally as FeO and/or FeO1.5 complexes. In the presence of sulfide melt oxidation to above the fayalite-magnetite-quartz equilibrium is difficult because the FeO component in sulfide melt tends to react with to SiO2 glass, stabilizing fayalite and constraining fO2 to near the FMQ equilibrium. In SiO2 glass, oxidation to beyond FMQ is possible only in the subsolidus temperature region.
Comparison of the ligand-promoted dissolution of kaolinite and goethite with different organic chelators at pH 6

DOMENIK WOLFF-BOENISCH AND SAMUEL J. TRAINA
Sierra Nevada Research Institute, University of California
Merced, CA-95344, USA

The cycling and environmental fate of many elements often involve the bioactivity of the microenvironment. The ability of organic acids to solubilize and complex key elements confer them a major role in the bioavailability of otherwise insoluble nutrients and toxins. The ligand-promoted dissolution of two major soil constituents, goethite and kaolinite, has been investigated in the presence of different organic ligands.

The polysaccharide alginate dissolves only little goethite until a second ligand enters the solution. The addition of oxalate and the siderophore DFO-B, respectively significantly enhances goethite dissolution. This synergistic effect on goethite dissolution in the 2-ligand systems alginate/oxalate and alginate/DFO-B can be explained by a considerable increase in the chemical affinity of the dissolution reaction in the presence of the second ligand (Wolff-Boenisch and Traina, 2007a). For oxalate, the ligand-promoted effect on goethite becomes only noticeable when the amount of goethite and/or oxalate in solution overcomes certain concentration thresholds. As to the siderophores, on an equimolar basis, far-from-equilibrium goethite dissolution rates in the presence of enterobactin are 5 times higher than analogous DFO-B-promoted rates although both chelators show low fractional adsorption <6%. Increased iron solubility and the related shift away from solution equilibrium is a more compelling explanation of the driving force behind goethite dissolution than surface complexation of these siderophores.

In separate systems, DFO-B and oxalate each caused a ligand-promoted dissolution of kaolinite and this rate increase is consistent with a mechanism involving ligand adsorption rather than chemical affinity or aluminum inhibitory effects (Wolff-Boenisch and Traina, 2007b). The concept of ligands competing for the same adsorption sites is corroborated by experiments where DFO-B and oxalate were employed to assess a potential synergistic effect on kaolinite dissolution. However, no such effect was observed. Species calculations as well as experiments indicate that DFO-B was preferentially adsorbed on the kaolinite surface. Further support for this hypothesis comes from the finding that siderophore-promoted dissolution of kaolinite showed the same relationship with aqueous ligand concentration as does the surface coverage: At low aqueous DFO-B concentrations <100 µM, increases in surface coverage and dissolution rates are more pronounced than at aqueous DFO-B concentrations >100 µM, where increase in these parameters is only marginal.

Experimental investigation of the CO₂ sealing efficiency of cap rocks

J. WOLLENWEBER, S. ALLES, A. BUSCH, AND B. M. KROOSS

Institute of Geology and Geochemistry of Petroleum and Coal, Lochnerstr. 4-20, RWTH Aachen University, 52056 Aachen, Germany (wollenwebber@le.k.wt-aachen.de)

Using a combination of experimental, petrophysical and mineralogical methods, transport processes of CO₂ in shales and marls, and its interactions with the mineral phase have been studied. The investigations comprised permeability, gas breakthrough and diffusion experiments under in-situ P/T conditions on cylindrical plugs of 10 - 20 mm thickness and 28.5 mm diameter.

Single phase flow tests with water were conducted to assess permeability coefficients and ensure complete water saturation of sample plugs before each gas breakthrough and diffusion experiment.

Capillary gas breakthrough tests were performed as described by Hildenbrand et al. (2002). To test for reproducibility and petrophysical changes due to the interaction of the samples with CO₂, repetitive runs were carried out on the same sample. Series of experiments with Helium and CO₂ under the same conditions have been conducted to compare the transport properties of inert and reactive gases.

CO₂ diffusion experiments were carried out according to the procedure described by Schloemer and Krooss (2004). These tests yielded unexpectedly high CO₂ storage capacities. Significant increases in (water) permeability coefficients were observed after CO₂ diffusion experiments.

Repetitive CO₂ gas breakthrough tests revealed irreversible changes of the petrophysical properties, possibly due to the interaction between the CO₂ and the sample. An increase in (water) permeability was noted after the first CO₂ gas-breakthrough test while permeability remained constant after the follow-up tests.

Mass balance calculations indicated significant CO₂ loss from the gas phase during the first breakthrough tests, whereas subsequent runs did not show any CO₂ loss. This loss of CO₂ from the gas phase is attributed to dissolution, sorption and mineral reactions.

High CO₂ storage capacities were also evidenced by manometric sorption experiments on powdered samples. In order to further clarify this issue, XRD analyses, BET tests, and Hg porosimetry measurements are presently being performed on the original and CO₂-exposed samples.

Surface charge and potential at carbonate mineral surfaces

M. WOLThERS1, P. VAN CAPPELLEN1 AND L. CHARLET2

1Department of Earth Sciences – Geochemistry, Faculty of Geosciences, Utrecht University, PO Box 80.021, 3508 TA Utrecht, The Netherlands, (wolthers@geo.uu.nl; pvc@geo.uu.nl)

2Environmental Geochemistry Group, LGIT-OSUG, University of Grenoble, F-38041 Grenoble, Cedex 9, France, (laurent.charlet@obs.ujf-grenoble.fr)

The surface chemistry of divalent metal carbonate minerals has received ample attention. The macroscopic properties of carbonate mineral surfaces were initially studied using electrokinetic measurements and potentiometric titrations. Since the 1990’s, the application of sophisticated surface imaging and spectroscopic methods plus the development of molecular models for (hydrated) carbonate mineral surfaces have significantly advanced our comprehension of the microscopic structure and reactivity of carbonate–aqueous solution interfaces. Surface complexation models for carbonate mineral–solution interfaces reproduce the macro-scale surface charging behaviour taking into account surface coordination sites derived from spectroscopic information [1,2]. Charge Distribution MULTIsite Ion Complexation (CD–MUSIC, [3]) modelling allows one to also include micro- and nano-scale information such as the presence of crystallographically distinct surface coordination sites, structural information of surface complexes, and possibly surface morphology. The CD–MUSIC model for carbonate mineral surfaces will be presented and tested against independent surface titration and potential measurements.

Barium isotope compositions of chondrites revisited

F. WOMBACHER AND H. BECKER

Institut für Geologische Wissenschaften, Freie Universität Berlin, Malteserstr. 74-100, 12249 Berlin, Germany (fwo@zedat.fu-berlin.de; hbecker@zedat.fu-berlin.de)

The decay of the short-lived nuclide $^{135}$Cs to $^{135}$Ba with a half-life of 2 Ma offers potential for the study of volatile loss. However, the application of Cs-Ba cosmochronometry is only feasible if sufficient live $^{135}$Cs was present in the early solar system and if nucleosynthetic isotope anomalies are absent to allow for the unambiguous identification of radiogenic effects. The initial $^{135}$Cs/$^{133}$Cs = $4.8 \times 10^{-4}$ reported in [1] should result in well resolvable $^{135}$Ba variations in chondrites. However, two studies reported nucleosynthetic Ba isotope anomalies [2, 3] in bulk chondrites. For example, Ranan and Jacobson [3] observed enrichments of $^{137}$Ba/$^{136}$Ba and $^{138}$Ba/$^{136}$Ba up to 25 and 60 ppm, respectively for carbonaceous and ordinary chondrites.

Here, we readdress the issue of nucleosynthetic and radiogenic Ba isotope anomalies in bulk chondrite samples. To this end, four chondrites (Murchison CM2, Allende CV3, Saint-Séverin LL6, Pillistfer EL6) and one terrestrial sample were analyzed using a ThermoFinnigan Triton thermal ionization mass spectrometer.

After normalization to $^{136}$Ba/$^{136}$Ba, the $^{135}$Ba/$^{136}$Ba isotope ratios for all samples agreed to within 20 ppm with the terrestrial Ba standard, and no radiogenic $^{135}$Ba isotope anomaly was resolvable within uncertainty (2 se). Also, the $^{137}$Ba/$^{136}$Ba and $^{138}$Ba/$^{136}$Ba ratios deviated by no more than 17 ppm which is within the measurement uncertainty (13 to 37 ppm, 2 se) and were not resolvable, except for Pillistfer which differed from the Ba standard value by 47±22 ppm and 53±33 ppm (2 se) for $^{137}$Ba/$^{136}$Ba and $^{138}$Ba/$^{136}$Ba, respectively.

Our first results suggest that i) live $^{135}$Cs was not abundant enough to provide a useful cosmochronometer in bulk chondrite samples and ii) nucleosynthetic anomalies in chondrite samples [2, 3] may be nonexistent and thus, the solar nebula was probably very homogeneous. In that regard, however, we need to further evaluate whether the $^{137}$Ba/$^{136}$Ba and $^{138}$Ba/$^{136}$Ba anomalies observed in Pillistfer are real.

A Late Jurassic A-type granitoid, named Baijuhuajian granite in western Zhejiang Province, SE China, emplaced along the Jiangshan-Shaoxing fault zone and intruded an Early Jurassic anticline volcanic basin bounded by Sinian sedimentary strata composed of sandstone and siltstone. The granite exhibits a porphyritic texture and is composed of alkaline feldspar phenocrysts, and groundmass of K-feldspar, plagioclase, quartz and biotite. The granite is peraluminous (A/CNK > 1.1) and shows A-type geochemical signatures. The granite is characterized by high contents of SiO₂ (>75%), total alkalis (Na₂O + K₂O ≥ 6.3%), total REE (223 – 438ppm), HFSE as well as high FeOt/MgO ratios (15 – 25). It is also characterized by low contents of CaO (0.57 – 1.02 %) and extremely low contents of P₂O₅ (<0.01%), TiO₂ (0.06 – 0.14%) and Sr (7.23 – 38.81ppm). The fine-grained groundmass with perthite indicates shallow-depth emplacement of a relatively high temperature dry magma. The granite falls into within-plate field in various discrimination diagrams and can be classified as A 2-type granites, which is indicative of emplacement in a post-collisional setting. These features are similar to the A-type granites from the Lachlan Fold Belt, Southeastern Australia.

U-Pb zircon dating constrains the age of this granite to be 141Ma. Slightly negative ε Nd(T) (-2.46) and negative to positive zircon ε Hf(T) (-0.3 to 4.56) suggest binary mixing of possibly mantle-derived magma and crustal materials.

The tectonic regime was compressional in the Mesozoic prior to the emplacement of the Baijuhuajian granite, resulted from the subduction of Paleo-Pacific plate underneath the SE South China Block. Our results suggest that the tectonic regime in SE South China changed at ~141 Ma, from collisional to extensional settings, leading to upwelling of the asthenosphere and mantle-derived magma interacted with crustal materials before the emplacement along the Jiangshan-Shaoxing fault zone in SE South China.

This study is supported by RGC grant HKU 7041/05P.

Fe-FeS-silicate partitioning of chalcophile and siderophile elements: Implications for core formation

B. J. WOOD, A. CORGNE1 AND J. WADE2

1GEMOC, Macquarie University, Sydney, Australia
2Planetary and Space Sciences Research Institute, Open University, Milton Keynes, UK; (j.wade@open.ac.uk)

The concentrations of weakly siderophile and chalcophile elements in the primitive mantle provide important constraints on the conditions of accretion and terrestrial core formation, in particular the possible role of late sulphide addition and of late volatile loss.

In order to explore the possible impacts of these processes, we have determined the partitioning of V, Cr, Cu, Zn, Ga, Nb, Ag, Tl and Pb between Fe-FeS liquids and a range of liquid silicate compositions at 1.5-14 GPa and temperatures of 1280-2300 °C.

Many of the observed variations in partition coefficient are consistent with the known properties of Fe-alloys. For pure Fe metal coexisting at 1700 °C with a silicate melt of mantle FeO content, the metal/silicate partition coefficients are as follows: V(0.12), Cr(0.3), Cu(36), Zn(0.9), Ga(6), Nb(0.015), Ag(20), Tl(1.1) Pb(3.5). Adding C (at graphite saturation) to the metal increases Metal/silicate partition coefficients of Nb by an order of magnitude, those of V and Cr by a factor of 3, has small negative effects on Cu and Zn and larger negative effects on Ag and Pb partitioning. On going from Fe to FeS liquid the sulphide/silicate partition coefficients change approximately to: V(0.6), Cr(0.9), Cu(100), Zn(2), Ga(3), Nb(0.4), Ag(100), Tl(40), Pb(35).

Using these and literature data, a protracted period of accretion under reducing conditions appears to be required to satisfy the observed V and Cr contents of the mantle. This type of accretion path leads to around 30% of earth’s Nb residing in the core. Application of these constraints to the other elements indicates that late sulphide addition to the core can explain the Pb and Tl contents of the mantle and their isotopic signatures, but the amount required (1.5-2%) seems precluded by the strongly chalcophile nature of Cu.
Storage of crustal forming events in lamprophyres: Examples from the Fennoscandian Shield

J. WOODARD AND O. EKLUND
Department of Geology, University of Turku, FIN-20014
Turku, Finland (jdwood@utu.fi; oleklu@utu.fi)

Lamprophyres are volatile-rich, peralkaline to alkaline, mafic to ultramafic igneous rocks, which typically occur as dyke swarms. Lamprophyres often contain mineral assemblages that were formed during the early stages of magmatic evolution, making it notoriously difficult to date their intrusive event (Rock, 1990).

The Fennoscandian Shield is composed of Archaean continental blocks in the northeast and the accretionary arc complexes of the Svecofennian Orogen (1.93-1.76 Ga) in the southwest. The magmatic end of the Svecofennian Orogen is represented by several low-volume bimodal shoshonitic granitoid intrusions as well as shoshonitic lamprophyres and carbonatites.

For this study, samples of shoshonitic lamprophyres intruded into both the Archaean and Proterozoic domains of the Fennoscandian Shield were examined. By analysing different isotope systems (e.g. U-Pb; Rb-Sr; Sm-Nd) as well as utilising the high spatial resolution capabilities of secondary ionisation mass spectrometry (SIMS), we aim to acquire geochronological data from the lamprophyres as well as the crust in which they have intruded.

Zircon grains were separated for SIMS analysis from three samples from the Lake Syväri region of eastern Finland and five samples from the western Lake Ladoga region of Russian Karelia. Zircon rims consistently yield ages between 1.78-1.77 Ga. These parallel the results of Eklund & Shebanov (2005) for the Áva ring intrusion in southwest Finland, and are similarly interpreted as the age of the lamprophyre intrusions. Cores yield a variable array of ages, which correspond to several well-established crustal formation events within the Fennoscandian Shield.

Preliminary Sm-Nd isochron ages from two Lake Ladoga samples are 1.67 Ga, while a Rb-Sr isochron from a Lake Syväri sample was 1.68 Ga. These are in agreement with K-Ar ages given by Haudenschild (1988) from the country rocks in eastern Finland, reflecting cooling and thus exhumation rates. εNd(1800) was found to be near zero for all three samples, indicative of shield scale mantle metasomatism at approximately 1.9 Ga. Partial melting of this subductively enriched mantle wedge generated the lamprophyric magma.

Our results show that by utilising several isotope systems coupled with high spatial resolution techniques, age data from diverse crustal forming events may be obtained from lamprophyres.

Ferric iron in clinopyroxene from the garnet peridotite facies: Systematics and partitioning behaviour

A.B. WOODLAND
Institut für Geowissenschaften, Uni. Frankfurt,
Altenhöferallee 1, 60438 Frankfurt, Germany
(woodland@em.uni-frankfurt.de)

Ferric iron is an important minor element in the Earth's mantle. Its presence in individual minerals is influenced not only by crystal chemistry and bulk rock composition, but also by the prevailing oxygen fugacity, which is known to vary laterally as well as with depth (e.g. Woodland & Koch 2003). Aside from garnet, pyroxene can be a significant carrier of Fe3+ in the garnet peridotite facies of the upper mantle. Fe3+ contents of clinopyroxene (cpx) measured by Mössbauer spectroscopy are reported for 32 garnet peridotite xenoliths from South Africa and Lesotho. Together with literature data, this enlarged data set allows a more robust analysis of the systematics of Fe3+ incorporation in cpx and partitioning behaviour of Fe3+ between cpx and garnet than that previously attempted (Canil & O'Neill 1995).

Measured Fe3+/Fe tot in cpx ranges from 0.10-0.38 and exhibits a general decrease with increasing equilibration temperature (the Fe3+ -insensitive BKN two-px thermometer). Such an anti-correlation is not found for Fe3+ cpfu in cpx. The reason for this is that the Fe3+ content of cpx also changes with temperature in the presence of garnet (i.e. Ellis & Green 1979). Fe3+ contents correlate with Na, underlining the importance of the aegerine component in these cpxs. Such a relationship is not observed in spinel peridotites (Woodland et al. 2006; Canil & O'Neill 1995), indicating a change in substitution mechanism for Fe3+ in cpx going from the spinel to the garnet peridotite facies.

Partitioning of Fe3+ between cpx and garnet is T-dependent. This has the effect of transferring Fe3+ into garnet with increasing T along a geotherm, which can influence how the fO2 will vary with depth.

Characterization of elemental release during interaction of bacteria with basalt and granite

LINGLING WU\textsuperscript{1}, ANDREW D. JACOBSON\textsuperscript{1} AND MARTINA HAUSNER\textsuperscript{2}

\textsuperscript{1}Department of Earth and Planetary Sciences, Northwestern University, Evanston IL 60208  
(lingling@earth.northwestern.edu, adj@earth.northwestern.edu)

\textsuperscript{2}Department of Civil and Environmental Engineering, Northwestern University, Evanston IL 60208 (mhausner@northwestern.edu)

We used batch reactors to characterize the rates and mechanisms of elemental release during the interaction of a single bacterial species (\textit{Burkholderia fungorum}) with basalt and granite at $T = 28^\circ\text{C}$ for 36 days. We supplied glucose as a C source, either NH\textsubscript{4}\textsuperscript{+} or NO\textsubscript{3}\textsuperscript{-} as N sources, and trace apatite in the rocks as a P source. We measured the release of Al, Ca, F, Na, Mg, P, Si, and Sr under several biotic and abiotic conditions with the aim of evaluating how actively metabolizing bacteria might influence basalt and granite weathering on the continents. Over the entire experimental period, reactors containing viable bacteria yielded the highest elemental release rates. Large pH decreases occurred when using NH\textsubscript{4}\textsuperscript{+}. No pH changes occurred when using NO\textsubscript{3}\textsuperscript{-}. We attribute pH lowering to either organic acid production or H\textsuperscript{+} extrusion during NH\textsubscript{4}\textsuperscript{+} uptake. Protons may be produced and consumed simultaneously during NO\textsubscript{3}\textsuperscript{-} uptake, resulting in a net zero pH change. Elemental release rates inversely correlate with pH, suggesting that proton-promoted dissolution was the dominant reaction mechanism. In the granite reactors, formation of Al-F and Fe-F complexes may have enhanced mineral solubility by lowering Al and F activities. Within the context of this study, bacteria appear to elevate the rate of long-term atmospheric CO\textsubscript{2} consumption by Ca-Mg silicate weathering between factors of 2 and 5 over corresponding inorganic rates. The effect is greater for basalt than granite. With respect to the granite experiments, we propose that microbially enhanced Ca release from apatite and fluorite may contribute to elevated Ca/Na ratios commonly observed in granitic watersheds.

Ab initio molecular dynamics study of Li speciation in aqueous fluid at high pressure

B. WUNDER, S. JAHN AND A. MEIXNER

GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany (wunder@gfz-potsdam.de)

Fluids play an important role in almost all geochemical processes, such as dissolution and precipitation of minerals, isotopic fractionation or mass transport in hydrothermal systems. A key parameter for a quantitative understanding of fluid properties and geochemical processes involving aqueous fluids is the complexation of the dissolved ions and molecules. Since the speciation does not only depend on the chemical composition, but also on pressure and temperature, any direct approach for studying the molecular structure and transport in fluids at conditions of the Earth’s interior requires in situ experimental techniques (e.g. x-ray diffraction, x-ray absorption, Raman and infrared spectroscopy). However, most of these methods are insensitive to low concentrations of light elements, such as Li. Recently, due to the massively increased computing power, ab initio molecular dynamics (AIMD) simulations have become a powerful technique for molecular modeling of fluids with a complex chemistry that are not well described by classical models.

Here, the hydration of a Li ion in aqueous fluid is studied as a function of pressure by AIMD simulation at constant temperature ($T=1000$ K) and constant volume. The pressure is derived from an equation of state of pure H\textsubscript{2}O fluid. The calculations show that structural changes of the H\textsubscript{2}O fluid in the studied pressure range from $P=3$ kbar to $P=60$ kbar also affect the hydration of the Li ion. Since the number of H\textsubscript{2}O molecules in the first hydration shell of the Li ion is subject to rapid dynamic change, a distribution of coordination numbers can be calculated for each pressure. With increasing pressure, the average coordination number increases with considerable decrease of 3- and 4-fold and respective increase of 5- and 6-fold coordinated Li. The ionic coordination changes in aqueous fluids as a function of pressure could affect the isotopic fractionation between minerals and fluids and consequently could have implications for models of the geochemical element cycles. As a test of the possible P-dependence of the Li-isotope fractionation, experimental studies on the model system spodumene - fluid are currently being performed and will be discussed.
Chemically altered basalt at high-latitudes on Mars: TES, OMEGA, and GRS integrated data sets

M.B. WYATT
Brown University, Department of Geological Sciences, Providence, RI 02912; (Michael_Wyatt@Brown.Edu)

TES, OMEGA, and GRS provide unique and complementary insights into martian compositions. TES and OMEGA measure the compositions of the upper hundred to tens of microns while GRS measures the upper few tens of centimeters. TES oxide abundances (wt. %) for the Surface Type 1 (ST1) and 2 (ST2) global spectral endmembers are calculated by combining compositions of mineral-phase endmembers in proportion to their relative modeled abundances (vol. %). TES chemical trends reveal higher abundances of FeO for ST1 (ST1 15.2 % vs. ST2 12.4 %) and higher abundances of SiO2 for ST2 (ST2 57.9 % vs. ST1 53.9 %). Results from OMEGA are in agreement with TES oxides. OMEGA pyroxene maps are closely correlated with the equatorial-distribution of ST1 (High FeO) while high-latitude ST2 materials lack evidence of mafic absorption bands and are consistent with an enrichment of high-silica phases.

Recent GRS studies report chemical trends (wt. %) for 'regions' dominated by TES ST1 (RT1) and ST2 (RT2) materials. GRS RT2 chemistries have higher abundances of FeO (RT2 20.1 % vs. RT1 17.6 %), K, and Th compared to RT1. Abundances of SiO2 (RT1 44.7 % and RT2 45.8 %) and K/Th ratio do not show significant spatial variations.

The constant K/Th ratio across RT1 and RT2 is not consistent with subaqueous or deep subaerial aqueous weathering of basalt as K would fractionate from Th. Fractional crystallization and subduction zone magmatism could enrich K and Th, however GRS does not detect an enrichment of Si as would be expected. The lack of any enrichment in SiO2 between GRS RT1 and RT2 indicates that evolved volcanics (andesites) are not present in high-abundances at regional-global scales. The favored model from the GRS team is thus initial bulk differentiation processes on Mars producing compositionally distinct magma source regions in the mantle. RT1 and RT2 basaltic provinces with distinct trace element compositions could then be produced. Differences in SiO2 between TES ST1 and ST2, however, must also be taken into consideration. Thin coatings or rinds of high-silica phases (tens of microns) affect the shape and position of absorptions in emission spectra of basalt. Such coatings on Mars may form from near-surface ice and/or surface-atmosphere interactions with little to no water penetrating or cycling into the surface. Limited degrees of alteration in only the upper few tens of microns of the surface would affect TES derived chemistries and may be undetectable to GRS due to a deep sampling depth. TES, OMEGA, and GRS data sets support: 1) Distinct magma source regions and basaltic compositions for ST1-RT1 and ST2-RT2 and 2) Secondary coatings or rinds of amorphous high-silica phases at high-latitudes on ST2-RT2 basalt.

New experimental constraints on the Na-in-cordierite thermometer and its application to high-grade rocks

S. WYHLIDAL, W.F. THÖNY AND P. TROPPER
Institute of Mineralogy and Petrography, University of Innsbruck, Innrain 52, A-6020 Innsbruck, Austria (stefan.wyhlidal@uibk.ac.at)

The mineral cordierite is a common and important rock-forming mineral in medium- and high-grade aluminous rocks of the amphibolite- and granulite-facies. Large cations such as Na and K in cordierite can also be considered for thermobarometry. Experimental investigations with synthetic starting materials have shown that the Na content decreases not only with increasing T (Mirwald, 1986; Thompson et al., 2002) but also strongly depends on aH2O (Thompson et al., 2002).

To investigate the systematic variation of Na-in cordierite with T in metapelites we performed experiments using a natural quartzphyllite sample (Grt + Bt + Mus + Chl + Ab + Qtz). The experiments were done in a hydrothermal apparatus at 0.3 GPa and at six different temperatures (T = 580°C, 630°C, 650°C, 680°C, 730°C, 780°C) with varying amounts of H2O present (dry, H2O-undersaturated, H2O-saturated). In addition, experiments which contain significant amounts of H2O were also buffered with respect to fO2 (HM-buffer). The experimental investigations yielded the assemblage cordierite + biotite + muscovite + quartz at 580°C. Above 650°C and 680°C, K-feldspar + plagioclase + melt were also observed. T conditions, calculated by using the coexisting feldspars, yielded T of 640°C and 682°C in excellent agreement with the experimental conditions, indicating a high degree of equilibration within the experiments. In all experiments cordierite is present and the Na content in cordierite shows a systematic variation which strongly decreases with increasing T ranging from 0.154 Na apfu at 580°C to 0.059 Na apfu at 780°C. Preliminary results indicates the variation of Na-in-cordierite can be described with a linear function such as: T(°C) = (Na [apfu] - 0.43002)/(-0.000474).

Application of this thermometer to contact metamorphic rocks from the island Kos (Kalt, 1998) and to migmatites from the Bayerische Wald (Variscan Belt, Germany, Kalt et al., 1999; Tropper et al., 2006) yields contrasting results. Whereas the agreement above 700°C is very good, below this T, our calibration yields T which is too high, compared to conventional thermometry. One of the reasons of the discrepancy could be the presence of Na-bearing muscovite in our experiments, which might perturb Na partitioning into cordierite at these T.

High resolution ion microprobe analysis of sulphur isotopes in speleothem carbonate

P.M. WYNN 1, I.J. FAIRCHILD 1, A. BAKER 1, S. FRISIA 2, A. BORSATO 2, M. MIORANDI 2, C. SPÖTL 3 AND E.I.M.F. 4

3Institut für Geologie und Paläontologie, Universität Innsbruck, Austria (christoph.spoetl@uibk.ac.at)
4Edinburgh Ion Microprobe Facility, Institute of Earth Science, University of Edinburgh (john.craven@ed.ac.uk)

Sulphur emitted into the atmosphere from the combustion of fossil fuels is regarded as a key mechanism in climate forcing at both the local and regional scale. Trace amounts of sulphate in speleothem carbonate at some cave sites show an increase in concentration towards the present day, reflecting the increase in SO2 emissions since the onset of the industrial era and the early 1980’s. This suggests speleothems may record local aspects of atmospheric sulphate content. However, speleothem sulphur concentrations are low and manual techniques for sulphur isotope analysis allow only low resolution sampling. Microanalytical techniques are thus required to build a comprehensive palaeoclimate record.

Ion microprobe analysis has been used to extract sulphur isotopes from speleothem carbonate at high resolution. Two stalagmites from the Italian and Austrian Alps have been used to pioneer this technique. Growth rates are less than 100 µm/yr and concentrations of sulphate range between pre-industrial levels of 10 ppm to modern day values of 70 ppm. Analysis at annual resolution encompassing the past 100 years demonstrates an excursion in sulphur isotopic composition from values close to the carbonate bedrock end-member value in the pre-industrial era, to values isotopically depleted in 34S, reflecting the increase in SO2 emissions with industrial activity.

Counting statistic errors for the low sulphur concentrations (~10 ppm) are ±4 % while for the higher concentrations (~ 70 ppm), these errors approach ±1.5 %. New, low sulphur standard material is being investigated so that instrumental conditions can be optimized to provide higher precisions at low (10-50 ppm) sulphur concentrations.

EMP Study of Early Cambrian Barite Deposits in East Guizhou, China

F. XIA 1,2, J-Y. PAN 1,2, FAN. XIA 3, D-S. MA 2 AND Z-X. SUN 3

1Key Laboratory for Nuclear Rersources and Environmental Research of Ministry of Education, East China Institute of Technology, Nanchang 330013, China (xj730@163.com)

3Shanghai Environmental Monitoring Centre, Shanghai 200030, China (xiahoufan@sohu.com)

Geological Setting

The Lower Cambrian black shale sequence of the Niutitang Formation in southeast Guizhou China hosts a barite layer. The ore-bearing rock series is composed of black silicalite, carbonaceous shale interbedded with phosphorite, barite and carbonate shale in ascending sequence. The stratified main ore bodies, partially in lenticular form, are dominantly embodied in the silicalite and black shale of the lower section of the Niutitang Fm. of the early Cambrian.

Discussion of Results

Systematical samplings for the election microprobe (EMP) were taken in the Dahebian barite deposit in Tianzhu County of Guizhou Province China. Samples of barite ore were analyzed using JEOL JXA8100 in the Key Laboratory for Nuclear Rersources and Environmental Research of Ministry of Education, East China Institute of Technology.

Based on the election microprobe (EMP) study, the hyalophane K,Ba[Al2Si2O8] was reported for the first time in the barite deposits which is a typical low-temperature mineral(Table 1), and we analysed the origin of hyalophane based on studying about its chemistry composition, optical character and their correlation, more, researched the genesis of Dahebian and Xinhuan barite deposits. The study provides mineral evidence for the submarine hydrothermal exhalative genesis of Dahebian and Xinhuan barite deposits

Affinity of the Trans-North China Orogen: Constraints from detrital zircon U-Pb and Hf isotope compositions from the Fuping Complex, North China Craton

XIAOPING XIA1, MIN SUN1, GUOCHUN ZHAO1 AND FUYUAN WU2

1Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong; minsun@hku.hk
2Institute of Geology and Geophysics, Chinese Academy of Science, Beijing 100029, China

There is a broad consensus that the North China Craton was assembled by the collision between the Eastern and Western Block along the Trans-North China Orogen at ~1.85 Ga [1]. However, controversy exists on the affinity of the Trans-North China Orogen. The Fuping Complex is located in the central segment of the Trans-North China Orogen and is considered to be the most promising area to investigate the evolution history of the North China Craton. In this study, we investigate the U-Pb and Hf isotopes of about 200 detrital zircon grains from the Wanzi Supracrustals, which are the major lithologies of the Fuping Complex, and the results provide important insights into the problem. The analytical results on metamorphic zircon rims give ages of 1825-1843 Ma, corresponding to the tectonothermal event that led to collision between the Eastern and Western Blocks. Other analytical data on igneous zircon cores mainly yield two age populations at ~2.1 and ~2.5 Ga, with some inherited ages scattering between 2.6 Ga and 2.8 Ga. These two groups of age are equivalent to those of the ~2.1 Ga Nanying granitic gneiss and the ~2.5 Ga Fuping TTG gneiss, respectively [2]. All zircons with ~2.5 Ga age from different samples possess positive initial $\varepsilon_{Hf}$ values, ranging from +1.4 to +10.9, with a peak at about +5. The depleted mantle Hf model ages of these zircons show a peak at about 2.8 Ga, identical to the main crustal formation age of the Eastern Block [3] and distinct from that of the Western Block [4]. These data suggested that the Fuping complex was emplaced in a continental margin arc system at the western margin of the Eastern Block, thus have affinity to the Eastern Block. The zircons of 2.1 Ga population have initial $\varepsilon_{Hf}$ values of -4.9 to +6.0 and a younger depleted mantle Hf model age peak at 2.61-2.67 Ga, interpret as a re-melting of the above 2.5 Ga rocks with minor juvenile material contribution. This study was supported by the Hong Kong RGC Grants (7048/03P, 7063/06P, 7058/04P and 7055/05P) and a NSFC grant (40429001).

Geochemical characteristics and isotope dating of moyite at the southeastern margin of the Kuruktag block, Xinjiang, China

PEIXI XIAO

Xi’an Institute of Geology and Mineral Resource , Xi’an 710054, China (xaxpeixi@cgs.gov.cn)

The plutons from the southeastern margin of the Kuruktag block, Xinjiang, which belong to Proterozoic or Carboniferous according to previous studies, are mainly the moyites. Geochemically, these rocks are metaluminous, alkaline I-type granites. The rocks are also characterized by enrichment of LREE and the REE-Chorinite patterns are similar to those of the he crustal granite. With respect to the trace element, the spider diagrams of the rocks are consistent with the volcanic arc granites. The zircon U-Pb dating yielded an age of the 430±1.0Ma (Fig 1), representing the emplacement age of these plutons. This study indicate that the existing of late Caledonia tectonic-magmas in the study area at the first time. The volcanic arc granites suggest the southeastern margin of Kuruktag block was a part of the east Tianshan early Paleozoic magmatism arc.

Keywords: Zircon U-Pb dating, moyite, the southeastern margin of the Kuruktag block

Li and B isotope characteristics of ultrahigh-pressure metamorphic rocks from Sulu, China

YILIN XIAO1,2, ROLF L. ROMER3, Jochen HOEFS2 and ANETTE MEIXNER3

1CAS Key Laboratory of Crust-Mantle and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, PR China
2Geowissenschaftliches Zentrum der Universität Göttingen, Goldschmidtstrasse 1, D-37077 Göttingen, Germany
3GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany

We analyzed the Li and B isotopic composition of metamorphic rocks from Sulu recovered by the Chinese Continental Drilling Program to constrain the behavior of Li and B and their isotopes through dehydration of subducted crust up to conditions of ultrahigh-pressure (UHP) metamorphism and to rehydration during exhumation of UHP rocks. The analyzed samples show large variations in both Li content and δ7Li, ranging from 4 to 29 ppm and -12.4 to 0.5‰ for fresh eclogite, 8 to 22 ppm and -3.6 to +3.6‰ for retrogressed eclogite, and 1.2 to 11.6 ppm and 1 to 3.1‰ for ultramafic rocks, respectively. Most samples are characterised by very low B contents (<1ppm), with δ11B values varying from -14 to 0‰ for fresh eclogite, -10 to -1‰ for retrogressed eclogite, and -3 to +12‰ for ultramafic rocks. The Li and B isotope data indicate that isotopically heavy continental basaltic rocks have been transformed during subduction into isotopically light eclogites. Fluids released from the subducted rocks may (i) induce local melting and eventually be “stored” in local melt pockets and veins within restitic rocks or (ii) metasomatize mantle rocks. In both cases, mobilization of Li and B through the fluids results in large heterogeneities in the concentrations of Li and B, δ7Li and δ11B on centimeter to decimeter scale. For instance, higher B content and heavier δ11B value in garnet peridotite relative to neighboring eclogite (subducted crustal rocks) indicate that mantle-derived rocks were metasomatized by fluids released from the subducted slab. Similar small-scale isotopic heterogeneity is also found between fresh and amphibolized eclogite, illustrating the addition of isotopically heavier Li and B during retrogression. Because of the superposition of the effects of dehydration and retrogression and the mineralogical control on the partitioning and isotopic fractionation of Li and B, Li and B and their isotopes may or may not behave coherently in the same system during slab subduction and subsequent exhumation of UHP rocks.
Geochemical characteristics of the Early-Cretaceous mafic rocks from eastern China

Z. XIE, Q.-Z. LI AND J.-F. CHEN
CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, China (zxie@ustc.edu.cn, liqzhong@mail.ustc.edu.cn, cjf@ustc.edu.cn)

Sr-Nd-Pb isotopic compositions of the Early Cretaceous mafic rocks from different tectonic units of the eastern China, including western Shandong province in North China, Dabie orogenic belt and northeast margin of the lower Yangtze region are studied to deduce the characteristics of the Early Cretaceous subcontinental lithospheric mantle (SCLM) of eastern China.

The results suggest that the sources of these mafic rocks from different units have significant different Sr-Nd-Pb characteristics. The mafic intrusions from Jinan and Zouping, west Shandong province, have lower initial Sr compositions of 0.7041 ~ 0.7055, $\varepsilon_{Nd}(t) = -6 ~ -18.7$, and $^{206}Pb/^{204}Pb(t) = 16.55 ~ 17.00$, $^{207}Pb/^{204}Pb(t) = 15.22 ~ 15.35$, $^{208}Pb/^{204}Pb(t) = 36.29 ~ 36.95$. Those from North Dabie have $^{87}Sr/^{86}Sr(t) = 0.7067 ~ 0.7085$, $\varepsilon_{Nd}(t) = -6.5 ~ -19.1$, $^{206}Pb/^{204}Pb(t) = 16.37 ~ 17.40$, $^{207}Pb/^{204}Pb(t) = 15.31 ~ 15.45$, $^{208}Pb/^{204}Pb(t) = 37.11 ~ 37.98$. Compared with the mafic rocks from North China craton, those from Dabie have higher $\mu$ data and Th/U ratios, much closer to EM I in the $^{206}Pb/^{204}Pb$-$^{207}Pb/^{204}Pb$ diagram. However, the basaltic rocks from Luzhong, east Yangtze block have $^{87}Sr/^{86}Sr(t) = 0.7057 ~ 0.7065$, higher $\varepsilon_{Nd}(t)$ data (-3.9 ~ -6.2), and also higher Pb isotopic ratios: $^{206}Pb/^{204}Pb(t) = 17.88 ~ 18.08$, $^{207}Pb/^{204}Pb(t) = 15.50 ~ 15.55$ and $^{208}Pb/^{204}Pb(t) = 37.93 ~ 38.18$, close to EM II. In $^{143}Nd/^{144}Nd(t)$ and Pb evolution diagrams, the samples from each unit are well coupled with the area of lower crust , respectively.

The enriched isotopic characteristics of the mafic rocks from all units suggest the contribution of the lower crustal materials into the mantle source. Based on geochemical, isotopic and geochronological data, crustal contamination during magma ascending can be eliminated. Thus, it can be concluded that the involvement of different lower crustal material is one of the main processes which resulted in different isotopic characteristics in the mantle sources of different tectonic units in Eastern China at the Late Mesozoic by source mixing. The lithosphere delamination may be a possible dynamic model for explaining the incorporation of the lower crustal materials into the mantle source, but metasomatism model cannot be ruled out.

Why carbonatites in the Lesser Qinling have high HREE compositions?

CHENG XU
Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (xucheng1999@hotmail.com)

Carbonatites are typically characterized by very high concentrations of LREE. They have very high LREE/HREE ratios. However, the carbonatite dykes in the Lesser Qinling, China, shows flat to weakly LREE-enriched chondrite-normalized patterns (La/Yb=1.0-5.5), which is in marked contrast with all other published carbonatite data. The calcite crystals analyzed by LA-ICPMS also show similar geochemical feature to their whole rocks. Xu et al. (2006) suggested that the carbonatites represent calcite-rich cumulate that had crystallized from a carbonatite melt. However, it cannot explain that why they contain higher HREE (e.g. Yb>30 ppm) than all other published carbonatite data. Calcite-rich cumulate is common in carbonatites (Woolley and Church, 2005). But the process cannot produce that other carbonatites have high HREE. Xu et al. (2006) considered that strong enrichment of HREE in the carbonatites may require their derivation by small degree of melting from a garnet-poor source. The explanation is not ideal, because other carbonatites may also derive from a garnet-poor source, and do not show high HREE contents. In addition, these carbonatite dykes is rarely intergrowth with pegmatitic quartz vein. Field observation indicates that their ages are close. Thus the high HREE abundances in the carbonatites may indicate that they underwent complex genesis processes. Regrettably, we cannot get unambiguous answer.

The age and reworking of Cathaysia crustal basement

XISHENG XU¹,², S. Y. O’REILLY², W. L. GRIFFIN², XIAOLEI WANG¹,², N. J. PEARSON², ZHENYU HE¹

¹State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, China
²GEMOC ARC National Key Centre, Macquarie University, NSW 2109, Australia

U-Pb dating and Hf isotope analysis of detrital zircons have been used to analyse the crustal evolution of the eastern and western parts of the Cathaysia Block in SE China. Zircons from the Oujiang River in eastern Cathaysia indicate that the basement is dominantly Paleoproterozoic (1850-1870 Ma, 2100-2400 Ma) in age with minor Archean components; it was extensively reworked in Jurassic-Cretaceous time (100-155 Ma) to produce the widespread Yanshanian magmatic suite. Both the 1850-1870 Ma event and the Yanshanian magmatism show wide ranges in Hf-isotope composition, consistent with mixing between crustal and juvenile magmas. Marked downstream changes in the relative proportions of zircon age populations emphasize the care required in using detrital zircon data to estimate continental growth rates. Zircons from the North River indicate that the crust of western Cathaysia was generated mainly during Neoproterozoic time, although it contains some Archean (2500-3500 Ma) to Mesoproterozoic components. This crust was strongly reworked during Caledonian (ca 450 Ma), Indosinian (ca 240 Ma) and Early Yanshanian (ca 160 Ma) thermal events; there is little evidence for juvenile crustal growth in any of these events. The distinct patterns of crustal evolution suggest that eastern and western Cathaysia may represent separate microcontinents, accreted to the older Yangtze craton, and transposed by extensive strike-slip faulting along major sutures.

Geochemistry of dissolved rare earth elements in the Xijiang River, China

ZHIFANG XU¹, GUILIN HAN³ AND YANG TANG²,³

¹The Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O.Box 9825, Beijing 100029, China (zfxu@mail.iggcas.ac.cn)
²The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China.
³Graduate School of Chinese Academy of Sciences, Beijing 100039, China.

Flowing in the south of China, the Xijiang River is the largest tropical and subtropical rivers in Asia. It originates in the Maxiong Mountain on the Yunnan-Guizhou Plateau, drains a large area of typical karst landform especially in its upper-middle reaches in Yunnan, Guizhou and Guangxi Provinces, where is the center of the Southeast Asian Karst Region. This work focuses on the geochemical characteristics of dissolved rare earth elements (REEs) in the rivers draining the karst regions.

Concentrations of dissolved REEs of the mainstream and its tributaries were measured by using a method involving solvent extraction and back-extraction and subsequent measurements on ICP-MS. The rivers have very low dissolved REEs concentrations, range from 24 to 689 ppt, with a mean value of 125 ppt. The pH value, major cation and DOC (dissolved organic carbon) concentrations of the river waters are the most important factor controlling the concentrations of dissolved REEs in the river water. Negative corrections are observed between dissolved REEs concentrations and pH and major cation concentrations, and a positive correction is also observed between dissolved REE concentrations and DOC concentrations.

Most of river samples have heavy REE enriched patterns relative to PAAS (Post Archean Australian Shales), with (La/Yb)N=0.26–0.94, mean value=0.68. The obvious negative correction are observed between (La/Yb)N ratios and pH value, HCO₃⁻ and DOC concentrations. Usually, fractionation of REEs occurs during weathering and transport processes. LREE (light rare earth element) were preferentially absorbed the particle, and HREE (heavy rare earth element) preferentially dissolved to solution from rock during weathering process. Moreover, The HREE forms stronger complexes than the LREE with inorganic ions, such as CO₃²⁻ and OH⁻. So the enrichments in heavyREE for the Xijiang river waters, which drains a large area of karst landform, are most easily explained by the formation of carbonate and hydroxide complexation in solution. Most of river samples show negative Ce anomalies, and the most pronounced negative Ce anomalies occur in rivers of high pH. So the negative Ce anomaly is strongly pH-dependent in alkaline rivers.

Dependence of the external and surface morphologies of matrix olivine particles on growth condition

J. YAMADA, H. KOBATAKE1, J. NOZAWA AND K. TSUKAMOTO

Graduate School of Science, Tohoku University,
yamadajy@ganko.tohoku.ac.jp
1Institute of Multidisciplinary Research for Advanced Materials, Tohoku University

We have synthesized olivine particles from silicate vapor to study the growth mechanism of the matrix olivine in meteorites like Allende chondrite.

These matrix olivine particles in primitive meteorites were found to exhibit various morphologies and surface microtopographs [Nozawa et al., 2007 this conference]. Since morphologies involve a lot of information about the growth conditions, we have experimentally tried to reproduce the morphologies and surface microtopographs to compare these morphologies with the natural one.

Forsterite melt droplets were prepared in a graphite cell (45×20×30 mm) in a vacuum chamber (Ar, 100 Pa). A 100W of CO₂ laser was employed to heat a forsterite polycrystalline spherule for melting in <100 sec. There is a temperature and gas concentration gradient along the graphite plate. The former and the latter were measured respectively by a thin (φ=0.1mm) thermocouple and by measuring the thickness increase interferometry during the experiment. The forsterite crystals were characterized by TEM, FE-SEM, AFM and DICM. The latter two have been employed to observe the surface microtopographs.

As the temperature T, decreased and thus the supersaturation, σ of the vapor increased, the forsterite morphology changed from a bulky type (T=1000-1450°C, δ<9) to a platy type (T=700-1000°C, δ=9-17 (Fig.1)), then to a columnar needle shape (T=500-820°C, δ=13-25), and finally to a droplet type (T<500°C, δ>25). Various 2-dimensional islands with the step height of 0.3 mm-few mm were observed: rectangular growth islands with a smooth-edge step (T=1200-1500°C, δ<2), islands with a rough-edge step (T=900-1200°C, δ=3-10), and a droplet type (T<800°C, δ>16). These external and surface morphologies have been compared with natural matrix olivines.

In conclusion, these external and surface morphologies are comparable to those of matrix olivine observed in the matrix of Allende meteorite. Therefore, these olivine are concluded to be formed at 2000°C followed by rapid cooling in ~10 s. down to 700°C.

Particle fluxes and scavenging of radionuclides in the western Northwest Pacific Ocean

MASATOSHI YAMADA AND JIAN ZHENG

Nakaminato Laboratory for Marine Radioecology, National Institute of Radiological Sciences, Hitachinaka, Ibaraki 311-1202, Japan (m_yamada@nirs.go.jp; jzheng@nirs.go.jp)

Introduction

²³⁰Th, ²¹⁰Pb and Pu are particle-reactive radionuclides and are therefore removed from the water column by a scavenging process. Because of substantial input of terrigenous materials from riverine input and atmospheric input of continental dust, and the relatively high primary productivity, the western Northwest Pacific margins may be important for removal of reactive radionuclides by scavenging (Yamada and Aono, 2006). The objectives of this study are to measure the activities of ²¹⁰Pb, ²³⁰Th and ²³⁹,²⁴⁰Pu in settling particles in the western Northwest Pacific margin and to discuss the removal of reactive radionuclides by scavenging and particle transport processes on the margins of the western Northwest Pacific Ocean.

Materials and methods

A mooring of three conical time-series sediment traps was deployed at two sites in the western Northwest Pacific Ocean for nine months. The analytical procedure for ²¹⁰Pb, ²³⁰Th and ²³⁹,²⁴⁰Pu was essentially the same as that described by Anderson and Fleer (1982). A double-focusing sector-field ICP-MS instrument was used for the determination of the Th and Pu isotopes in settling particle samples (Zheng and Yamada, 2006).

Results and discussion

Total mass fluxes, ²¹⁰Pb fluxes, ²³⁰Th fluxes and ²³⁹,²⁴⁰Pu fluxes showed large seasonal variations and their weighted mean fluxes tended to increase with depth, with an especially large increase near-bottom. The ratios of the observed ²¹⁰Pb fluxes to the ²¹⁰Pb deficiency fluxes in the near-bottom traps ranged between 1.22 and 2.63. The mean total ²³⁰Th fluxes at the near-bottom traps were 4.2–6.7 times higher than that expected from production in the overlying water column. The high fluxes of particulate ²¹⁰Pb, ²³⁰Th and ²³⁹,²⁴⁰Pu collected by the near-bottom traps reflect a combination of enhanced scavenging of dissolved ²¹⁰Pb, ²³⁰Th and ²³⁹,²⁴⁰Pu by the high fluxes of particles in the region, as well as the lateral redistribution of particulate matter itself by downslope gravitational settling and by alongshore transport by currents.

Coupled C-S-Fe isotope variations in Archean-Paleoproterozoic shales trace microbial metabolisms and redox state in the early Earth

K.E. YAMAGUCHI$^{1,2}$, C.M. JOHNSON$^{2,3}$, B.L. BEARD$^{2,3}$, S.R. POULSON$^{2,3}$, AND H. OHMOTO$^{2,5}$

1IFREE, JAMSTEC, Japan, (kosei@jamstec.go.jp)

5Dept. Geosciences, The Pennsylvania State Univ., USA

Systematic variations among $\text{C}_{\text{org}}$, $\text{S}$, and Fe isotope and elemental compositions in 89 low-metamorphic grade drillcore samples of fine-grained Archean-Paleoproterozoic sedimentary rocks (Kaapvaal and Pilbara cratons) constrain microbial metabolisms and redox state between ~3.3 and ~2.2 Ga. Mineralogical and chemical compositions vary greatly: Fe (1~35 wt.% as total Fe), S (0~4 wt.%), and $\text{C}_{\text{org}}$ (0~12 wt.%). $\text{C}_{\text{org}}$-rich rocks have strongly negative and variable $\delta^{56}\text{Fe}$ values (-2.3 to +0.6‰), where the most negative $\delta^{56}\text{Fe}$ values are restricted to samples where $\delta^{13}\text{C}_{\text{org}} < -35$, down to -50‰, suggesting that Fe$^{3+}$ reduction may have been driven by methanogens in these samples. $\delta^{34}\text{S}$ and $\delta^{56}\text{Fe}$ values for these samples are negatively correlated, where $\delta^{34}\text{S}$ values as high as +15‰ suggest bacterial sulfate reduction under sulfate-limited conditions, consistent with an important role for methanogenesis. The negative $\delta^{56}\text{Fe}$ values, however, indicate that reactive Fe$^{3+}$ was not limited. These relations provide powerful evidence that low-$\delta^{56}\text{Fe}$ Archean sedimentary rocks do not owe their origin to a low-$\delta^{56}\text{Fe}$ Archean ocean via extensive precipitation of oxides, as has been proposed, but instead reflect major biogeochemical cycling processes.

In contrast, S- and $\text{C}_{\text{org}}$-poor samples have restricted $\delta^{56}\text{Fe}$ values (-0.6 to +0.2‰), higher $\delta^{13}\text{C}_{\text{org}}$ values (35 to -25‰), and modestly positive $\delta^{34}\text{S}$ values (0 to +5‰). The Fe budget in these samples is dominated by detrital components, and $\text{C}_{\text{org}}$ and $\text{S}$ isotope compositions record a component of photosynthesis and bacterial sulfate reduction, respectively. Some of these rocks have high Fe$^{3+}$/Fe$^{2+}$ ratios, suggesting significant oxidation at ~3 Ga.

Collectively, these results provide evidence for a diverse biosphere in the Archean that involved a consortium of microbial communities that included cyanobacteria, sulfate-reducing bacteria, and methanogens/methanotrophs; bacterial Fe$^{3+}$ reduction may have been driven by dissimilatory iron reducing bacteria, sulfate-reducing bacteria, methanogens/methanotrophs, or a combination of these. The significant inventory of Archean sedimentary rocks that have highly variable $\text{C}_{\text{org}}$, S, and Fe isotope compositions indicates that extensive microbially-mediated redox cycling of Fe, S, and $\text{C}_{\text{org}}$ occurred in the Archean-Paleoproterozoic oceans. The Archean oceans could have been at least temporally, locally, and slightly oxygenated in order to form and retain sulfate and reactive Fe$^{3+}$. Therefore the oceans between ~3.3 and 2.2 Ga must have been, to some degree, stratified in redox state.

In situ isotope analysis of Fe in pyrite using laser ablation-ICPMS

HIROKI YAMAMOTO AND TAKAFUMI HIRATA

Laboratory for Planetary Sciences, Department of Earth and Planetary Sciences, Tokyo Institute of Technology, O-okayama 2-12-1, Meguro-ku, Tokyo 152-8551 (hiroki-y@geo.iit.ac.jp)

Introduction

Iron isotope provides us various key information about how the oxidative-reductive circumstance of the very dawn time was. Pyrite (FeS$_2$) is the most important mineral in sediments because of several unique features such as chemical robustness through mechanical transmutation or secondary metamorphic events. In order to derive precise and reliable Fe isotopic data from pyrite, recently developed laser ablation-ICP-mass spectrometry (LA-ICPMS) has been widely employed (Horn et al., 2006). However, in-situ isotopic analysis of Fe from pyrite using the LA-ICPMS technique has been retarded mainly because of poor analytical sensitivity and repeatability of the isotopic ratio measurements. It is widely recognised that the deterioration in analytical sensitivity and precision can be attributed to redeposition of sample around the laser ablation pit, and the measured isotope ratios (e.g., $^{56}\text{Fe}/^{54}\text{Fe}$) changed through ablation time (Jackson and Guenther, 2006, Hirata et al., 2005). In order to improve the reliability and precision of the Fe isotopic ratio measurements, resulting precision and accuracy of the $^{56}\text{Fe}/^{54}\text{Fe}$ ratio data obtained by the LA-ICPMS technique were rigorously tested.

Method

The graph below illustrates the changes in measured $^{56}\text{Fe}/^{54}\text{Fe}$ ratio against ablation time obtained by laser ablation of pyrite sample, demonstrating the isotopic fractionation (ca. 1‰ level) through laser ablation.

Series of experiments revealed that mass bias factor on $^{56}\text{Fe}/^{54}\text{Fe}$ ratio measurement was seriously dependent upon the amount of sample re-deposition around the ablation pit. In this paper, we will describe the new approach to minimize the isotopic fractionation using a femto-second laser ablation system.

Sulfur system in anoxic confined aquifers in the northeastern Osaka Basin, Japan

Masaru Yamanaka1, Takanori Nakano2 and Norio Tase3

1Department of Geosystem Sciences, College of Humanities and Sciences, Nihon University, Setagaya-ku, Tokyo 156-8550, Japan, (yamanaka@ch9s.nihon-u.ac.jp)
2Research Institute for Humanity and Nature, Kamigyo-ku, Kyoto 602-0878, Japan
3Graduate School of Life and Environmental Sciences, University of Tsukuba, Ibaraki 305-8572, Japan

We used δ34S values and chemical compositions of groundwater to investigate the influence of sulfate reduction and sulfide oxidation processes in a confined aquifer system in the northeastern Osaka Basin (NEOB), central Japan. Shallow confined groundwater (<100 m) in the basin is recharged mainly from mountainous areas to the north, and flows south and southwest through the aquifer system. Anion composition of the groundwater is dominated by HCO3– throughout the basin. However, concentrations of redox-sensitive species such as dissolved oxygen, NO3–, Fe2+, and Mn2+ show that groundwater conditions become increasingly anoxic along the flowpaths. Moreover, SO4/(SO4 + 2HCO3) molar ratios decrease with increasing δ34S along the flowpaths, which demonstrates that sulfate is reduced in the NEOB aquifer system. Groundwater with both high total dissolved solids and high SO4 content was observed mainly in areas down-flow from faults. Because of the high SO4 content, the anion composition of this groundwater cannot be adequately explained by a simple sulfate reduction process. A Rayleigh distillation model with ε = –20‰, which allows for sulfide oxidation within marine sediments in proximity to faults, explains the chemistry of all groundwater samples, including those with high SO4 content. The model demonstrates that 76% of initial sulfate is reduced at maximum, and that reduced SO42– content is up to 48.5 mg/L after sulfide oxidation in the NEOB aquifer system.

Adsorption and coprecipitation behaviors of platinum(II) complex ions on and with manganese(IV) dioxide and manganese(II) hydroxide: Model reactions for the concentration mechanism of platinum into oceanic manganese nodule

M. Yamashita1, T. Taniguchi1, Y. Okaue1, Y. Takahashi2 and T. Yokoyama1

1Department of Chemistry, Faculty of Sciences, Kyushu University, Ropponmatu, Chuo-ku, Fukuoka 810-8560, Japan; (yamashita@molrc.kyushu-u.ac.jp)
2Department of Earth and Planetary Systems Science, Faculty of Sciences, Hirishima University, Kagamiyama, Higashi-Hiroshima, Hiroshima 739-8526, Japan

In oceanic manganese nodule and crust, platinum (Pt) is more concentrated than sea water and earth’s crust. However, the concentration mechanisms of Pt and its chemical state have not been clarified because of its extremely low concentration. From thermodynamic investigation, Pt is considered to be present as Pt(II) complex ion ([PtCl4–n(OH)n]2-) in deep ocean water. Therefore, we investigated the adsorption behavior of Pt complex ions ([PtCl4–n(OH)n]2-) on manganese(IV) dioxide (δ-MnO2) and the coprecipitation behavior of Pt complex ions with manganese(II) hydroxide (Mn(OH)2) as model reactions for the concentration mechanisms of Pt into manganese nodules and crusts. δ-MnO2 and Mn(OH)2 that is finally oxidized to manganese(IV) dioxide by dissolved oxygen are regarded as model compounds of manganese nodule and crust. Pt(II) complex ions were vigorously adsorbed on δ-MnO2. The XPS and XANES spectra for Pt showed that the Pt(II) complex ions adsorbed on δ-MnO2 were oxidized to Pt(IV). Based on the analytical result of EXAFS spectrum, the Pt(IV) was present as PtO4 species, suggesting that the adsorbed Pt(II) may be oxidized and substituted with Mn(IV) in δ-MnO2. Pt(II) complex ions were also coprecipitated effectively with Mn(OH)2. The Pt(II) may be oxidized to Pt(IV) after the oxidation of Mn(OH)2 to MnO2.

In conclusion, the concentration mechanism of Pt into manganese nodule and crust can be deduced as oxidative substitution by the redox reaction between Pt(II) in [PtCl4–n(OH)n]2- and Mn(IV) in manganese(IV) dioxide.
Transition from MORB through intermediate type to IAT magmatism in the northern Oman ophiolite

S. YAMAZAKI1 AND S. MIYASHITA2
1Graduate school of Science and Technology, Niigata University, Japan (shu-saku@mvd.biglobe.ne.jp)
2Department of Geology, Faculty of Science, Niigata University, Japan (miyashiti@sci.niigata-u.ac.jp)

Wadi Rajmi area in the northern Oman ophiolite had been recognized as an “anomalous” crustal section in the Oman ophiolite, including the dike swarms crosscutting sheeted dike complex and large occurrence of gabbro-norite (e.g. MacLeod & Rothery, 1992). In this area, the crustal section shows over 7km thick sequence of layered gabbro, layered wehrlite, heterogeneous gabbro-norite, isotropic diorite-tonalite, foliated gabbro, isotropic and pegmatitic gabbro, sheeted dike complex and pillow lava, from bottom to top. Besides three boninitic dike swarms are found from this area, and they are intruding into lower crust to pillow lava. Layered wehrlite, heterogeneous gabbro-norite and isotropic diorite-tonalite are regarded as the late intrusive complex intruding into layered gabbro and foliated gabbro. Layered gabbro blocks rarely appear in heterogeneous gabbro-norite. The boninitic dike swarms crosscut all earlier plutonic rocks including the late intrusive complex and dikes.

Based on mineral and bulk chemistry, we could distinguish three types of magma products (MORB, IAT and intermediate type) in the crustal sequence of Wadi Rajmi area. Trace element and REE contents of the boninitic dike swarms indicate a very low-Ti (TiO$_2$= 0.14-0.61 wt.%) and a depleted chondrite-normalized REE pattern (La$_{chondr}$/Sm$_{chondr}$= 0.63-1.67). These characteristics indicate that the boninitic dike swarms have IAT affinities and some of these have high-Ca boninite affinities. Clinopyroxenes from the boninitic dike swarms are a very low TiO$_2$ (<0.33 wt.%) in consistent with the bulk rock characteristics. Clinopyroxenes from gabbro-norite indicate slightly lower TiO$_2$ content (0.05-0.74 wt.%) than those of layered gabbro and foliated gabbro (TiO$_2$=0.18–0.91 wt.%; corresponding to MOR gabbro). Clinopyroxenes from layered wehrlite have a very low TiO$_2$ content (0-0.15 wt.%) and REE patterns with are comparable with those of boninite dike swarms. These mineral chemistry of the late intrusive complex indicate that these rocks crystallized from intermediate type magma between MORB and IAT.

The occurrence of three types of magma suggests that the tectonic setting of the Oman ophiolite was changed from accretion stage of MORB oceanic crust at mid-ocean ridge through reconstruction stage of oceanic crust by intrusion of intermediate type magma to IAT magmatism stage (subduction related magmatism).

2.7 Ga Re-Os age for C-rich slate of the Joy Lake sequence, western Wawa subprovince, Minnesota

G. YANG1, J.L. HANNAH1,2, A. ZIMMERMAN1, H.J. STEIN1,2, AND A. BEKKER1
1AIRIE Program, Dept Geosciences, Colorado State U, Fort Collins, CO 80523-1482, USA; (gang.yang@colostate.edu)
2Geological Survey of Norway, 7491 Trondheim, Norway
3Geophysical Laboratory, Carnegie Institute of Washington, 5251 Broad Branch Road, NW, Washington, DC 20015

Re-Os dating of carbonaceous rocks using H$_2$SO$_4$-CrO$_3$ dissolution [1] provides a powerful new geochronologic tool for application in Archean terranes. Using this method, we determined ages of ~2.7 Ga for C-rich slates in the Joy Lake sequence, the oldest Re-Os ages yet reported for C-rich sedimentary rocks. The Joy Lake supracrustal sequence (western Wawa subprovince, Superior province, north-central Minnesota) consists of volcanic and sedimentary strata with intercalated mafic tuffs, intruded by layered peridotite-pyroxenite-gabbro sills of the Deer Lake complex. Poor exposure and lack of geochronologic data for this sequence hinder construction of a geologic framework for the Wawa supracrustal rocks, compromising correlation with other sedimentary sections in the Superior province.

Carbonaceous slates of the Joy Lake sequence have well-developed cleavage subparallel to bedding and contain nodules, disseminations, and bedding-parallel stringers of pyrite [2]. Samples from two drill holes (DH26503 and DH26506) yield isochron ages of 2695±14 Ma and 2684±16 Ma and initial $^{187}$Os/$^{188}$Os (Os$_i$) of 0.15±0.16 and -0.29±0.20, respectively. The ages, identical within uncertainty, are consistent with ages for Timiskaming-type sequences in the Wawa (~2688 to 2695 Ma) and Abitibi subprovinces (~2677 to 2680 Ma) [3,4], that represent late-orogenic deposits and likely postdate the Joy Lake sequence.

A chondritic Os$_i$ (0.109 at 2.69 Ga) is expected in Archean shales [5], but the negative Os$_i$ for DH26506 requires explanation. Re may have been released from intercalated high Re/Os mafic tuffs during recent exposure and local oxidation. The C-rich rocks are a ready sink for mobile Re. This could shift isochron data points to higher $^{187}$Re/$^{188}$Os with minimal slope change, increasing scatter and uncertainty for the Os$_i$. This would shift the isochron to the right, producing a spuriously low or negative Os$_i$ intercept. If the Re addition is recent, the age is not affected. Notably, the shales in DH26506 are in direct contact with pyroxenite [2].

Geochemistry and origin of black shale hosted Ni-Mo-PGE-Au mineralization in south China

JING-HONG YANG, SHAO-YONG JIANG, LIANG LI, YONG-QUAN CHEN AND HONG-FEI LING
State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, P.R. China (yangjh@nju.edu.cn)

Most of the world’s PGE mineralizations are mainly associated with mafic intrusions. There is, however, increasing evidence that economic levels of PGEs can be found in other environments. In this regard, the black shale-hosted PGE deposit has recently become a promising important source of PGE and many other metals in the world.

In the Yangtze Platform of South China occurs a thick sequence of metal-rich black shales of Neoproterozoic to early Cambrian age. An extreme multi-metal enriched sulfide ore bed has been identified in the lowermost strata of the Niutitang Formation in Lower Cambrian. Compared to average upper continental crust value, this multi-metal rich ore layer contains >10,000 times enrichment in Re and Os, and >1,000 times enrichment in Pt, Pd, Ag, and Au. In recent years, we have conducted a detailed geochemical and isotopic investigation in an attempt to decipher the depositional environments, to trace the source of metals, and to establish an ore genetic model for this special type of mineralization. Our Re-Os and Pb-Pb isotope dating of the black shales and sulfide ores suggested an age of ~530 Ma for deposition of the black shales and Ni-Mo-PGE-Au mineralization. A detailed trace element study shows that both the sulfide ores and their host black shales share similar element distribution patterns with pronounced depletion in Th, Nb, Hf, Zr, Ti, and extreme enrichment in U, Ni, Mo, and V compared to average upper crust. The high field strength elements such as Zr, Hf, Nb, Ta, Sc, Th, rare earth elements, Rb and Ga show significant interelement correlations and may have been derived mainly from terrigenous sources. The redox sensitive elements such as V, Ni, Mo, U, and Mn; base metals such as Cu, Zn, Pb; Sr and Ba may have been derived from mixing of seawater and venting hydrothermal sources. The chondrite-normalized REE patterns, positive Eu and Y anomalies, and high Y/Ho ratios for the Ni-Mo-PGE-Au sulfide ores are suggestive for a submarine hydrothermal-exhalative origin. Hence, we suggest that this type of mineralization is different from the magmatic-hydrothermal or epithermal origins as proposed for some black shale hosted PGE-Au mineralization elsewhere. A modern analogue of such type deposit could be organic-rich sediments of the Bering Sea, which are known to have high PGE concentrations.

Using isotope geochemistry to trace the origin of ore forming materials in the Jiaodong gold province, China

LIQIANG YANG1,2, JUN DENG1,2, QINGJIE GONG1,2*, JING ZHANG1,2, QINGFEI WANG1,2 AND WANMING YUAN1,2

1State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing 100083, China (lyang@cugb.edu.cn; djun@cugb.edu.cn)
2Key Laboratory of Lithosphere Tectonics and Lithoprobing Technology of Ministry of Education, China University of Geosciences, Beijing 100083, China

The Jiaodong gold province is the most important gold concentration area in China and the largest hydrothermal vein gold producing area in the world. For tracing the origin of oreforming materials in this region, we integrated and analyzed the composition of sulfur, lead and strontium isotope in the major gold ore deposits and the host late Archean Jiaodong Group, Mesozoic Linglong biotitegranite and Guojialing porphyritic granodiorite.

The value of δ34S in the Jaiodong Group is 4.7‰ in average and ranges from 3‰ to10‰. This in the Mesozoic granites is 7.4‰ and 6‰-10‰, respectively. The δ34S of gold ore ranges from 4.0‰ to 11.8‰, and shows a tower distribution. The value of 206Pb/204Pb in the Jiaodong Group, Linglong biotite granite and Guojialing porphyritic Granodiorite ranges from 16.111 to18.025, 17.143 to 17.288 and 16.408 to 17.851, respectively. The value of 207Pb/204Pb in the three geologic bodies varies from 15.043 to 15.762, 15.413 to 15.456 and 15.342 to 15.581, respectively. The value of 208Pb/204Pb in the three geologic bodies is 36.752-38.824, 37.625-37.855 and 36.645-38.394, respectively. The initial ratio of Sr in the Mesozoic granite, gold ore, altered rocks or minerals and fluid inclusions ranges from 0.706 to 0.716, 0.709 to 0.712, 0.703 to 0.713 and 0.710 to 0.716, respectively.

Similarity exists in isotope components among gold deposits and host rocks. This indicates that the oreforming material is the mixture between crustal and mantle. The gold deposits may be formed in the relative close environment, where had no large scale intrusions entering in continental crust.
Noble gas isotopic ratios of volcanics and xenoliths from northern Taiwan-Luzon Arc

T. F. YANG1, M. D. KURZ2, J. MATUSTA3 and T. MATSUMOTO3

1Department of Geosciences, National Taiwan University, Taipei, Taiwan (tyyang@ntu.edu.tw)
2Department of Marine Chemistry & Geochemistry, WHOI, MA02543, U.S.A. (mkurz@whoi.edu)
3Department of Earth and Space Science, Osaka University, Osaka, Japan (matsuda@ess.sci.osaka-u.ac.jp)

The Taiwan-Luzon Arc, which was generated in response to the subduction of the South China Sea Plate, is currently colliding with the eastern margin of the Eurasian continental plate at the arc’s southern and northern ends. Systematic temporal and spatial variations in the geochemistry of the magmas erupted along the arc are ascribed to the involvement of the subducted continent-derived sediments or crustal slivers close to the collision zones.

Three 3He/4He ratios of hornblende, biotite and pyroxene separated from the arc volcanics near the collision zone were obtained. The ratios of Hsiaolanyu lava from northern arc are less than 2.3 and 1.3 times atmospheric ratios (Ra). The other is 3.0 Ra of Mt. Arayat lava from southern part of the Taiwan-Luzon arc. This implies that the crustal component played an important role in the petrogenesis of the arc magmatism, at least near the collision zone, to lower the 3He/4He ratios of the lavas.

The helium isotopic ratios of olivines from xenoliths of Lanyu, Batan and Diogo island fall in a range from 8.1 to 10.1 Ra. They are close to the value of the average MORB ratio. However, the co-existing amphibole from the same nodule of Batan Island (8.4 Ra of olivine) shows a much lower ratio of 4.7 Ra, which are similar with the ratios of the arc lavas. In addition, pyroxenes and amphiboles from gabbroic xenoliths of the arc lavas exhibit a wide range from 2.3–7.6 Ra. It infers that they cumulates in origin at different stages of fractionation in former magma chamber.

Combined with the Sr-Nd-Pb and helium isotopic data, we can conclude that at least two components, i.e., crustal component (Ra<1) and MORB component (Ra ~8), are necessary for the generation of Taiwan-Luzon arc magmatism.

Tracing water exchange between mantle and continental crust with the δD values of NAMs in granulate

X. YANG1-2, E. DELOULE1 and Q.K. XIA2

1CRPG-CNR, Vandoeuvre-les-Nancy, France (deloule@crpg.cnrs-nancy.fr)
2CAS Key Lab. of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, USTC, Hefei, China.

Introduction

A poorly defined parameter of the inner Earth water budget is the possible flux through the mantle and continental crust boundary. Therefore, in the aim to obtain new constraints on Mantle-Crust exchange, we undertook to determine the D/H ratio of granulates from North China Craton.

Results

3 set of granulates were analyzed: Archean-early proterozoic granulate xenoliths from Nushan, granulate from Hannuoba archean terrain, and phanerozoic granulate xenoliths from Hannuoba, for which the water contents have been previously determined by FTIR spectrometry (Xia et al, 2006 and Yang et al, submitted), with value ranging from 150 ppm up to 2300 ppm. The CRPG IMS 1270 ion microprobe were used for D/H ratio in situ measurements of Cpx, Opx and Plag. Measurements where performed with a 0–10 µm diameter primary beam, and calibrated against already known NAMs and hydrous minerals. The δDSMOW values obtained for Plag of the 3 samples set range from –80 to –150, for Opx from –150 to –100 for Nushan, -150 to –50 for Hannuoba Terrains and –100 and – 20 for Hannuoba xenoliths and all the measurements on Cpx range from –60 to +20.

Discussion and conclusion

The high δD values observed for Cpx suggest that Cpx were affected by a diffusion hydrogen loss, as well as some Opx from Hannuoba. The preferential loss of hydrogen from Opx and then Opx may be associated to their high initial water and iron content, both supporting H loss. Therefore the initial granulate δD values should be the one preserved in Plag and part of the Opx, and is similar in the 3 localities, mostly ranging in between –100 and –150. This low δD value may reflect either a lower continental crust or a deep mantle plume signature, but significantly differ from the expected composition of the upper mantle (~60 to ~80). This suggests that not any water flux affected the granulate H isotopic composition, even for the Proterozoic granulate from Nushan that were transported to the surface during Cenozoic volcanism.

Study on fluid inclusions of volcanic rocks in Songliao basin: The significance for natural gases

X.Y. YANG\textsuperscript{1,2}

\textsuperscript{1}CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University Science and Technology of China, Hefei 230026, China (xyyang@ustc.edu.cn)

\textsuperscript{2}State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

Introduction

The Songliao basin is the largest sedimentary basin in China with most significance in producing oil and natural gases. In recent years, Chinese geologists found and explored the natural gases genetically linked to Mesozoic volcanic rocks in this basin (Qin et al., 2001). Three types of volcanic rocks have been identified in the basin, which are basaltic igneous flows, andesite and rhyolite. All those volcanic rocks are richness in fluid inclusions (Fig.1). The widely spreading Mesozoic-Cenozoic volcanic rocks along Tan-Lu fault belt in east China and the gas-liquid compositions from fluid inclusions are drawn great attention to geochemists. This study focus on the compositions of fluid inclusions bearing in these different volcanic rocks series.

Experiment and Results

The chemical compositions of fluid inclusions are determined with RM-1000 laser Raman spectroscopy produced by Renishaw Company at Institute of Geology & Mineral Resources, Xi’an. The results show that most of the fluid inclusions are mainly composed of CO\textsubscript{2}, CH\textsubscript{4}, CO, H\textsubscript{2}, N\textsubscript{2}, H\textsubscript{2}S and SO\textsubscript{2}. The relative high concentrations of CO\textsubscript{2} in fluid inclusions are correspondent to funding of CO\textsubscript{2} reservoir with inorganic genesis widely distributed in different sub-sags of the basin in the past decade. In contrast, the other components in fluid inclusions among the combustible CH\textsubscript{4}, CO and H\textsubscript{2} consist of main components of the natural gases explored in the basin. The compositions of fluid inclusions of volcanic rocks are also good proxies to trace the mantle degassing since Mesozoic in east China.

Different accumulation of Pb, Zn, and Cd in river sediments and in lake sediments originated from ancient zinc smelting activities in northwestern Guizhou, southwestern China

YUANGEN YANG, ZHISHENG JIN, XIANGYANG BI, FEILI LI, JIE LIU AND ZHIYOU FU

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, CAS, China

Zinc smelting in northwestern Guizhou, southwestern China resulted in significant heavy metal accumulation in sediments. In this study, river sediments were collected in a river in the smelting region, and lake sediments were collected in a lake ca. 10km downwind from zinc smelters. Concentrations of Pb, Zn, and Cd in the river sediments varied greatly in the range of 4,375-21,850, 7,275-30,425, and 42.0-95.0 mg kg\textsuperscript{-1}, averaging in 14,022, 24,441, and 72.9 mg kg\textsuperscript{-1}, respectively. Ratios of Pb/Cd and Zn/Cd in river sediments were in the range of 104-266 and 173-390, respectively. However, Concentrations of Pb, Zn, and Cd in lake sediments were in the range of 66.0-160, 130-1200, and 2.60-71.0 mg kg\textsuperscript{-1}, averaging in 99.7, 536, and 26.0 mg kg\textsuperscript{-1}, respectively. Ratios of Pb/Cd and Zn/Cd in lake sediments varied narrowly in 2.14-25.4 and 16.9-50.0, respectively. Normally, Pb, Zn and Cd accumulated vertically in the lake sediments in the depth of 0-15cm, and then their concentrations dramatically decreased to sediment baselines. In river sediments, Pb was mainly in carbonate bound fraction (35-51%) and iron and manganese bound fraction (26-47%); Zn was in carbonate bound fraction (32-39%) and iron and manganese bound fraction (38-48%); whereas Cd in residue fraction (16-50%) and carbonate bound fraction (15-45%).However, in surface lake sediments, organic bound fraction was the dominating chemical forms of Pb (34-82%), Zn (3.8-46%), and Cd (31-84%); while residue bound fraction accounted for 14-39% for Pb, 17-69% for Zn, and 4.0-55% for Cd, respectively. High organic matter content (14-45%) may reasonably explain high concentrations of organic bound metals in lake sediments. In river sediments, Pb\textsuperscript{206}Pb/\textsuperscript{207}Pb, Zn\textsuperscript{206}Pb/\textsuperscript{208}Pb ratios varied in 1.182-1.185, 0.399-0.403, respectively; however, in lake sediments, these ratios were in the range of 1.178-1.220, 0.477-0.486, respectively. These results suggested that Pb, Zn, and Cd in river sediments were from release of zinc smelting slags, however, in lake sediments, they were originated from dust deposition of zinc smelting emits. Elemental fractionation during smelting may cause big differences in Pb/Cd and Zn/Cd between river sediments and lake sediments.

Some anaerobic microbial communities in peat bogs and the influence on the biogas formation

S. P. YAO, J. CHEN, H. DING AND K. ZHANG

Department of Earth Sciences, Nanjing University, Nanjing, China (spyao@nju.edu.cn)

Microorganisms play important roles in the transformation of peaty organic matter. The interplay between organic matter transformation and microbial activities is complex in the peat environment and the underlying mechanisms or pathways for carbon cycling may vary from case to case. The goal of this study was to investigate distribution of anaerobic microbial communities under varying geological or chemical conditions in different peat environments, and search for patterns of microbial organic carbon transformation under varying organic matter types conditions by simulate experiment. Samples were collected from mangrove bog (modern to 10,000 years) in Hainan province and from burial peat (Holocene) in Yunnan province of China. Content of total organic matter ranged from 27.6% to 55.7%.

There are four kinds of main advantage germ clusters in the peat bogs including fermentation bacteria, anaerobic cellulose-degrading bacteria, sulfate-reducing bacteria and methane-producing bacteria. Fermentative bacteria ($10^4$ to $10^6$ cells/g) based on MPN were significantly higher than sulfate-reducing bacteria or acetogens (< $10^3$ cells/g) in all peat samples. The distribution or number of fermentative bacteria to some extent correlated positively with the organic matter content (e.g., humic acids) in some but not all samples, suggesting that organic matter content may not be the only factor controlling the population of fermentative bacteria. We focused on fermentative bacteria because they play a critical role in transforming cellulose organic matter to smaller organic molecules bio-available to other dissimilatory microorganisms such as sulfate-reducing bacteria or methanogens.

On the other hand, fermentative bacteria create anaerobic environment, which removes oxygen and enriches hydrogen in the organic matrix. By concentrating and purifying the advantaged species of the fermentation bacteria, we culture the advantaged germ in different matrix. Highly nutritious peat environment could be simulated and then the bacterial-degradation experiments of plant may be controlled well. The experiment has already carried on for 6 months, The degrader of Fermentation bacteria causes that organic matter from the plant lost a great deal of oxygen, and cause the matrix enrich more hydrogen. we can also know that the production rate of bacteria-degrading biogas is 5-10 times larger than the production rate of hydrolysis gas without bacteria. Thus fermentative process may help enhance the quality of organic carbon preserved as fossil fuel in geological formation.

Extreme fractionation of low salinity magmatic fluids

BRUCE YARDLEY¹, DAVID BANKS¹ AND VICTORIA VRY¹,²

¹School of Earth and Environment, University of Leeds, LS2 9JT, UK
²now at: Dept. of Earth Science and Engineering, Imperial College London, SW7 2AZ

Most crustal magmatic fluids are predominantly chloride solutions, but in certain situations, notably in some granite pegmatites, water-rich fluids occur which have low salt contents (<seawater salinity). The consequences of low salinity include higher gas solubilities, resulting in potentially higher bicarbonate levels, and low concentrations of Ca, permitting higher concentrations of additional ligands such as fluoride and phosphate. LA-ICP-MS analysis provides a means of determining many of the significant pegmatite components in single inclusions, and has been carried out in Leeds using a Geolas Q laser ablation system (193nm ArF Excimer laser) coupled to an Agilent 7500c ICP-MS. Calibration is with glass SRMs and with solutions loaded in capillaries.

Fluid inclusions from the quartz core of the Muiane Li-pegmatite, Mozambique (sampled by O. Von Knorring), are 3 phase at room temperature, with CO₂ liquid and vapor. Large inclusions (25-60 µm) are common. LA-ICP-MS analysis of individual inclusions reveals significant variations within texturally similar settings, and in particular Na/K (wt) ranges from <1 to >15. Extreme enrichment in Cs (to >2000 ppm) and Li (to c.3000 ppm) is associated with high Na/K ratios and possibly arose as K-feldspar and micas were precipitated. Such fluids are also enriched in B (to c.3000ppm). Not surprisingly, spodumene is a major mineral in the deposit and pollucite has been reported. Some high Na/K fluids are very rich in As (>25000ppm), while others contain only a few thousand ppm As. A solid As daughter phase has been observed in a few very large inclusions.

The results are taken to indicate that in the final stages of magmatic fluid evolution, extreme fractionation effects can be produced, reflecting the growth of new solid phases. However vapour-liquid separation may play an important role in the development of the decoupled As-enrichment.
The influence of minor elements on melting of eclogite in the mantle

G.M. YAXLEY1, C.S. SPANDLER1, D.H. GREEN1, A. ROSENTHAL1 and G.P. BREY2

1Research School of Earth Sciences, The Australian National University, Canberra (greg.yaxley@anu.edu.au)  
2Institut für Geowissenschaften, Universität Frankfurt, Frankfurt am Main (brey@em.uni-frankfurt.de)

An important role for recycled mafic crust in upper mantle magma-genesis is frequently postulated. Models vary between those in which siliceous to basaltic melts from minor mafic heterogeneities in peridotitic upper mantle are extracted directly from their upper mantle source regions without significant interaction with peridotite wall-rock before eruption, to those which postulate reaction and resorption into enclosing peridotite of siliceous partial melts from eclogite or pyroxenite, resulting in refertilisation of the peridotite and formation of new, opx-enriched lithologies. Melting of these refertilised peridotites provides the erupted magmas.

Critical to testing these opposing models is detailed knowledge of the partial melt products of mafic lithologies at high pressure. We report experimental investigations of high pressure melting of volatile-free eclogite and carbonate-bearing eclogite, focussing on the importance of some minor elements in controlling subsolidus mineralogy, low degree melting relations and partial melt compositions.

We determined the phase relations and partial melt compositions of a nominally anhydrous altered MORB composition (GA2) with 49.7 wt% SiO2, 0.37 wt% K2O, 3.34 wt% Na2O, 0.23 wt% P2O5 and 1.82 wt% TiO2 from 3-5 GPa and 1200-1600°C. We identify two distinctive melting regimes. Low degree melting (≤20%) is eutectic-like and is dominated by contributions from accessory phases (K-feldspar, rutile, quartz/coesite and possibly apatite), with additional components from garnet and clinopyroxene. At 3 GPa K-fd, rt and qz are residual phases up to about 40°C above the solidus, but at higher pressures K-fd and rt melt out close to the solidus. At higher degrees of melting, once accessory phases are melted out, melt compositions are controlled by melting along ga-cpx cotectics. Low degree melts are dacitic and trend towards andesitic and basaltic andesitic with increasing temperature. At 3 GPa Na, Ti and K are incompatible, but at 4 and 5 GPa Na becomes compatible, yielding increasingly fractionated Na/Ti and Na/K in melts.

Similar dual melting behaviour is observed in partial melting of Ca-Mg-carbonate-bearing eclogite, where low degree partial melts are sodic calcio-dolomitic to dolomitic and are controlled by eutectic melting relations on the calcite-magnesite join, with minor contributions from ga + cpx. Increasing degrees of melting, or melting of residues after carbonate melt extraction, result in progressively more siliceous partial melt compositions. Interactions between these carbonated melts and peridotitic wall rock could generate a spectrum of enriched source lithologies suitable for some magmas.

Heavy metal concentrations in soils and tea plants in Sürmene and Çayeli area (NE -Turkey)

G. YAYLALI1, N. TUYSUZ AND M. TUFECI

1Karadeniz Technical University, Trabzon-TR

The study area covers two geologically different regions which have intensively been carpeted by tea plants in the Eastern Black Sea. The rocks exposed in the region contain considerable amount oftrace metals due to Upper Cretaceous massive sulfide formations and Tertiary epithermal mineralizations. Tea plants grow over the soils derived from such mineralized rocks indicate different concentration in Cu, Pb, Zn, Fe, Cd, P, Al, Na, K, S. Most of the analyzed elements except Al shows higher content ratios in basaltic and sedimentary rocks. Al content is found to be high only in tea plants growing on the dacritic rocks.

The highest average Cu values (26.17 ppm) occur in tea plants in Çayeli area. Pb reaches the highest value in Çayeli (1.94 ppm) in tea plants. The highest Cu, Pb, Zn concentrations were recorded in soils at Sürmene area whereas the highest Al (7.56 %) concentration was observed in Çayeli. The soils in Sürmene area sampled during the first sprout period of tea plants contain relatively high amount of Cu.

In order to better understand the element distribution processes in tea plants, some experimental studies were undertaken. Young tea plants were planted in small boxes and were applied with Cu, Zn, Cd and Mn element complexes and fertilizers. The effect of fertilizers in element mobility was undertaken. Young tea plants were planted in small boxes and were applied with Cu, Zn, Cd and Mn element complexes and fertilizers. The effect of fertilizers in element mobility was found to be significant. Especially Ammonium sulfate fertilizer increased element uptake of tea plants by lovery pH. Bioavailability coefficients of the applied elements are as follows, Cu: 0.14, Zn: 0.18, Cd: 2.45 and Mn: 0.15. The differences in the amount of irrigation played an important role in bioavailability and uptake of elements both in soil and tea plants. Cu, Zn, and Mn are relatively easily uptaken by the tea plants from the soils often watered. The amount of water has no effect on Cd uptake.

The Pb concentration sharply decrease from road side (1.08 ppm) to 100 m in land (0.37 ppm).
Geochemistry of biotites in Ali-Abad and Darreh-Zereshk porphyry copper deposits, Yazd, Central Iran

MOHAMMAD. YAZDI
Dept. of Geology, Shahid Beheshti University, Tehran, Iran

Darreh-Zereshk and Ali-Abad are two relatively small porphyry copper deposits in Central Iran. The biotite compositions used to interpret nature, physicochemical conditions of magma source and petrogenesis of these granitoid rocks. Biotites from granitoids of the Aliabad-Darreh Zereshk areas are green and brown types. On the basis of IMA classification, these biotites can be classified mainly as phlogopite on the basis of ratios of 100 (Mg/ (Mg + Fe)) which vary between 17 and 22. Also, plotting of 100Fe2+/(Fe2+ + Mg ) ratio of the studied biotites on a stability diagram correspond to temperature about 600 to 750°C and confirming magmatic origin for these biotites. In addition, biotite composition used for discrimination of the granitoid magma. The chemical composition of studied biotites show that the granitoids of the Aliabad-Darreh Zereshk areas are calc-alkaline I-type.

The main substance constitutes and chemical composition characters of the dust in the urban district of Beijing

RONG YE 1, XUEQIU WANG 2, YONGLI SHEN 1 AND BIMIN ZHANG 2

1 China University of Geosciences, Beijing 100083, China (yerong@cugb.edu.cn)
2 Institute of Geophysical and Geochemical Exploration, 065000, Langfang, China

With the development of urbanization, industrialization, population growth, and traffic growth, the environmental pollution has been more serious in the city. The statistic shows that one third of the population live in the city. The study of heavy metals’ characters and migration in the city is of highly important and practical because of its toxicity and accumulation in organism. The dust in the urban area tend to form a repeated cycle of rising and sinking under the action of external forces and develop into particles that are likely to be breathed by human bodies, thus causing great harm to human health and environment.

Dust has been collected and studied as the medium carrying heavy metal pollutants. The dust samples are collected within the 4th Ring Road and the composition, chemicals and granularity was tested. The dust in the urban area is mainly composed of quartz, plagioclase, dolomite, calcite, and hornblende, which account for 80 to 90 per cent of all the minerals. Besides, there is a small quantity of mica, microcline, sericited feldspar, carbonaceous granule, glass, etc. The content of K2O and Na2O is higher in the coarse grains than in the fine grains. The averages of content of 16 elements are all higher in the fine grain than in the coarse grain. The sequence of the heavy metals from most seriously contaminates to the slightly contaminates in the dust are cadmium, mercury, zinc, copper and arsenic.

The mantle neon from the Jinchuan sulfide deposit, NW China

X. R. YE, C. A. YU, AND L. DING

1Key Laboratory of Gas-Geochemistry, CAS, Lanzhou, 730000, China (xrye287@sohu.com)
2Institute of Tibetan Plateau Research, CAS, Beijing, 100085, China (dinglin@mail.igcas.ac.cn)
3Graduate University of Chinese Academy of Sciences, Beijing 100049, China (yuchuanao@eyou.com)

The noble gas isotopic compositions in the clinopyroxene, olivine, orthopyroxene and chalcopyrite from the second diggings of the Jinchuan sulfide deposits, NW China, have been determined. Stepwise heating method had been taken in order to get the noble gas isotopic compositions from the different micro-sections in a sample. The ranges of the neon contents and isotopic compositions in the samples studied were shown in the following table.

Apparently, the neon isotopic compositions of the samples were different from atmospheric. Higher 20Ne/22Ne values were found at 400ºC and 700ºC with an average of 10.58 and 10.39, respectively. In the three isotopes diagram of neon, the data points are dispersive, which shows a characteristic mixed on multi-member fluid. However, the data points are concentrated or show a correlation between 20Ne/22Ne and 21Ne/22Ne at every temperature step. It is noticeable that the line at 400ºC closed to Loihi line, the line at 700ºC trends to MORB line, and the lines at 1000ºC, 1300ºC and 1600ºC shown an addition of radiogenic neon. The fluids released at lower temperature were mainly come from fluid inclusion, so it is surmisable that the mineral captured mantle fluid during crystallization.

Background

The redox cycling and mineralization of selenium is largely controlled by microbial processes. Phylogenetically diverse species of Bacteria and Archaea are able to reduce soluble selenate oxyanions [Se(VI), SeO₄²⁻] to insoluble elemental selenium [Se(0)]. Although Se-reducing bacteria are known to govern the redox transformation of selenium in a broad range of terrestrial and aquatic environments, the mechanisms of microbial selenate reduction remain poorly understood. In this study, we apply molecular techniques to identify the genes involved in selenate reduction pathway.

Methods

Transposon mutagenesis and direct cloning techniques were used to identify genetic regions in the Se-reducing bacterium Enterobacter cloacae SLD1a-1 associated with selenate reductase activity. The mini-Tn5 transposon system was used to produce mutants that have lost the ability to reduce selenate. E. cloacae mutants and genomic library clones heterologously expressed in E. coli S17-1 were screened for activity on LB agar supplemented with sodium selenate. The rate of selenate reduction by the clones was measured in liquid minimal media, and the Se(0) minerals formed by the clones were examined using XANES and SEM.

Results and Discussion

Essential genes required for microbial selenate reduction were identified. The experiments showed that mutation of the Fumurate Nitrate Reduction regulator gene, menaquinone biosynthesis operon, and twin-arginine translocation operon produces derivative strains that are deficient in selenate reductase activity. Complementation by the wild-type sequences restores the ability of mutant strains to reduce Se(VI). These results demonstrate that: 1) oxygen sensing molecules regulate the expression of selenate reductase genes; 2) selenate reduction activity is dependent on the secretion of the reductase enzyme to the periplasmic space; and 3) anaerobic electron carriers are involved in the shuttling of electrons to the terminal selenate reductase protein. We propose a molecular model to describe microbial Se(VI) reduction.
Metamorphic evolution and tectonic implications of the Qianlishan-Zhaozhishan complex, westernmost part of the Paleoproterozoic Khondalite Belt in the Western Block of the North China Craton

CHANGQING YIN, GUOCHUN ZHAO, MIN SUN, WINGHANG LEUNG AND JIAN ZHANG

Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong; (yincq@hkusua.hku.hk)

A major advance has been made in understanding the Paleoproterozoic amalgamation of the North China Craton at ~1.85 Ga following recognition of two Paleoproterozoic continent-continent collisional belts, named the Trans-North China Orogen and Khondalite Belt[1-2]. In the last few years, extensive work has been done on the Trans-North China Orogen[3-5], but few investigations have been carried on the Khondalite Belt in the Western Block, which has hindered the further understanding of the tectonic amalgamation of the Yinshan and Ordos Terranes and the formation of the Western Block. In this study, we present metamorphic data for the khondalites in the Qianlishan-Zhaozhishan Complex in the westernmost part of the Paleoproterozoic Khondalite Belt, which places rigorous constraints on the evolution of the belt and amalgamation of the Western Block. The Qianlishan-Zhaozhishan Complex is composed predominantly of S-type granites and supracrustal rocks, including Al-rich gneisses, quartzites, marbles and calc-silicate rocks, collectively called khondalite series in the Chinese literature. Petrographic studies show that the Al-rich gneisses from the Qianlishan-Zhaozhishan Complex underwent four distinct metamorphic stages. M1 is represented by quartz + plagioclase + muscovite + biotite + garnet core, forming at 550-650°C and 6-7 kbar. The M2 stage formed sillimanite, garnet, cordierite, K-feldspar, plagioclase and quartz at the T-P conditions of 750-800°C and 6-7 kbar. It was then followed by the M3 stage that represents the formation of cordierite coronas surrounding garnet, indicating a nearly isothermal decompression. Finally, the rock experienced a retrogressive stage (M4) represented by the appearance of andalusite and late muscovite. These mineral assemblages and their approximate P-T estimates define a clockwise P-T path involving nearly isothermal decompression for the Qianlishan-Zhaozhishan Complex, supporting the recently proposed model that the Western Block formed by the collision between the Yinshan and Ordos Terranes along the Paleoproterozoic Khondalite Belt.

This study was financially supported by the Hong Kong CERG grants (7055/05P, 7058/04P, and 7063/06P) and a Chinese NSFC Grant (40429001).

The source and distribution of volatile elements on Hadean Earth

R. YOKOCHI¹ AND B. MARTY²

¹Dept. of Earth and Environ. Sci., Univ. of Illinois at Chicago, 845 W Taylor Street (MC186), Chicago IL, 60607, U.S.A. (yokochi@uic.edu)
²CRPG, CNRS, 15 Rue Notre Dame des Pauvres, 54220 Vandoeuvre les Nancy, Cedex, France

The Earth’s atmosphere is an integrated product of planetary evolution processes that reflects the chemistry of the contributing materials (precursors) and the energy supplied. According to astrophysical models, potential precursors that could have delivered significant quantity of water or hydrogen to the primitive Earth include the solar nebula, comets and carbonaceous chondrite-like materials of different sizes (planetary embryos, micrometeorites and IDPs). The comparative study of H, N and C isotopic compositions between those potential precursors and the Earth suggests that a major source of highly volatile elements is carbonaceous chondrite-like material (e.g. Marty and Yokochi, 2006). As such components cannot be the major building blocks of the Earth, however, the mode and timing of their supply as well as the possible events having affected the water and other volatile elements need to be constrained in order to understand the evolution of the primitive Earth’s surface environment. In this context, noble gases are advantageous tracers of physical processes and their time scales given that they are chemically inert and that several radiogenic isotopes of appropriate production rates exist.

Xenon isotopes indeed provide an exceptional set of chronological tracers: ¹²⁹Xe was produced by the now extinct β-decay of ¹²⁹I (T₁/₂= 15.7 Myr), and ¹³¹-¹³⁶Xe were produced by the spontaneous fission of ²³⁸U (T₁/₂= 4.45 Gyr) and now extinct ²⁴⁴Pu (T₁/₂= 82 Myr). As the respective proportions of ²⁴⁴Pu and ²³⁸U fissions to ¹³¹-¹³⁶Xe isotopes are poorly constrained due to the similar relative yields, we determined the proportions of ²⁴⁴Pu and ²³⁸U fission derived ¹³⁶Xe according to the relative abundances of ⁴He-²¹Ne-¹³⁶Xe, for a set of new noble gas data obtained for Kola plume (Russia) samples (Yokochi and Marty, 2005). The ²⁴⁴Pu contribution of mantle plume-related component is estimated to be 33-60 % of total fission ¹³⁶Xe. This value is significantly lower than what is expected for a chondritic reservoir (96 %), and is similar to the previously proposed best estimate for the MORB mantle (32 ± 10 %). This result implies that the whole mantle was subject to degassing after the decay of ²⁴⁴Pu, over the entire Hadean. In line with this result, a model age of the atmosphere based on the ratio of radiogenic ¹²⁹Xe/³⁶Ar suggests that the atmosphere was subject to hydrodynamic loss over 150 Myr after solar system formation, much longer than previous model estimates using xenon isotopes alone.

More on Os isotope anomalies in chondrites: Possible carriers

TETSUYA YOKOYAMA1, VINAI K. RAJ2, CONEL M. O’D. ALEXANDER3 AND RICHARD J. WALKER1

1Dept. of Geology, Univ. of Maryland, USA
(yokoyama@geol.umd.edu)
2Dept. of Chemistry and Biochemistry, UC San Diego, USA
3DTM, Carnegie Institution of Washington, USA

Recent, highly-precise isotopic analyses of various bulk meteorites and acid residues have revealed that some primitive chondrites contain isotopically anomalous presolar grains which record diverse stellar nucleosynthesis. Another essential but still unsolved issue is whether or not the chondrite precursors, including presolar grains, were homogeneously distributed in the early solar nebula at the time of planetesimal formation. We have previously demonstrated that bulk samples of carbonaceous, enstatite and ordinary chondrites have uniform 186O/188Os, 188Os/186Os and 190Os/188Os ratios when decomposed by an alkaline fusion total digestion method, although acid residues of some carbonaceous chondrites were enriched in Os isotopes produced by s-process nucleosynthesis [1]. These results suggest that chondrite precursors were thoroughly mixed in the early solar nebula, and we speculated that the main carrier of the anomalous s-process Os was presolar SiC grains. Reisberg et al. [2], similarly carried out sequential acid leaching of the bulk Murchison meteorite, and found that an s-process-enriched Os-rich component was accessible with mild leaches (e.g. hot HCl treatment). They proposed that the main carrier of the s-process Os may not be presolar SiC grains but rather more easily digestible presolar phases such as graphite or metal alloy.

To investigate this issue further, we have carried out a hot HCl leaching experiment for the Murchison acid residue prepared by a relatively mild CsF/HF technique. The bulk sample of this residue was strongly enriched in s-process Os (ε186Os = +11.0). The hot HCl leaching recovered ~10% of the Os in the residue, which was also enriched in s-process isotopes (ε186Os = +8.0) but not as high as the bulk residue. This indicates that the HCl insoluble phase in the residue is more enriched in s-process Os, corroborating the existence of acid resistant SiC grains as an s-process Os carrier. The leachate is known to have a 54Cr anomaly, an isotope that can be produced by r-process nucleosynthesis [3]. Therefore, the leachate may contain an HCl digestible, r-process Os carrier, the existence of which may be masked by the HCl digestible s-process Os carrier. The likely hosts of the s- and r-process Os remain unclear. We will conduct further leaching tests (e.g. HNO3, HClO4) on the Murchison residue as well as other chondrite acid residues to better identify the carrier of isotopically anomalous Os in the chondrites.

REE geochemical study on the formation environment of the Hishikari epithermal gold deposit, Japan

K. YONEZU1, A. YASUMATSU2, Y. OKAUE3, A. IMAI1, K. WATANABE1 AND T. YOKOYAMA2

1Department of Earth Resources Engineering, Kyushu University, 744 Motooka, Nishi-ku, Fukuoka, 819-0395 Japan (yone@mine.kyushu-u.ac.jp)
2Department of Chemistry, Kyushu University, 4-2-1 Ropponmatsu, Chuo-ku, Fukuoka, 810-8560 Japan (yokotscc@mbox.nc.kyushu-u.ac.jp)

In order to investigate the formation environment, especially redox environment, during the mineralization at the Hishikari epithermal gold deposit, Kagoshima prefecture, Japan, the concentration of rare earth elements (REE) and Y in the Hosen No.1 auriferous quartz vein were determined by ICP-MS after acid dissolution and selective separation. The Hosen No.1 vein shows well symmetric banded structure and it was classified into four main bands (band I - IV). This vein was consisted of quartz, adularia and smectite associated with electrum and metal sulphides (e.g. pyrite, sphalerite and galena). Adularia could be commonly observed in each band, especially it is abundant in the earliest precipitation stage of each band. Electrum and other metal sulphides occurred with adularia and/or smectite. The quartz vein samples were collected from each band at -20 and +62.5 meter levels. The samples collected in the band II were analyzed separately by specific minerals due to the existence of electrum and sulphide-rich band called “ginguro” band.

The total concentration of REE including Y was varied from 9.72 to 0.45 and from 5.11 to 0.66 ppm at -20 and +62.5 meter levels, respectively. The highest concentration at each level was obtained in the samples obtained from the band II containing “ginguro”. The chondlomite normalized REE patterns of all the samples at both -20 and +62.5 meter levels showed a strong positive Ce anomaly. These results suggest that the Hosen No.1 quartz vein was precipitated and formed by mixing with oxidizing fluid (groundwater or meteoric water) and hydrothermal fluids after loss of H2S and CO2 gasses, and increase in pH due to boiling.

In order to investigate this issue further, we have carried out a hot HCl leaching experiment for the Murchison acid residue prepared by a relatively mild CsF/HF technique. The bulk sample of this residue was strongly enriched in s-process Os (ε186Os = +11.0). The hot HCl leaching recovered ~10% of the Os in the residue, which was also enriched in s-process isotopes (ε186Os = +8.0) but not as high as the bulk residue. This indicates that the HCl insoluble phase in the residue is more enriched in s-process Os, corroborating the existence of acid resistant SiC grains as an s-process Os carrier. The leachate is known to have a 54Cr anomaly, an isotope that can be produced by r-process nucleosynthesis [3]. Therefore, the leachate may contain an HCl digestible, r-process Os carrier, the existence of which may be masked by the HCl digestible s-process Os carrier. The likely hosts of the s- and r-process Os remain unclear. We will conduct further leaching tests (e.g. HNO3, HClO4) on the Murchison residue as well as other chondrite acid residues to better identify the carrier of isotopically anomalous Os in the chondrites.

Mantle heterogeneity as evidenced by Raobazhai peridotite, North Dabieshan, China

ZHENDONG YOU, ZENQIU ZHONG AND SHUTIAN SUO
China University of Geosciences Wuhan 430074, China
(zhendongyou@tom.com)

The peridotite bodies occurred near Raobazhai, in north Dabieshan trends northwestwards extending more than 10Km. The peridotite body consists mainly of harzbergite and dunite, with a few lherzulite mostly amphibolized due to amphibolite facies metamorphism. All of them are highly serpentinized. Major mineral paragenesis of the peridotites are Ol+Opx+Spl and Ol+Spl. The peridotite bodies are highly deformed and are mylonitized. REE distribution pattern and trace element geochemistry evidenced the chemical heterogeneity of these mantle-derived rocks.

There are a number of garnet pyroxenite enclaves scattered within the peridotite body as small pods, decimeters in size, enclosed in the serpentinized peridotites. Major mineral components of the garnet pyroxenite are: garnet (Prp25—35), sodium augite(Jd 10—25 ) with a small amount of ilmenite. There are two stages of retro- metamorphism: the retrogressive granulite facies superimposed by amphibolite facies. On the basis of garnet–clinopyroxene geothermometry Kd=4.06–5.28; T=793–919℃, P=1.5 Gpa are estimated for the garnet pyroxenite.

It is inferred that the peridotites are mantle rocks about 60Km in depth. During the exhumation of the orogenic belt it was tectonically emplaced into the lower crust in solid state and then uplifted to shallow depth. The REE distribution pattern and the Ni-Co-Sc diagram reveal that they are chemically equivalent respectively to the basaltic melt and ultramafic residua. Incompletely removing of mantle melting products from source area could be a possible mechanism for the mantle heterogeneity.

Si and Mg isotopic constraints on the astrophysics of CAI formation in the early solar system

E.D. YOUNG¹ AND A. SHAHAR¹
¹Department of Earth and Space Sciences, University of California Los Angeles, 2676 Geology Building, Los Angeles, CA 90095-1567 (eyoung@ess.ucla.edu)
²Institute of Geophysics and Planetary Physics, UCLA

Silicon and magnesium isotope ratios can be used to constrain the pressure ($P_{H2}$) and duration of melting of calcium-aluminum-rich inclusions (CAIs) in the early solar system. Recent results (Shahar and Young 2007) show that these primitive protoplanetary objects most likely melted for integrated timescales of tens of days at $P_{H2} < 10^{-6}$ bar. Here we show that the isotopic compositions of CAIs further require that they formed not only at lower pressures than the more abundant chondrules with which they are found, but also at orders of magnitude lower number densities, constituting an important constraint on the astrophysical setting of CAI formation.

The substantial Si and Mg isotope fractionation in CAIs suggests that their number densities were too low to permit an overall elevation in background partial pressure of Mg and SiO that would have prevented fractionation. We quantify this effect by estimating the pressure of gas molecules or atoms produced by a population of evaporating CAIs:

$$ P_{i,vac} = \frac{3J_i r_t^2 N_{CAI}}{(D_{gas} T)^{3/2}} kT $$

where $N_{CAI}$ is the number of CAIs within a sphere defined by a radius equal to the characteristic length scale for diffusion in the gas $(D_{gas})^{1/2}$ and $J_i$ is the flux of an element $i$ (e.g., Mg or SiO) from a single CAI. Modification of $J_i$ by $(1+P_i/P_{i,eq})$ to account for deviations from vacuum and approaches to equilibrium vapor pressures results in the expression

$$ \frac{P_i}{P_{i,eq}} = \frac{P_{i,vac} / P_{i,eq}}{1+P_{i,vac} / P_{i,eq}} $$

For typical conditions indicated by Si and Mg isotope fractionation, including $T = 1673$ to 1873 K, $P_{H2} = 10^{-9}$ to $10^{-4}$ bar, equations (1) and (2) yield a maximum number density of CAIs during their melting of $1x10^{-3}$ to $2.0$ m$^{-3}$, or a linear spacing of $> 0.8$ to $8$ meters. This number density is four orders of magnitude lower than that for chondrules (Young and Galy 2004; Cuzzi and Alexander 2006).

Cenozoic volcanism of kamafugite and carbonatite in Western Qinling, China: Evidence of DUPAL-like asthenospheric mantle flow

XUEHUI YU, XUANXUE MO, ZHIDAN ZHAO
China University of Geosciences (Beijing), Beijing, 100083 (xhyu@cugb.edu.cn)

Dispersed Cenozoic potassic volcanism appeared over much of Tibet plateau and adjacent area during late stages of India-Eurasia plate collision and post-collision. Although widespread this volcanic activity appears to be distinct from that producing Large Igneous Provinces being characterized by greater compositional diversity and a lack of evidence for deep-mantle plumes. However, an additional feature is the dominance of DUPAL-like Pb isotopic compositions and εNd in asthenosphere-derived melts, attributed variously to the influx of Indian Ocean mantle, endogenous mantle plumes or delaminated cratonic substrate. “Dispersed” volcanism may therefore pose fundamental questions concerning the dynamic behavior of sub-continental mantle in relation to continental plate collision. Is the asthenosphere mobilized during such plate collision? and to what extent and by which mechanisms may plate kinematics coupled to mantle flow? May be, the studies of Cenozoic Carbonatite and kamafugite in Western Qinling, China can answer the questions.

The kamafugite and carbonatite in Western Qinling, China located to the northeastern boundary of Tibet plateau. The volcanic rocks have the characteristics rich in LILE, LREE and HFSE (such as Nb, Zr, Th and U et al.) especially. The distribution patterns of REE chondrite-normalized is very like to OIB. Initial 87Sr/86Sr are lower (in the range of 0.70381-0.7094 for kamafugites, of 0.70529-0.71332 for carbonatites), initial 144Nd/143Nd (in the range of 0.512924-0.512404 for kamafugites, of 0.512928-0.512221 for carbonatites) are higher but homogeneous comparing to Sr isotopes of the volcanic rocks. A lot of volcanic rocks have the εNd (in ppm) and εNd (vs. 87Sr/86Sr).

All of these mentioned above show that WQL Cenozoic kamafugites and carbonatites are a ultra-potassic volcanism related to mantle plumes and contained EM1 and EM11 end members in their mantle sources. Despite the apparent lack of plumes in the Western Qinling, the studies of Western Qinling Cenozoic volanic rocks of kamafugite and carbonatite, and seismic tomography suggests the Cenozoic volcanism in Western Qinling is matched by swell-like low-velocity anomalies in the upper mantle or shallow-level perturbations of the asthenosphere. Spatial and temporal associations of the volcanism further suggest that discrete asthenosphere, i.e. so-called “crust-mantle transitional belt” were generated during late stages of the Idia- Eurasia continental collision.

Study of Lu-Hf geochronology - A case study of eclogite from Dabie UHP Belt

HONG-LIN YUAN1,2, SHAN GAO2,1, YAN LUO3, CHUNLEI ZONG1 AND MENGNING DAI1

1State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi’an, 710069, China (HLYUAN@263.NET)
2State Key Laboratory of Geological Processes and Mineral Resources, Faculty of Earth Sciences, China University of Geosciences, 430074, China (SGAO@263.NET)
3Department of Earth and Environmental Science, Vanderbilt University, VU Station B, #351805, 2301 Vanderbilt Place, Nashville, TE, U.S.A. (yan.luoyan@gmail.com)

We developed Lu-Hf isotope geochronology with isotope dilution multiple collector inductively coupled plasma mass spectrometry (MC-ICP-MS). Chemical separation of Lu and Hf from bulk rock is set up while the Lu cut of the chromatography contains Yb and 176Lu/176Yb is always larger than 30. The correction of Lu and Yb interference on Hf adopted in this work is based upon an exponential law although Lu and Yb concentration in the Hf cut is very low (176Lu/176Hf and 176Yb/176Hf are less than 2×10^-6 and 2×10^-7, respectively). Internal precision of 176Hf/177Hf measurements for natural samples is better than 0.0015% while the external precision is better than 0.0010%.

Fig 1 176Lu/177Hf-176Hf/177Hf isochron of eclogite sample SH02. The middle two points are isotopic compositions of the mixture of garnet and bulk rock. The mixing proportion of garnet with whole rock and omphacite are 0.5 and 0.3 respectively.

We obtained a garnet-whole rock isochron age of 254 ± 16 Ma (2σ) for a Shanghe eclogite from the Dabie ultrahigh pressure metamorphic belt (see fig 1). The relative larger error is due to the low Lu concentration in garnet (1.1 µg/g) and close 176Lu/177Hf ratios in both garnet and bulk rocks (0.05 vs 0.01).

The result of Lu-Hf isochron represents the garnet formation age during continental subduction and late peak- and post- ultrahigh pressure(UHP) metamorphism didn’t disturb the Lu-Hf isotopic system in garnet.

Zircon and apatite fission track study on the mineralization of Nanliang gold deposit, eastern Hebei, China

WANMING YUAN¹, JUN DENG¹, JINQUAN DONG² AND ZENGKUAN BAO²

¹State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (ywml010@yahoo.com)
²Laboratory of Nuclear analysis techniques, Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, 100039, China

Xiayingfang gold ore district, Hebei province, China, occurs in Xinglong-Kuancheng arcuate fold area of Yanshan platform fold belt in eastern Yinshan-Yanshan EW tectonic belt. A granite-porphyry intrusion, the principal part of magma activity in this area, is close related to the gold mineralizing process. This paper aims at studying the hydrothermal metallogenetic epoch and thermal history of Xiayingfang gold deposit, based on zircon and apatite fission track analyses for different alteration zones.

The zircon and apatite ages of six samples from ore and altered rocks range from 154 Ma to 120 Ma and from 114 Ma to 103 Ma respectively, indicating a about 22-50 Ma metallogenic duration, and the metallogenic time falls into early Yanshan epoch. The age data and quantitative AFT modelling show that there are two stages of gold mineralization, in which the first stage is of higher temperature and rapidier cooling rate than the second stage and the time and temperature of the turning point between them is about 120 Ma and 100°C. The first stage of mineralization resulted from intrusion of a granite-porphyry body and took place in about 150 Ma, and second stage of the mineralization was related to both rhyolite-porphyry and magma cryptoexplosive breccia and occurred in about 135 Ma. Combined with the minerogenetic temperature of 370-290°C, 230-170°C and 150-80°C in vanward-, main- and late-mineralization period respectively, the ZFT and AFT ages correspond to the main- and late-mineralization period separately. Since the samples from different places are heated in different degree by the metallogenetic hydrothermal solution, the less the distance from the thermal source and the long the heating time is, the lower the measured fission track age. It is demonstrated that the quartz-sericitization alteration is earlier and lasts longer than the potassic alteration. Therefore, we consider fission track analysis of the minerals is useful to researching the metallogenetic epoch and thermal evolution history of hydrothermal deposits.

Mass transfer during volatile exsolution in magmatic systems:
Insights from the analyses of silicate melt and magmatic fluid inclusions

Z. ZAJACZ1, WE. HALTER1, T. PETTKE2 AND M. GUILLONG1

1Institute of Isotope Geochemistry and Mineral Resources, ETH Zürich (zajacz@erdw.ethz.ch, halter@erdw.ethz.ch, guillong@erdw.ethz.ch)
2Institute of Geological Sciences, University of Bern (thomas.pettke@geo.unibe.ch)

We analyzed silicate melt and primary magmatic fluid inclusions in numerous granitic systems and in the basaltic andesites of the Villarrica volcano to quantify the distribution of several elements between silicate melts and magmatic volatiles.

LA-ICPMS analyses of co-existing silicate melt and fluid inclusions, entrapped in mairalitic quartz crystals, allowed direct quantitative determination of fluid/melt partition coefficients. Investigations of various granitic systems (peralkaline to peraluminous in composition, log fO2=NNO-1.7 to NNO+4.5) exsolving fluids with various cholorinities (1 to 13 mol/kg) allowed us to assess the effect of these variables on the fluid melt partition coefficients (D). Partition coefficients for Pb, Zn, Ag and Fe show a nearly linear increase with the chlorinity of the fluid (D Pb~6*MCl, DZn~8*MCl, DAG~4*MCl, DE~1.5*MCl, where MCl is the molarity of Cl). This suggests that these metals are primarily dissolved as Cl-complexes and neither oxygen fugacity nor the composition of the melt affects significantly their fluid/melt partitioning. Partition coefficients of Mo, As, Sb and Bi are highest into low salinity (1-2 mol/kg Cl) fluids with maximum values of DA~20, DAs~10, DSB~8, DW~15 indicating dissolution as non-chloride (e.g., hydroxy) complexes. Fluid/melt partition coefficients of copper are highly variable, but highest between vapor like fluids and silicate melt (D Cu~2700), indicating important role of ligands other than Cl. Fluid/melt partition coefficients of Sn and W show a weak positive correlation with the chlorinity of the fluid (D Sn~0.3-42, DW~0.8-60), but likely decrease with decreasing oxygen fugacity or melt peraluminosity.

In situ quantitative determination of fluid/melt partition coefficients in mafic systems with the use of natural samples is limited due to the lack of well preserved fluid inclusions. However, very high excess concentrations of Cu and Ag have been analyzed in plagioclase-hosted silicate melt inclusions in basaltic andesites compared to those in co-genetic pyroxene and olivine (up to 4800 ppm Cu vs. 40-200 ppm Cu in plagioclase vs. pyroxene and olivine hosted melt inclusions). The excess Cu is due to heterogeneous entrainment of a high temperature (~1000 °C) vapor phase rich in Cu, Ag and S. This suggests that high-temperature magmatic vapors may play an essential role in the transport of Cu, Ag and S from mafic to felsic magmas in complex magmatic reservoirs.

Geochemical fractionation and anthropogenic metal pollution in sediments of Nakagawa River in Tokyo, Japan

H. M. ZAKIR1, 2 AND N. SHIKAZONO1

1Laboratory of Geochemistry, Dept. of Applied Chemistry, Faculty of Sci. & Tech., Keio University, Hiyoshi 3-14-1, Yokohama 223-8522, Japan; (sikazono@apple.keio.ac.jp)
2Dept. of Agricultural Chemistry, Faculty of Agriculture, Bangladesh Agricultural University, Mymensingh-2202, Bangladesh; (zakirhm.ac.bau@gmail.com)

Nakagawa River sediments were collected from the whole river and analysed for heavy metals in the less than 63 µm grain size fraction. The geochemical fractionation of heavy metals was examined with a sequential extraction scheme and the concentration of iron, manganese, lithium, cobalt, cadmium, chromium, copper, nickel, lead and zinc were measured in the liquid extracts by flame atomic absorption and inductively coupled plasma mass spectrometry. A certified reference stream sediment sample (JSd-2) provided by the Geological Survey of Japan was also analysed using the same procedure as a check. The association of Cr and Pb with oxides and Zn with carbonatic and oxides were comparatively higher. Nakagawa River sediment was considered to be polluted on the basis of unpolluted sediments and geochemical background values with respect to Cr, Pb and Zn, which were several times higher than the limiting concentration where toxicological effects are expected. The geoaccumulation index for most of the sampling points also lies above zero indicating contamination in Nakagawa sediment for the aforesaid metals. The pollution could be linked to anthropogenic activities such as industrialization, urbanization, deposition of industrial wastes and others. A final evaluation of the Nakagawa River sediments heavy metal pollution will be made from the study results.
The evolution of \( m_u \) and the isotopic composition of lead in the early solar system and young Earth

ROBERT E. ZARTMAN\(^1\) AND EMIL JAGOUTZ\(^2\)

\(^1\)EAPS, Massachusetts Institute of Technology, Cambridge, MA 02139, USA (rzartman@mit.edu)
\(^2\)Max Planck Institute for Chemistry, D-55020 Mainz, Germany (Emil@jagoutz.de)

A loss of volatile elements during the condensation of the solar nebula is the main fractionating process of CM, CO, CV and ordinary chondrites. These building blocks (constituting 85% of meteorite falls), from which the terrestrial planets accrete over the next 10-40 Ma, retain CI refractory element relative abundances but display deficiencies in their volatile elements correlating with condensation temperatures. As a consequence, these earliest condensates from the cooling solar nebula display, on average, an order of magnitude increase in \( m_u \) (\( m = 238\text{U}/204\text{Pb} \)) from \( \sim 0.1 \) to \( \sim 1 \). Additional volatile element loss and further increase in \( m_u \) continues to occur from impact melting on various scales throughout the accretion process. Differentiation of planetesimal bodies, such as metal-silicate separation, also produces chemical heterogeneity that may affect \( m_u \). Our best value for the bulk Earth \( m_u \) comes from analyses of terrestrial Pb, which has evolved uniformly in isotopic composition over geologic time and provides an integrated \( m_u \) value of \( \sim 9 \) for the crust and upper mantle. However, the possibility of other reservoirs in the core and lower mantle has hampered efforts to precisely determine the total bulk Earth \( m_u \) value.

New and published meteorite data are presented to examine the effects of volatile element loss on U-Pb isotope systematics in the early solar system. Recent studies using the extinct Hf-W chronometer have shortened older estimates of the time between the origin of the solar system and the separation of the Earth’s core. Accordingly, some proposed solutions to the Pb paradox—the positioning of both the Earth’s crust and mantle to the right of the Geochron on Pb-Pb diagrams—that were based on a \( >50 \) Ma time span for Earth’s accretion and core formation, are invalid. Allowing only 10-20 Ma for production and loss of radiogenic Pb before being retained by the Earth causes but minor rotation of a Geochron anchored to Canon Diablo initial Pb. Scenarios for the evolution of \( m_u \) in the early solar system and young Earth, and comparisons with Mars, the Moon and other meteorite parent bodies will be given. It is concluded that the Pb paradox as well as the \( \kappa \) conundrum are due predominantly to long-term storage of radiogenic Pb in, and decoupled U, Th, and Pb transport among terrestrial reservoirs. In contrast, \( m_u \) values are established at the time of planetary formation by the accretion of material that has suffered earlier and concurrent loss of volatile Pb, and can differ significantly among the terrestrial planets.

Relative and absolute timescales in metamorphism - Observations, calculations, estimations

A. ZEH

Mineralogisches Institut, Am Hubland, D-97074 Würzburg, Germany (armin.zeh@mail.uni-wuerzburg.de)

Presently there are several ways to record metamorphic processes through time. (i) In first order, metamorphic petrology is needed to set constraints on the relative record of metamorphic processes, and to provide information about the prograde and retrograde P-T evolution, and the metamorphic peak. Presently, detailed P-T paths can be reconstructed by comparison of information obtained from thin section observations (assemblage sequences, mineral zonations, mineral growth and resorption textures) and such gained by thermodynamic calculations, e.g. by using quantitative phase diagrams. (ii) Second, detailed petrographic observations are necessary to relate the evolution of rock forming minerals - used for P-T path reconstructions- to the evolution of accessory minerals commonly used for geochronology. In this context, trace element (TE) zonation patterns of rock-forming and accessory minerals can be useful. However, their application as thermometers and as “correlators” must be considered with caution, because their incorporation in accessory and rock forming minerals, as well as their distribution among minerals on a thin section scale is far from well understood. These problems can strongly influence the interpretation of P-T-t paths as well as dating results (e.g. Lu-Hf dating of metamorphic garnet). (iii) Dating of accessory and rock-forming minerals will provide evidence about the absolute timing of metamorphic processes, and the duration of orogenies. In addition it allows to discriminate between mono- and polymetamorphic evolutions, which cannot be distinguished unambiguously on the basis of structural and petrological data. Furthermore, the combined use of different dating techniques may allow to estimate cooling rates of metamorphic rocks, and our growing understanding between the evolution of accessory and rock-forming minerals to estimate the timing of prograde P-T paths. (iv) The use of T-t dependent processes, like mineral growth rates and diffusion rates, can set additional constraints on the timing of metamorphic processes. E.g. the knowledge of mineral growth rates may help to clarify the timing of prograde P-T histories, whereas diffusion rates can be used to model cooling rates of orogenic processes.

Finally, I should emphasize that only the combination of different techniques will lead us to a true understanding of the crustal evolution through time.
Zircon formation versus zircon alteration – New insights from combined U-Pb and Lu-Hf in situ LA-ICP-MS analyses, and consequences for the interpretation of Archean zircon from the Limpopo Belt

A. ZEH1 AND A. GERDES2
1Mineralogisches Institut, Am Hubland, D-97074 Würzburg, Germany (armin.zeh@mail.uni-wuerzburg.de)
2Institut für Geowissenschaften, Mineralogie, Abt. Geochemie & Petrologie, Altenhöferalle 1, 60438 Frankfurt am Main, Germany (gerdes@em.uni-frankfurt.de)

We demonstrate that the combination of U-Pb and Lu-Hf isotope data obtained by LA-ICP-MS provides a powerful tool, which allows distinguishing zircon domains grown during several metamorphic-magmatic events from altered domains affected by complete single and/or multiple Pb-loss. This discrimination is possible, because the U-Pb and Lu-Hf isotope systems are decoupled during zircon alteration. We show that the initial \(^{176}\text{Hf}/^{177}\text{Hf}\) ratio once "incorporated" into the zircon lattice remains nearly unaffected during later alteration processes which cause Pb loss. Newly formed zircon overgrowths always have higher initial \(^{176}\text{Hf}/^{177}\text{Hf}\) than previously grown domains, due to the incorporation of additional radiogenic \(^{176}\text{Hf}\) formed by \(^{176}\text{Lu}\) decay in the rock’s matrix between the different zircon growth events. Such \(^{176}\text{Hf}\) is not incorporated into zircon domains affected by post-growth alteration. By applying the U-Pb and Lu-Hf systems, in combination with cathodoluminescence (CL) imaging, we can show that zircon grains in the Sand River gneiss of the Limpopo Belt grew during three events; during magma crystallization at 3.28 Ga, a first anatexis at 2.64 Ga, and a second anatexis at 2.02 Ga. Our data also show that abundant zircon domains underwent multiple Pb loss, and that many of the 2.02 Ga old zircon domains result from complete Pb-loss of zircon domains already formed at 2.64 Ga. In contrast, all domains of complex zoned zircon grains from the Zanzibar granodiorite gneiss were formed during a single magmatic event at 2.61 Ga, but most of them suffered single and/or multiple Pb loss.

Recent bimodal eruptions from the Torfajökull-Veidivötn volcanic system, south-central Iceland: Insights into magmatic processes and their rates

G. F. ZELLMER1,2, K. H. RUBIN1, K. GRÖNVOLD3, AND Z. JURADO-CHICHAY1
1Department of Geology and Geophysics, SOEST, University of Hawaii at Manoa, 1680 East West Road, Honolulu, HI 96822, USA
2Institute of Earth Sciences, Academia Sinica, 128 Academia Road, Sec. 2, Nankang, Taipei 11529, Taiwan, R.O.C.
3Volcanological Institute, University of Iceland, IS-101, Reykjavik, Iceland

Historical bimodal composition eruptions spanning Torfajökull central volcano and neighbouring Veidivötn fissure swarm in southeastern Iceland were studied to examine the nature and timing of basalt and rhyolite petrogenesis at an active divergent plate boundary. Post-glacial eruptions in the area have sampled both tholeiitic and transitional alkaline basalts as well as co-eruptive high-K rhyolites. Physical mixtures of these magmas were erupted at the boundary between these volcanoes, although this study focuses instead on lavas and tephras that most closely approach the mafic and felsic endmember magma compositions that fed the most recent eruptions in 871AD and 1477. Major and trace element data demonstrate that the samples sit near the ends of previously defined regional mixing trends. Whole rock and mineral U-Th-Ra-Sr isotopic compositions are consistent with both limited compositional variation in magma sources and relatively rapid petrogenetic timescales. Rhyolites display the greatest \(^{230}\text{Th}\) excesses of up to 17%, yet have only slightly lower \(^{230}\text{Th}/^{232}\text{Th}\) activity ratios than co-eruptive Veidivötn basalts. Both magma types display small but significant \(^{226}\text{Ra}\) excesses, up to \(~ 10\%\) in the rhyolites and \(~ 60\%\) in the basalts. Trace element and isotopic data are consistent with crustal melting of a mafic source protolith of Holocene age to generate the 871 and 1477 rhyolites. The requirement for a young rhyolite protolith is inconsistent with previously suggested models involving old silicic segregation lenses or isotatically subsided source rocks to make Icelandic rhyolites. Mineral separates yield zero-age U-Th isochrons, and Ra-Th isochrons of a few kyrs, indicating that the crystals formed shortly prior to eruption, consistent with petrographic and mineral chemistry indicators that they are phenocrysts. We propose a model to explain the compositional similarity of west Torfajökull rhyolites with historically erupted rhyolites in which the former are produced by partial melting of transitional alkaline basalts, while the latter are sourced from mafic protoliths that are chemically similar to the Veidivötn tholeiites but have suffered extensive K-metasomatism prior to melting.
Geochemical effects of deep subduction on the continental crustal materials

LINGSEN ZENG AND FULAI LIU
Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037 (lzeng@ccsd.org.cn)

Subduction of continental crustal materials to depths >100 km is well documented worldwide. However, how subduction affects the geochemistry of subducted continental materials is poorly understood. Deeply subducted (>100 km) sedimentary and granitic rocks from the Chinese Continental Scientific Drilling (CCSD) project are used to address such a critical question. Geochemical data on fresh pelitic, psammitic, and granitic rocks from 2800-3000 m and 4300-5000 m of CCSD main borehole show that (1) at similar SiO$_2$, Al$_2$O$_3$ and CaO, leucogranitic gneisses have the highest magnitude of variations in Rb/Sr and Rb/Cs ratios; (2) degrees of variation in Rb/Sr and Rb/Cs ratios appears to depend on K$_2$O; and (3) strong fractionation of Cs from Rb, and U from Th, resulting in highly elevated Rb/Cs (up to 400), and Th/U (up to 32) (Fig.). This can be explained by hydration induced K-feldspar to phengite transformation [1] which preferential retain Rb over Sr and Cs that preferentially partition into a fluid. Pre-HP dehydration or HP-UHP hydration of continental materials also fractionates Th over U, which greatly increased the Th/U ratio of the hydrated continental materials, leaving lower Th/U ratios in the residue fluids. Zircons grown from such a fluid could have lower Th/U ratios, which is common in UHP metamorphic zircons [2].

Environmental vanadium distribution in soil in a V-Ti-Fe magnetite ore area, Panzhihua, south-west of China

Y. ZENG, S. J. NI, C. J. ZHANG AND Y. HUANG
Department of Geochemistry, Chengdu institute of technology, Chengdu, 610059

Vanadium (V) is a widely distributed trace element in the earth’s crust. It had been confirmed that vanadium is an essential element for human and animals by the end of 1970’s (Cantly, 1978) and has high or middle poisonous to animals when its bioaccumulation reaches to a certain degree. The transfer ability and bioaccumulation of V in surface environment depends on its concentration, as well as its speciation.

Panzhihua, located at the upstream of Yangtze River, P. R. China, has a world famous V-Ti-Fe magnetite ore. It is the biggest V-Ti-Fe ore in China, which occupies 64% of the total vanadium in China. The investigated soil is of Xigeda type.

In this paper, the distribution of total vanadium and its speciation in soil got from different depths (4 layers, 0-5 cm, 15-25 cm, 30-50 cm and 50-75 cm) in this famous V-Ti-Fe magnetite ore area has been studied. The contents of total vanadium and vanadium speciation were determined by sensitive catalytic oscillopolarography.

The result show that the average content of vanadium in soil is 102 µg·g$^{-1}$, which is much higher than the average value 86 µg·g$^{-1}$ in China; the vanadium contents in soil samples came from mining area and smelting area are obviously higher than that from agricultural area and non-mining area. At the same sampling site, the content of vanadium is decreased by the increasing of sampling depth.

The sequential extraction analysis procedure of Tessier et al (1979) for heavy metals was used for the vanadium speciation separation. Although the main existing form of vanadium is residual form, the biological effect of vanadium in this area can be ignored. The summation content of exchangeable V and carbonate bound V, which can be directly bioaccumulated in natural conditions, is over 2 µg·g$^{-1}$, while in most other research area is usually less than 1 µg·g$^{-1}$. So the vanadium in this area has high transfer ability and high biological effect.

The solubility of gold in H₂S vapor

D. ZEZIN, ART MIGDISOV AND A.E. WILLIAMS-JONES

Department of Earth and Planetary Sciences, McGill University, 3450 University Street, Montreal, Quebec, Canada H3A 2A7 (zezin@eps.mcgill.ca)

Although there is extensive evidence that magmatic vapors are capable of transporting high concentrations of some ore metals, modeling of the processes responsible for ore deposition is severely limited by the paucity of data on the solubility and speciation of metals in the vapour phase. As complexes with HS⁻ and H₂S are the principal forms of dissolved gold in aqueous liquids and H₂S partitions strongly into the vapor phase of hydrothermal systems, it is likely that gaseous H₂S is important in promoting the volatile transport of gold. In this paper, we report the results of the first of a series of experimental studies designed to investigate the solubility of gold in H₂S-bearing water vapor.

This first study examines the solubility of gold wire in H₂S gas. The experiments were conducted in titanium alloy autoclaves at 300 to 400°C and pressures up to 230 bars. The total pressure was assumed to be equal to the pressure of H₂S gas and was calculated from the PVT properties of this gas. The redox potential was controlled by the S/H₂S pair. At the end of an experiment, the autoclaves were quenched and Au condensed on the walls of the vessel was dissolved in aqua regia. The solubility of Au in H₂S gas was calculated from its concentration in this acid. The results of our experiments indicate that the solubility of Au in H₂S increases with both temperature and fH₂S, reaching a concentration of 95 ppb at 400°C. Based on the fH₂S dependency, we propose that the species controlling the solubility of Au in H₂S gas has the form AuS·(H₂S)n or AuHS·(H₂S)n with a solvation number between 1 and 2 at 300-400°C. The equilibrium constants for the reactions controlling formation of these two species are log K = -11.1 ± 0.2 at 300°C (both species), -10.7 ± 0.3 and -10.5 ± 0.3 at 350°C, and -10.6 ± 0.2 and -10.4 ± 0.2 at 400°C, respectively.

Results of this study and preliminary experiments in the Au-H₂S-H₂O system, which yielded even higher Au solubilities, provide evidence that H₂S may play a major role in dissolving Au in hydrothermal vapor, something which may be key to understanding the genesis of porphyry and epithermal gold deposits.

Influence of ‘A’ cation ionic-radius on the structure and bulk modulus of ABO₃ perovskite and postperovskite

B.H. ZHANG¹, 2, J.S. XU¹, J.J. LU¹ AND X.P. WU¹

¹CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, P. R. China; (zhangbh@mail.ustc.edu.cn)
²School of materials Science and engineering, Hefei University of Technology, Hefei, Anhui 230009, P. R. China

Recently, high-pressure experiments and theoretical calculations demonstrate that (Mg,Fe)SiO₃ postperovskite is the predominant mineral in the lowermost mantle called the D° layer, and phase transition from perovskite (Pv) to postperovskite (PPv) has significant geophysical implications for the nature of the D° layer (Hirose 2006). The available experimental data of bulk modulus and 0 K transition pressure from Pv to PPv were investigated for ABO₃ perovskite and postperovskite, it was found that a linear relationships between the radius of ‘A’ cation and bulk modulus exists in ABO₃ Pv and PPv. The bulk modulus decreased linearly with increasing the radius of ‘A’ cation. On the other hand, there is also a positive linear relation between the ‘A’ cation ionic radius and the 0 K transition pressure for germinates perovskite, which indicates the transition pressure increasing linearly with the increasing the radius of ‘A’ cation, so the transformation into postperovskite phase becomes more difficult with the large ionic radii of ‘A’ cation in ABO₃ perovskite (see Fig.). As the phase transitions from Pv to PPv is due to the distortion of BO₆ octahedra in Pv, our results suggest that the ionic radius of ‘A’ cation probably play an very important role on the structure and the phase transformation of ABO₃ compounds.

Environmental geochemistry in relation to agriculture and human health in Hainan Island, China

State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China (glzhang@issas.ac.cn)

As the biggest island in tropical China, Hainan Island possesses advantageous hydrothermal conditions, high biodiversity and soil diversity.

The environmental geochemistry of this area is determined mainly by the special geological background and pedo-geochemical processes, which are characterized by the diversified lithology and tropical soil formation processes.

One major problem is the high Al toxicity of soils of the island. Total and exchangeable aluminum of soils in different weathering stages are high as compared to that of parent materials. About a half of the studied soils contain exchangeable aluminum higher than the threshold value of causing hazard to plant. Soils developed from basalt in the north part of the Island have the highest aluminum content while that from marine deposit lowest.

Agricultural production, including tropical cash crop cultivation, is affected soil acidity and acidification. Rubber cultivation has an accelerated acidification. Rice and upland crops also changed the acidity of soils of the Island.

Calcium is severely deficient in soils, surface water and plant. One nutritional problem is the intake of Ca of local people from their daily diet is much lower than that of nation-average as well as that of subtropical region.

It is suggested that based on the understanding of the environmental geochemistry problems, we are able to adjust agricultural structure in the way of interfering the cycling of some important plant nutrients for improving agricultural production and human health in this tropical Island.

Dynamic reactivity of metals in soils – Relevance to uptake by plants

HAO ZHANG, NIK LEHTO AND WILLIAM DAVISON
Environmental Science Department, Lancaster University, Lancaster, LA1 4YQ, UK (h.zhang@lancaster.ac.uk)

To predict the availability of metals to biota, it is necessary to understand both solution and solid phase supply processes in the environment. The kinetics of metal release from particles and complexes can limit the rate of uptake of metals. Complex dissociation rates in solution can be measured by several approaches. The rate of release of metal ions from particles in soils and sediments has been difficult to assess directly. The technique of DGT (diffusive gradients in thin-films) had been used to measure dissociation kinetics in solution and release from solid phase in soils. DGT perturbs the equilibrium system by lowering the local concentration of metals and measuring their supply. By modelling the dynamics of the DGT-soil system, kinetic information, such as the rate constant of supply from the solid phase and the labile pool size of metals, can be obtained.

Measurements have been performed in several metal soil systems. The results show that the rates of Zn and Cd supply are generally faster than those of Ni for the same soil. Relative slow rates of supply for Ni are consistent with general understanding of its kinetics of release from complexes. In clay soils the rate of release of Zn and Cd are generally too fast to measure, but measurable rates can be observed in some sandy soils. The rate of supply of Zn in freshly spiked soils is generally too high to measure, but measurable rates can be observed in some sandy soils. The rate of As release from solid phase to solution in the rhizosphere was much slower than that in the bulk soil. These kinetic findings are relevant to the uptake of metals by plants because DGT emulates the prime effect of the plant on soil, namely removal of metals.

To assess the metal dynamics in soils in relation to uptake by plants, we have used the measured Michaelis-Menten parameters of plants to predict the fluxes of metal that they remove from a given soil. The fluxes were comparable to the fluxes measured by DGT, showing that plants and DGT perturb the metal chemistry of the soil to similar extents. The soil kinetic parameters measured by DGT which influence the metal uptake by the device, will therefore also exert a control on the metal uptake by plants.

Structural and geochronological studies of the Fuping Complex: New constraints on the tectonic evolution of the Trans-North China Orogen

JIAN ZHANG, GUOCHUN ZHAO, SANZHONG LI, MIN SUN, SHUWEN LIU AND CHANGQING YIN

Department of Earth Sciences, The University of Hong Kong, Hong Kong, China (h0392041@hkusua.hku.hk)

The Trans-North China Orogen (TNCO) is interpreted as the site where two discrete continental blocks, called the Eastern and Western Blocks, amalgamated to form the coherent basement of the North China Craton in the late Paleoproterozoic[1-2], but its deformatonal history and timing have not been well constrained. In this study, we present structural and SHRIMP zircon data for the Fuping Complex, one of the largest complexes in the TNCO. Detailed mapping and structural investigations reveal that the Fuping Complex experienced four distinct deformatonal episodes (D1 to D4). The D1 is characterized by isoclinal tight fold (F1), penetrative F1 fold axial planar foliation (S1) and mineral lineation (L1). Earliest L1 displays a preferred NW-SE orientation with a shallow plunging angle, indicating the earliest direction of collision. The D2 is the major deformatonal episode in the complex, represented by ubiquitous E to SE-verging isoclinal, overturned -to- recumbent folds (F2) of varying scales, F2 fold axial planar foliation (S2) and crenulation lineation (L2). Both D1 and D2 deformations corresponded for the prograde metamorphism (M1). The extensional D3 generated regional-scale NW (W)-SE (E) trending upright open folds (F3) that warped the whole complex into dome and basin patterns. The last D4 is characterized by brittle fabrics and low-angle detachments, which are related to the complete exhumation of the complex. Both D1 and D4 corresponded for the decompression (M2) and retrograde (M3) metamorphism, respectively.

SHRIMP U-Th-Pb zircon ages from leucocratic dykes reveal that pre-D1 leucocratic dykes were emplaced at 2484±13 Ma, whereas zircons from syn-D2 folded leucocratic dykes yield SHRIMP zircon ages of 1843±12 Ma and 1844±18 Ma, respectively. Zircons from post-D2 leucocratic dykes give SHRIMP zircon age of 1817±14 Ma, older than published zircon ages of 1790±8 Ma and 1799±9 Ma for post-tectonic undeformed granitic pegmatite dykes. Structural and SHRIMP U-Th-Pb zircon data indicate that the Fuping Complex, together with adjacent Wutai and Hengshan Complexes, underwent uniform deformatonal histories incorporated into an eastwards subduction during final assembly of the North China Craton at ~1.85 Ga.

This research was financially supported by a NSFC Grant (40429001) and Hong Kong RGC grants (7063/06P, 7055/05P and 7058/04P).

FTIR features of coals from the Ordos Basin (NW China): Implications on hydrocarbons from coal

K. ZHANG, S. P. YAO AND J. CAO

Department of Earth Sciences, Nanjing University, Nanjing, China (donco.zhang@gmail.com)

The Ordos Basin, located in NW China, is typical of accumulation of multi energy resources including oil, gas and coal. We have performed the study on some coal samples with variable maturation from brown coal to anthracite by Fourier Transform Infrared (FTIR) Spectroscopy analyses. The goal is to have a deeper understanding of the evolution of hydrocarbons from coal. The method of curve-fitting analysis was used in order to more precisely quantify peak areas of different coal structure. Despite of the fact that the studied samples are not along a natural series due to different bioprecursors, they may also imply the ability and evolution of hydrocarbon generation of coals. Analytical results indicate that variation of IR spectra corresponds to the stage of hydrocarbon generation relatively well.

Firstly, when vitrinite reflectivity (Ro) of the samples is below 0.6%, IR spectra area around 1705 cm⁻¹ which represents stretching vibration of oxygenous groups in coal descends fastly with the maturation increasing. This implies that a lot of hydroxyl group and methoxyl group break off from coal and become carbon dioxide to migrate. IR spectra area of 2950 cm⁻¹ and 2920 cm⁻¹ represents asymmetric stretching vibration of methyl and methylene, respectively. However, we did not observe a clear change of these two function groups. In this stage, only a few amounts of oil and gas were generated based on thermal simulation experiment of brown coal.

Secondly, when Ro of the samples reaches 1.3%, FTIR spectra area around 1705 cm⁻¹ decreases to zero. Meanwhile, IR spectra area of 2950 cm⁻¹ and 2920 cm⁻¹ diminish continuously, which means plenty of aliphatic group and aliphatic ring break off to becoming oil and gas. The ratio of methyl (CH₃) to methylene (CH₂) representing the length of aliphatic chains of coal and a branching index increases. This may be ascribed to the break of long aliphatic chains and the conversion of hydroaromatic methylene structures to aromatic rings during hydrocarbon generation. A large amount of oil and gas have been generated through the thermal simulation experiment, and the coal almost reaches the hydrocarbon generation peak in this stage.

Thirdly, when Ro exceeds 1.3%, IR spectra area of 2950 cm⁻¹ and 2920 cm⁻¹ disappear, and the process of hydrocarbon generation from coal stopped. The CH₃/CH₂ ratio does not represent the length of aliphatic chains here. In summary, abundance of hydrogen and oxygen in coal decreases and carbon concentrates along with the coal rank increasing and hydrocarbon generative maturation.

A general kinetic model of plagioclase dissolution

LI ZHANG1 AND ANDREAS LÜTTEGE1,2

1Department of Earth Sciences, Rice University, 6100 Main street, Houston, TX 77005, USA. (lizhang@rice.edu, aluttege@rice.edu)
2Department of Chemistry, Rice University, 6100 Main Street, Houston, TX 77005, USA.

Feldspar dissolution is of great geochemical interest and has been intensively studied in the laboratory. The plagioclase solid-solution series provides a unique candidate for fundamental investigations of feldspar dissolution. Factors that affect dissolution kinetics of a particular plagioclase composition include saturation state, pH, ionic strength, organic ligands and temperature. Feldspars consist of a tectosilicate framework where variation in the distribution of Al and Si generate order/disorder phenomena. In the entire plagioclase feldspar solid solution series, the Al content increases from endmembers albite (Na[AlSi3O8]) to anorthite (Ca[Al2Si2O8]). These factors have significant influence on the dissolution kinetics and are potential indicators of dissolution mechanism.

We use a stochastic model to study plagioclase dissolution. The model incorporates bond-breaking, bond-forming, surface diffusion, detachment and attachment of various Si- and Al- ions and complexes to and from solution. The resulting dissolution is the outcome of the stochastic treatment designed to explore the kinetic behavior of a many-body process. The model involves the full crystal structure, highlighting the essential correlation of dynamics of neighboring sites on the surface.

We examined eight different plagioclase compositions, representing the entire solid solution series. Our results indicate that “unlimited deepening” into the bulk structure by leaching of Al yields a consistent log-linear dependence of dissolution rate on anorthite content. Only when the dissolution process is confined to the top several surface layers, the transitional point (about An70) can be successfully generated. At this point rates accelerate rapidly, and log(rate) departs positively from its linear relationship with An. In the case of (Al, Si) disorder, unlimited leaching of Al results in a 5-fold increase in dissolution rate from low albite to totally disordered high albite. In contrast, (Al, Si) disorder had no discernible effect on reaction mechanism involving the top layers. Subsequent modeling results on ∆G dependence, aluminum inhibition and surface chemistry are all comparable with previous experimental data in the framework of top-layer reaction mechanism. This confirms (1) feldspar dissolution under acidic conditions is a surface-controlled process, (2) surface processes modify the uppermost unit cells by leaching of Al, and (3) a thick layer of precipitates is generated on top of the leached interface.

Partial melting during the exhumation of the UHP rocks in Dabieshan Massif

LI ZHANG12 AND Z. ZHONG12

1State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, 430074, P.R. China (lizhang535@yahoo.com.cn)
2Faculty of Earth Sciences, China University of Geosciences, Wuhan, 430074, P.R. China (zqzhong@cug.edu.cn)

The partial melting associated with or induced by decompression during the exhumation of the UHP rocks is one of the most important physicochemical processes postdating the collision event in an orogen. The strongly deformed foliated granite (orthogneiss) and associated felsic or pegmatitic granite pods and veinlets are widespread in the UHP and HP units in Dabieshan massif, which can be interpreted as the result of decompositional partial melting of the UHP rocks in the mid-lower crust under amphibolite conditions. The granitic and felsic pods or veinlets are clearly intrusive, as they contain deformed enclaves of eclogite, retrograded eclogite and country rock gneiss, and the contact in some cases is cross-cutting. In some localities where larger UHP eclogite bodies occur, there is a gradual transition, from eclogite → amphibolized eclogite → eclogitic amphibolite → amphibolite (frequently with symplectites of plagioclase + amphibole) → (garnet bearing-) biotite hornblende plagioclase gneiss (so called UHP rocks) → (garnet bearing-) foliated granite. The REE distribution patterns of the UHP rocks suggest a common type of protolith. The foliated granite has the geochemical characteristics of A-type granite and formed in the post-COLG environment. The geochemical features and Pb-Sr-Nd isotope tracing indicate that its magma source is related to the UHP rocks.

Most of the partial melting phenomena are concentrated in the fractures within the eclogite, retrograded eclogite and their country rocks, which supports that the partial melting must be happened during the decompressive retrogression of the eclogite to amphibolite facies and the uplift of eclogite to lower-middle crustal level. The large-scale migmatites (metatexites) and the foliated granite (anatexite) of the UHP/HP terrane in the Dabie massif are important geologic records of partial melting and the transfer of the thermal state in the crust. It is also an important physicochemical process in decreasing the competence, enhancing the deformability of the rocks and stimulating the transformation from the compressional regime to the extensional regime.

The research was supported by the National Priority and Development Program of China (2006CB403502) and NSFC of China (No. 40372094).
Dissolution morphology as an indicator of respiration mechanism in *S. oneidensis*

M. ZHANG1; J. R. DALE2, T. J. DiCHRISTINA,2 AND A.G. STACK1

1School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta GA (mengnizhang@gatech.edu)
2School of Biology, Georgia Institute of Technology

The mechanisms and kinetics of dissimilatory iron respiration by bacteria are important to a variety of globally significant environmental processes. As a tool to examine iron respiration, the dissolution of iron (oxy)(hydr)oxide particulate coated glass slides under a variety of conditions was observed with atomic force microscopy (AFM). It was found that the dissolution morphology of the particulates in the presence of wild-type *S. oneidensis* MR-1 is heterogeneous (Figure 1), whereas an abiological chemical reductant, 9,10-anthrahydroquinone-2,6-disulfonate (AH2DS, oxidized form of AQDS), dissolves the coatings homogeneously. The behaviour of a gspD deletion mutant (deficient in solid-iron mineral respiration) respiring via an exogenous electron shuttle, AQDS, was also examined. The resulting dissolution morphology was homogeneous, similar to the abiotic experiments using AH2DS. These results suggest that the kinetics of respiration of wild-type *S. oneidensis* MR-1 may be in part controlled by transport, whereas, the action of chemical reductants are primarily limited by surface processes. It is likely that wild-type organisms respire on iron (oxy)(hydr)oxides using a different reduction pathway(s) or kinetic regime(s) from AH2DS and may explain the difficulty in comparing the kinetics of bacterial respiration to a chemical reductant.

Figure 1: Heterogeneous dissolution of iron oxyhydroxide particulates exposed to wild type *S. oneidensis* MR-1 for one day. Image size is 85 µm and Z-scale is 436.32 nm.

Zircon U-Pb age and Hf isotope evidence for growth and reworking of the Yangtze continental nucleus

S.-B. ZHANG AND Y.-F. ZHENG

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (sbzhang@mail.ustc.edu.cn)

To understand the connection between continental cratonization and global tectono-thermal event is essential for recognizing the formation and evolution of continental crust. For this purpose, a combined study of zircon U-Pb and Hf-O isotopes was conducted on migmatite, gneiss and metapelite from the Kongling complex (the only Archean microcontinent outcropped in South China) and the Liantuo sandstone in Yichang. The results show great significance for growth and reworking of Yangtze continental nucleus. A detrital zircon as old as 3.8 Ga was revealed by SHRIMP U-Pb dating for the Liantuo sandstone of middle Neoproterozoic age, implying the existence of crustal materials with this age in the Yangtze Block. Its Hf isotopes suggest growth of juvenile crust at 4.0 Ga. Zircon U-Pb ages for the migmatite and gneiss from the Kongling complex suggest two episodes of magmatism at 3.2-3.3 Ga and 2.9-3.0 Ga, probably marking formation of Yangtze continental nucleus at Mesoarchean. Their Hf isotopes suggest extraction of mafic protolith from the depleted mantle no later than 3.5 Ga ago.

U-Pb ages of 1.97±0.03 Ga were obtained with low Th/U ratios of 0.01 to 0.14 for metasediments and amphibolite from the Kongling complex, indicating that the ages are a record of Paleoproterozoic metamorphic event. εHf(t) values of about −6.5 and model Hf ages of about 3.0 Ga were acquired for zircons from the metapelites, suggesting an Archean source. Thus a response to the Paleoproterozoic global tectono-thermal event in South China is reworking of Archean continental nucleus. A survey of Paleoproterozoic ages throughout the Yangtze Block suggests that metamorphic event and subsequent magmatic activity occurred in the north, but only magmatic activity in the south. Both metamorphic and magmatic activities are associated with formation of a unified basement responsible for cratonization of the Yangtze Block. This provides a geodynamic connection between the formation of this craton and the global tectonomagmatism in the Paleoproterozoic, marking continental accretion by arc-continent collision orogeny during assembly of the supercontinent Columbia.

A number of Neoproterozoic U-Pb ages were also dated in detrital and metamorphic zircons, consistent with those widely occurring in the periphery of the Yangtze Block. This period of tectono-thermal events is associated with contemporaneous rift magmatism in response to the Rodinia breakup. It results in not only remelting of Archean and Paleoproterozoic arc-derived crust but also prompt reworking of Neoproterozoic juvenile crust. Therefore, the growth of continental crust in the Yangtze Block started since the early Archean, but a stable craton through reworking did not occur until the Paleoproterozoic.
Controlling mechanism of thermochemical sulfate reduction
S.C. ZHANG, Y.H. SHUAI AND G.Y. ZHU
Research Institute of Petroleum Exploration & Development,
Beijing, China (sczhang@petrochina.com.cn,
yhshuai@petrochina.com.cn)

Thermochemical sulfate reduction (TSR) is the reaction to form H₂S, which not only can critically affect the economic value of hydrocarbon gas, but is highly toxic and corrosive for production equipment. However, the exact nature and reaction mechanisms which influence the TSR are not known. In present study elemental sulfur and different sulfates are applied to investigate hydrocarbon reduction in different aqueous. Our result suggests that the nature of the aqueous is critical for TSR reactions and products. Aqueous with elemental sulfur can trigger the reaction quickly and complete the reaction within short time, but gas products dominated by H₂S and CO₂ with minor amount of hydrocarbon gas (<5%) clearly contradict those natural gases from most TSR areas. Acid salt aqueous phase formed by strong acid and weak base (Ca, Mg) seems facilitate TSR, and produces gases dominated by hydrocarbons with well situated amount of H₂S (0~25%). However, aqueous with alkali metal (Na, K) sulfate is hard to trigger TSR reaction because of the neutral pH of salt aqueous phase by strong acid and strong base. Therefore, slightly acidic medium with abundance SO₄²⁻ should be the prerequisite for initiating TSR at carbonate reservoirs. Therefore, the likelihood and intensity of TSR can be predicted on the base of concentrations of four type of anions (Cl⁻, SO₄²⁻, CO₃²⁻, HCO₃⁻) and two type of cations (alkali metal ions such as Na⁺, K⁺ and alkaline earth metal ions such Ca²⁺, Mg²⁺) in formation water. This result is compatible with our case study in the Sichuan Basin where the aqueous within TSR occurrence area contains high concentration of SO₄²⁻ ion and alkaline earth metal ions (Ca²⁺, Mg²⁺) with low concentration of CO₃²⁻ and HCO₃⁻ ions.

Mantle metasomatism in the peridotite xenolith from Panshishan,
Jiangsu Province, China
W.L.ZHANG, L.H.CHEN AND X.S.XU
State Key Laboratory of Mineral Deposits Research,
Department of Earth Sciences, Nanjing University,
Nanjing 210093, China (zhangwl@nju.edu.cn)

Panshishan alkaline basalt is located in the joint area of Jiangsu and Anhui Provinces. It is a Cenozoic volcanic cluster (N13) of Luhe-Yizheng in the SE seaboard of China. The alkaline basalt contains a lot of spinel lherzolite xenoliths. Detailed electron-microprobe study revealed that substantial mantle metasomatism taken place, and many metasomatic mineral phases related to mantel melt/fluid occur in the intergranular spaces of primary ones. Detailed observation revealed that the course-grained metasomatic Cr-diopsides develop between the primary olivine grains, and a primary Cr-spinel is found in it. A lot of fine-grained Cr-spinels develop in the Cr-diopside, which exsolved from the Cr-diopside. At the joint position of the Cr-spinel and Cr-diopside a kind of silicate glasses develops, rich in Si, Al and K and poor in Fe and Mg, which are believed to be derivatives of the metasomatic process of melt fluid. And between the Cr-diopside and the primary olivine a spong-rim develop, which consists of feldspar + silicate glasses (Fe-,Mg-rich, Si-,Al-,K-poor and volatile-rich) + olivine + apatite + Cr-spinel. It is suggested that the upper mantle rock could have been at least undergone two periods of mantle metasomatism in the area. First period of metasomatism formed the mineral assemble of feldspar + olivine + apatite + Cr-spinel + Cr-diopside, which could be related to a melt/liquid with higher viscosity; And the second period of metasomatism formed the silicate glasses rich in Fe and Mg and depleted in Si and Al, which might indicate a melt/liquid with lower viscosity. The Metasomatic phenomeon can account well for that the mantle source of the alkaline basalt had been undergone enrichment process during Neocene.

Lithogenic inputs over the Kerguelen Plateau (Southern Ocean) traced by the dissolved REE concentrations and Nd isotopic composition

Y. ZHANG, F. LACAN AND C. JEANDEL
LEGOS (CNES/CNRS/UPS/IRD), OMP, 14 Ave E. Belin, 31400, Toulouse. (Yan.zhang@legos.cnes.fr; Francois.Lacan@legos.obs-mip.fr; Catherine.Jeandel@legos.obs-mip.fr)

The Southern Ocean is regarded as a key region in understanding the role of biogeochemical cycling on the variation of global climate (Marinov et al. 2006). Although this Ocean is characterized by HNLC conditions, areas of high biomass do occur including the Kerguelen plateau. These bloom occurrences are attributed to natural fertilization due to iron inputs from the Kerguelen archipelago and plateau (Blain, Treguer et al. 2001). The major goal of the KEOPS project was to study the result of this natural iron fertilization, and in particular to identify its sources.

REE are an extremely coherent group in terms of chemical behavior (Elderfield and Greaves 1982). Seawater Nd isotopic composition is a tracer of water mass pathways and of their interactions with continental material. Although the oceanic cycles and sinks of dissolved Fe and REE are different, the dissolution of lithogenic material constitutes the main source for both dissolved Fe and REE in the ocean. Therefore, we propose to use REE concentrations and Nd isotopic compositions in the Kerguelen Plateau waters to 1) trace the origin of the observed iron enrichment and 2) quantify the fluxes of the lithogenic inputs.

We will present dissolved seawater REE concentrations and Nd isotopic compositions from 9 stations upstream from and above the Kerguelen plateau. The REE patterns display positive Eu anomalies in the water masses above the plateau, which are similar to those of the Kerguelen basalts, suggesting that the high dissolved REE contents observed in the waters above the plateau result from the dissolution of lithogenic material, such as from Kerguelen or Heard Islands. Lithogenic fluxes were estimated larger than 110 ± 21 ton Nd y⁻¹ and 37000 ton Fe y⁻¹, for dissolved Nd and Fe, respectively. The under processing Nd isotopic composition analyses will allow a better understanding of the dissolved/particulate exchange occurs at Kerguelen Plateau/water masses boundaries and also allow to quantify this exchange.

Spherical diffusion couple, closure of core composition, and geospeedometry

YOUXUE ZHANG¹,²
¹Department of Geological Sciences, The University of Michigan, Ann Arbor, MI 48109-1005, USA
²Key Laboratory of Orogenic Belts and Crustal Evolution, MOE, School of Earth and Space Sciences, Peking University, Beijing 100871, CHINA

In dealing with diffusion in minerals, a spherical diffusion couple is often encountered. Examples include diffusion between the core and mantle (or two concentric layers) of garnet, or spinel, or zircon. This problem does not seem to have been solved analytically before. I present an analytical solution for a spherical diffusion couple. The concentration evolution is shown in Figure 1 and differs from the one-dimensional diffusion couple in a couple of ways. One is that the mid-concentration position (or interface) moves to the shell with smaller radius as a function of time. Nonetheless, a spherical diffusion couple may be fit well by an error function: diffusivity obtained from such a fit is only slightly different from the actual diffusivity, but the interface position is noticeably away from the original interface. Therefore, the original boundary between two layers is not at the position of mid-concentration. The solution is applied to derive the closure conditions for the center of the core, which is compared with the numerical solution for the specific case of oxygen diffusion in zircon (Watson and Cherniak, 1997). Furthermore, given a measured concentration profile, if it can be shown that it is due to diffusion (not growth), the mean diffusion distance may be obtained, from which the cooling rate may be inferred.
Preliminary studies on Sr/Ca and Mg/Ca ratios in aragonitic marine bivalve shells by ICP-OES, ICP-MS and LA-ICP-MS

ZENGJIE ZHANG1,2, BERND R. SCHÖNE1, YANN LAHAYE2 and DIETER GARBE-SCHÖNBERG3

1Department of Applied and Analytical Paleontology, Institute of Geosciences, University of Mainz, Becherweg 21, 55128 Mainz, Germany (zzhang@uni-mainz.de)
2Department of Geosciences, University of Frankfurt, Altenhöferallee 1, 60438, Frankfurt am Main Germany
3Department of Geology, University of Kiel, 24098 Kiel, Germany

The trace element composition of marine biogenic carbonates is gaining increased attention as a proxy for past climates and environments. We have employed ICP-OES, ICP-MS, and LA-ICP-MS to determine the trace element ratios of the shells of Arctica islandica. We evaluated the applicability of these three instruments and explored the characteristics of Mg:Ca and Sr:Ca ratios.

The sample material was life-collected from different localities around Iceland. Each shell was sampled in youth, mature and gerontic life stages (umbo, middle part, tip). The results are as follows: 1) Sr:Ca ratios: ICP-OES data are similar to the ICP-MS results; LA-ICP-MS data for middle portions are same as ICP-OES values; 2) Mg:Ca ratios: LA-ICP-MS results of umbonal and middle shell portions are lower than corresponding ICP-OES results, but the data from tip parts are slightly higher; And ICP-OES results are higher than corresponding the ICP-MS results, this findings coincides with previous findings by Andreasen et al (2006);

For a better interpretation of the results, we used EMPA to analyze the spatial distribution of Sr and Mg in cross-sections of the specimens. According to these element distribution maps, Mg is less homogeneously than Sr. In many portions of the annual increment, the Mg concentration is very low and Sr high. These data suggest that Mg and Sr ions behave totally different in aragonitic shells than in calcitic skeletons. The Mg content may be related to the organic matrix, while Sr may be more related to the carbonate matrix. This may be the reason for the difference in the three analyses.

He and Ar isotopic composition of pyrite and its significance in XZ uranium ore-field, South China

ZHANSHI ZHANG1,2, SHUAI LIU1 and RENMIN HUA2,

1. Key Laboratory of Nuclear Resources and Environment (East China Institute of Technology), Ministry of Education, Nanchang, 330013, China; (zhzszhang@ecit.edu.cn)
2State Key Laboratory for Mineral Deposit Research, Nanjing University Nanjing 210093, China

XZ uranium ore-field was one of the most important granite-type uranium deposits in China. Many arguments such as mefeworic, magma ann mantle derived fluid on the original of the ore-forming fluid. Isotopic composition of He and Ar in pyrite, one of the most important paragenetic minerals with pitchblende in XZ uranium ore-field been applied to reveal the origin of the ore-forming fluid in this paper. Pyrite paragenetic with pitchblende was sampled from the mine galley. He and Ar isotope was analyzed by the MI-1201G inert gases mass spectrometer. Calculated results shown in table 1 and the results discussed below:

Table 1. He and Ar isotope composition of Pyrite

NB: Ra=1.39×10⁻⁶; radiogenic origin ⁴He* correct formula

³He/⁴He value varied in 0.79–0.06Ra, higher than 0.01–0.05Ra, the crust ³He/⁴He value, but lower than 6–7Ra, the continental mantle ³He/⁴He value. All samples distributed between the crust original and the mantle original in ³He/⁴He diagram, which suggests that it had the crust and mantled mixed original of the ore-forming fluid. ⁴⁰Ar/³⁶Ar value varied between 282–319, all samples distributed between the crust original and the mantle original range in Re/Ra vs.⁴⁰Ar⁴He diagram, which also suggest the characteristic of mixed Ar original. The isotopic composition of He and Ar in pyrite might suggest that ore-forming fluid of XZ uranium ore-field might be the mixed product of crust and mantle fluid.

Geochemical constraints on the petrogenesis of Devonian arc picrites and associated lavas from the North Junggar terrane, NW China

ZHAO-CHONG ZHANG, JING-HONG CAI, LI ZHAO
State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (zczhang@cugb.edu.cn)

The Junggar terrane in Xinjiang Province, sits adjacent to the Siberian and Kazakhstan plates. Recently, we recognized a near 100-m-thick picritic lava flow in a Devonian arc in Jungguar terrain. The picritic lavas, which occur in the lower part of the Middle Devonian strata, are overlain by basalts and andesites. The picrites are highly porphyritic. Olivine, clinopyroxene and rare chrome spinel with Cr# (Cr/Cr+Al) values (0.63–0.86) are phenocrysts, embedded in a matrix of groundmass plagioclase, clinopyroxene, and Ti-magnetite. Glass does not appear to be preserved, but minor metal sulfides are present. All lavas are characterized by negative Nb, Ta and Ti anomalies with similar abundances of HFSE with MORB, exhibiting typical for island arc volcanic rocks. The Zr/Nb ratios (23–66) of the picrites and basalts resemble the MORBs (10–66), suggesting the MORB-like sources. However, the Ti/V (23–35) and Zr/Sm (18–23) ratios of basalts are higher than those of picrites (14–17 and 14–15 respectively), and the basalts display flat-type REE-chondrite patterns whereas the picrites are characterized by lower total REE concentrations and slight enrichment of light REE. In contrast, the andesites have much higher total REE abundances and LREE/HREE. All suggest that they are not cogenetic related. However, they have similar ($^{87}$Sr/$^{86}$Sr)t (0.70328–0.70433) and εNd(t) values (6.4–7.3), overlapping with modern island arc field. Consequently, primary magmas were most likely generated in N-MORB-type mantle, which was modified by the addition of a fluid component derived from subducted basaltic crust. However, the basalts were generated by partial melting of amphibole-bearing spinel peridotite, and the picrites resulted from low degrees of partial melting of garnet peridotite with residual garnet, and the andesites may have been generated by partial melting of eclogites.

Continental paleotemperature reconstructions: Distribution of GDGTs in a variety of lakes

ZHAOHUI ZHANG, RAYMOND S. BRADLEY AND STEVEN T. PETSCHE
Department of Geosciences, University of Massachusetts, 611 North Pleasant Street, Amherst, MA 01003, USA.
(zhaohui@geo.umass.edu; rbradley@geo.umass.edu; spetsch@geo.umass.edu)

In spite of the rising tide of using the TEX86 index in the reconstruction of marine sea surface temperature, applications to lake environments are still limited, with only a few large lakes surveyed. Calibrations of modern environmental conditions with surface sediment Tex86 temperatures in smaller lakes are lacking or not apparent in many settings. We have collected surface sediments from a variety of lakes extending from the Arctic, to southern Patagonia and northern Chile. These include Norwegian cirque lakes, a maar lake in Patagonia, Argentina, a meteorite impact crater lake in Siberia, and a glaciated valley lake in England. In each case, we collected a suite of measurements of the physical parameters of the lake, such as temperature, salinity, pH, etc, in order to determine how the modern distribution of GDGTs correspond to the current environmental conditions across a large range of limnologic conditions. Preliminary results indicate the temperatures calculated from the TEX86 index are consistent with the measured annually averaged surface water temperature, although complications related to soil-derived sources are apparent in some cases. A complete set of data and selected downcore reconstructions of late Holocene conditions will be reported at the conference.
Molecular level simulations of the H$_2$O, CO$_2$ and CO$_2$-H$_2$O systems up to high temperatures and pressures

ZHIGANG ZHANG AND ZHENHAO DUAN
State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China

H$_2$O, CO$_2$ and CO$_2$–H$_2$O are the most frequently encountered fluid systems in and around the Earth, widely existent in various geospheres, as revealed from direct measurements or from the study of fluid inclusions in various rocks and ore deposits. In this study, we have carried out a series of molecular dynamics and Monte Carlo simulations to predict the properties of these systems up to high temperatures and pressures, which are difficult or even impossible to attain with experimental measurements.

For pure water, we selected a potential model (SPCE) established at normal temperature and pressure and found remarkable reproducibility of molecular dynamics simulations over wide temperature and pressure ranges. Compared with the most recent published high-pressure experimental data up to 5.0 GPa, the simulation results show very good agreement with errors less than 1.0% and reveal a trend to be more accurate as the increase of pressures.

For carbon dioxide, we have proposed an optimized potential model utilizing the established techniques of molecular dynamics and histogram reweighting grand canonical Monte Carlo simulations. This model is demonstrated to show excellent predictability for thermodynamic, transport, and liquid structural properties in a wide temperature-pressure range with remarkable accuracies.

Thereafter, through comprehensive isothermal-isobaric molecular dynamics simulations, the pressure-volume-temperature-component (PVTx) data of CO$_2$–H$_2$O have been extended beyond experimental range (below 1673.15 K, 1.94 GPa) to about 2573.15 K and 10 GPa.

Finally, an equation of state (EOS) was laboriously developed for the H$_2$O, CO$_2$ and CO$_2$–H$_2$O systems. This EOS reproduces all the experimental and simulated data covering a wide temperature and pressure range from 673.15 to 2573.15 K and from 0 to 10.0 GPa within experimental or simulation uncertainty.

Diagenetic environment of Qingbulake basic complex, Xinjiang, NW China

ZUOHENG ZHANG 1, JINGWEN MAO2, ZHILIANG WANG3, AND YANBIN WANG 4

1State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China; Institute of Mineral Resources, CAGS, Beijing, 100037, China (zuoheng@hotmail.com)
2Institute of Mineral Resources, CAGS, Beijing, 100037, China (jingwenmao@263.net)
3Institute of Mineral Resources, CAGS, Beijing, 100037, China (zlw0813@163.com)
4Institute of Geology, CAGS, Beijing, 100037, China (wang_yanbin@hotmail.com)

The Qingbulake basic complex is located 120km southeast to the Tekesi County, Xinjiang, NW China. As the Sm-Nd age is similar to the Karatunk complex in the south margin of Altay orogenic belt and Huangshandong complex in eastern Tianshan, these intrusions were considered to be formed in the similar post-collisional environment.

In this study, the high precise SHRIMP zircon U-Pb age of 434±6.2 Ma for diorite from the complex reveal that the major mafic magmatic events took place in the early to middle Silurian. According to recent research on the regional tectonic evolution (e.g., Li et al., 2006, Gao et al., 2006), at least in early Silurian, the southern Tianshan oceanic crust began the subduction to central Tianshan plate and ended in early Carboniferous. Geochemical studies of the Qingbulake basic complex show that it is characterized by low content of Ti, depletion of Nb and Ta and enrichment of large lithosphile elements and slight enrichment of LREE. The magma also displays some features of inland arc magma (Zhang et al., 2006).

So the Qingbulake mafic complex may be closely related to the subduction of southern Tianshan ocean crust to Yili-Central Tianshan plate.

The Trans-North China Orogen –
A long-lived arc:
Evidence from SHRIMP U-Pb zircon ages of granitoid gneisses in the
Lüliang Complex

GUOCHUN ZHAO¹, SANZHONG LI² AND XUPING LI³,
¹Department of Earth Sciences, The University of Hong Kong; (gzhao@hkucc.hku.hk)
²College of Earth Sciences, Ocean University of China; (sanzhong@ouc.edu.cn)
³Shandong University of Science & Technology; (lxuping@sdust.edu.cn)

The Lüliang Complex is situated in the central segment of the Trans-North China Orogen (TNCO), a continent-continent collisional belt along which the discrete Eastern and Western Blocks amalgamated to form the basement of the North China Craton [1-5]. The complex consists of supracrustal and granitoid gneisses, of which the latter can be subdivided into the Yunzhongshan TTG gneisses, Guojiazhuang granitic gneisses and Chjianlan-Guanlishan granitoid gneisses. These granitoid gneisses are mostly calc-alkaline and considered to have formed in a magmatic arc environment. SHRIMP U–Pb analyses reveal that the Yunzhongshan TTG gneisses were emplaced at ~2499 ± 9 Ma, representing the earliest arc-related magmatic event in the Lüliang Complex. This was followed by the intrusion of the Guojiazhuang granitic gneisses at 2375 ± 10 Ma. The most widespread arc-related magmatic event in the region was the emplacement of the Chjianlan-Guanlishan granitoid gneisses at 2199-2173 Ma, respectively. Metamorphic zircon overgrowth rims from a tonalitic gneiss yielded a weighted mean 207Pb/206Pb age of 1872 ± 7 Ma, consistent with the metamorphic age range of 1880-1820 Ma defined by metamorphic zircons from various high-grade rocks in the TNCO. Thus, the evolution of the Lüliang Complex involved emplacement of the Yunzhongshan TTG suite at ~2499 Ma, the Guojiazhuang granites at ~2375 Ma and the Chjianlan-Guanlishan granitoid gneisses at 2199-2173 Ma, with the final collision between the Eastern and Western Blocks in this area occurring at 1872 ± 7 Ma, the whole series of magmatic events lasting nearly 650 Ma. This suggests that the Trans-North China Orogen represents a long-lived magmatic arc. This study was financially supported by the Hong Kong CERG grants (7055/05P, 7058/04P, and 7063/06P) and a Chinese NSFC Grant (40429001).

Crustal architecture of the Dabie orogen: Constraints from U-Pb age,
Hf and O isotopes in zircon from UHP granitic gneiss

Z.-F. ZHAO AND Y.-F. ZHENG

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (zfzhao@ustc.edu.cn)

Zircon U-Pb dating, Hf and O isotope analyses were carried out for granitic gneiss from North Dabie, the largest lithotectonic unit of ultrahigh-pressure (UHP) metamorphic rocks in the Dabie orogen, east-central China. The results are used to provide not only insight into its protolith origin and metamorphic history with respect to continental subduction, but also constraints on crustal architecture prior to and after collision. Zircon U-Pb dating gives consistent ages of 751 ± 7 Ma for protolith crystallization, and two group ages of 213 ± 4 to 245 ± 17 Ma and 126 ± 4 to 131 ± 36 Ma for metamorphism. Most of zircon Hf isotope analyses show negative εHf(0) values of –5.1 to –2.9 with crust Hf model ages of 1.84 to 1.99 Ga, suggesting that their protolith was originally derived from reworking of Paleo-proterozoic crust. The remaining analyses from one sample exhibit strongly positive εHf(0) values of 10.6 ± 0.8; some of them have the highest values of 12.4 to 14.5, corresponding to the youngest Hf model ages of 743 to 827 Ma relative to the depleted mantle. Thus, gneiss protolith was derived from reworking of the Paleoproterozoic crust due to rift magmatism in response to the Rodinia breakup at about 750 Ma. This differs from bimodal protolith of the classic Central Dabie UHP metamorphic zone, which has zircon Hf isotope features indicating prompt reworking of Neo-proterozoic juvenile crust. Oxygen isotope analysis yields zircon δ18O values of ~3.26 to 2.79‰, which are considerably lower than those of the normal mantle. This suggests differential involvement of meteoric water in protolith magma by remelting of hydrothermally altered low δ18O rocks. It appears that North Dabie shares the same ages of Neoproterozoic low δ18O protolith and Triassic UHP metamorphism with Central Dabie, but it was significantly reworked at Early Cretaceous. The Rodinia breakup at about 750 Ma would lead to not only growth of juvenile crust in an active rift zone for bimodal protolith of Central Dabie, but also reworking of Paleoproterozoic crust in an arc-continent collision zone for the North Dabie protolith. The difference in the occurrence of Cretaceous ages between North Dabie and Central Dabie suggests that the two UHP metamorphic units were not located on the same level during the Cretaceous magma emplacement, but a lower level for North Dabie. This also provides a constraint on the source depth of Cretaceous granitoids, which was probably deeper than the North Dabie gneiss.
Artificial radionuclides recorded in lacustrine sediments in Bosten and Qinghai Lakes, NW China

J. ZHENG, F. C. WU, M. YAMADA, H. Q. LIAO, AND G. J. WAN

1Nakaminato Lab for Marine Radioecology, National Institute of Radiological Sciences, Japan (jzheng@nirs.go.jp)
2State Key Lab of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, China (wufengchang@vip.skleg.cn)

Establishing accurate historical records of the distribution, inventory and source of artificial radionuclides in the environment is important for environmental monitoring and radiological health protection due to their high toxicity, and useful for identification and risk assessment of possible future environmental inputs of radionuclides from nuclear weapons testing and from accidental release from the nuclear fuel reprocessing plants. Historically, variation of studies, such as the reconstruction of pollution history of accurate dating of lake sediments, is important for many characteristic for various Pu sources. On the other hand, a useful tool for next researchers to study the history of anthropogenic pollutants in the environment.

We applied a sector-field ICP-MS to study the recent sedimentation in ca. 10 lakes in China via measurements of both Pu and U isotopes, besides the conventional radiometric determination of 239Pu. In this work, we report the results of Lake Bosten and Qinghai in the Northwestern China. The Pu activity profile obtained with SF-ICP-MS was in agreement with a γ spectrometric 137Cs profile, indicating that the 137Cs and Pu activities convey essentially the same information about sedimentation processes in the investigated lakes. Based on the isotopic compositions of Pu and U isotopes, the sources of artificial radionuclides and the potential application of Pu isotopes for sediment dating will be discussed.

The Re-Os systematics of the Bixiling eclogites, Dabieshan, central China

L. ZHENG, L. REISBERG, AND X.C. ZHI

1CAS Key Lab of Mantle-Crust and Environment & School of Earth and Space Sci., USTC, Hefei, 230026, China; (zhengh3@mail.ustc.edu.cn; xezhi@ustc.edu.cn)
2CRPG-CNRS UPR 2300, Vandoeuvre-les-Nancy, France; (reisberg@crpg.cnrs-nancy.fr)

The Bixiling ultrahigh pressure (UHP) mafic massif, located in the North Dabie high-T/UHP granulite-facies zone, Dabieshan, central China, is one of the largest and most extensively studied outcrops of eclogite-facies rocks in the world [1]. This massif is involved in Triassic subduction and subsequent exhumation of the Yangtze craton beneath the North China craton, as is well recorded by garnet-omphacite Sm-Nd isochrones [2]. However, the ages of possible older metamorphic events and of protolith formation are still debated, which adds uncertainty to the geodynamic models of the Dabie-Sulu orogenic belt.

Here we present preliminary Re-Os results of 15 eclogites and 2 granite gneisses collected near the eastern edge of the Bixiling massif (N:30º43', E:116º17'). Os and Re were extracted using Carius tube digestion + bromine extraction + micro-distillation/anion exchange techniques and analyzed by NTIMS (Os) or by ICPMS (Re). Non-radiogenic Os concentrations are extremely low (<1 pg/g) in all eclogites except DB42 (386 pg/g). This is consistent with the formation of the massif by fractional crystallization of a roughly cogenetic magma in a crustal intrusion. DB42 is thought to represent a basal norite cumulate, which stripped Os from the overlying magma as it formed. Re concentrations vary from 51 pg/g to 2835 pg/g. With the exception of a ratio of 0.1565 for DB42, 187Os/188Os ratios vary from 8 to 390. These high ratios are mainly due to the very low non-radiogenic Os concentrations. Except for one sample (BXL-3, with 2835 pg/g Re), all Re-Os data yield unreasonably old TMA ages, implying significant Re loss, most likely during subduction-exhumation.

If a 750 Ma protolith age is assumed, 20%-60% Re loss is calculated, which is similar to that inferred for subduction of oceanic crust [3,4]. On the other hand, Sm-Nd results from garnets suggest that the Bixiling protolith formed less than 300 Ma before subduction [2]. Our Re-Os results are consistent with only the oldest limit of this estimate; younger ages would require a protolith with an unreasonably high Re concentration. Analysis of mineral separates prepared from BXL-3 indicates that garnet and omphacite host only a small fraction of the total Re in this sample. An additional phase (sulfide?) is required to explain the missing Re.
Relationship between Hg and sulfur in coal from Huaibei coalfield, China

LIUGEN ZHENG, GUIJIAN LIU, AND CUICUI QI
CAS Key Laboratory of Crust-Mantle Materials and Environment, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

Many authors have reported that Hg in coal can exist in solid solution within pyrite. Correlations between sulfur and Hg are often attributed to this mode of occurrence and are most common in coals that are extremely enriched in Hg.

The result of this study shows that coal samples from the Huaibei coalfield have relatively low sulfur values (average 0.59%). The correlation coefficient between ash and sulfur is -0.08, indicating that sulfur in the Huaibei coals has an intermediate (organic and inorganic) affinity. In a study of 29 coal samples from the Huaibei coalfield, We observed that organic sulfur is the dominant sulfur form when the total sulfur is near 0.5%. Some literatures report that organic sulfur compounds can capture Hg and result in the enrichment of Hg in coals.

The conclusion shows the relationship between Hg and sulfur in all 29 coal samples that we examined; note that the correlation coefficient is only 0.17 (n=29). Interestingly, and it shows a significant positive correlation between Hg and sulfur (n=21, R=0.64, p<0.05) is obtained by excluding the eight samples from the No. 5 and 7 coal seams, which were influenced by a magmatic intrusion. This suggests that the magmatic intrusion not only increased the concentration of Hg in seams 5 and 7, but also changed the mode of Hg occurrence in these seams. The significant, positive correlation between Hg and sulfur in coals from the No. 3, 4, and 10 seams suggests that Hg in these coal seams is bound to both organic sulfur moieties and within sulfide minerals.

Rb-Sr isochron age of gold-rich quartz veins in the Lingqueshan gold deposit, Shandong Province in China

PEI-XI ZHENG¹, YAN ZHOU², TIE-FU WANG² AND YANJIE ZHANG²
¹College of Earth Sciences, Jilin University, Changchun, China 130026
²Center of Analysis and Testing, Jilin University, Changchun, China 130026

Mineralogenetic matter, mineralogenetic liquid, and mineralogenetic age are three core problems in mineral deposit Research. Among them mineralogenetic age is a important aspect in mineral deposit research. To ascertain the mineralogenetic age of a mineral deposit has significance in ascertain the relation between the mineralogenetic function, regional tectonics function, metamorphic function and magma function, and has significance in research of mineralogenetic matter, mineralogenetic liquid, and mineralogenetic cause of formation. Now direct determination to the mineralogenetic age method mainly are K-Ar method, Ar-Ar method, fluid inclusion Rb-Sr isochrone method, Sm-Nd method, Pb-Pb method, and so on. Since in 80th in 20 century the method of fluid inclusion Rb-Sr isochrone was used in mineralogenetic age research, many domestic and overseas scholars did attempts in this aspect, and some scholar put forward some oppugn with the lack and dependability of this method. The paper has determined the Rb-Sr isochron age of Gold-rich quartz veins in the Lingqueshan gold deposit, and discusse the mineralogenetic age.

The Zhao-Ping fracture zone is the master gold metallogenic zone in China, but the study on the gold deposit lays in the hanging wall of the Zhao-Ping fracture zone is very rudimental. The Lingqueshan gold deposite lays in the hanging wall. In order to know the timing of the gold deposition, so the Rb-Sr isochron dating methods have been adopted to date deposite, the result indicates that the age of the Lingqueshan gold deposite is 118±9.4Ma. It is consistency with the age of Jiaodong gold deposits concentration zone (120±10Ma). That is to say, the large-scale metallogeny of the Zhao-Ping fault zone hanging wall took place in early cretaceous occurred in north western Jiaodong Peninsula.
Zircon U-Pb age, Hf and O isotope insight into origin of Neoproterozoic granitoids in South China

Y.-F. Zheng, S.-B. Zhang and R.-X. Wu

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (yfzheng@ustc.edu.cn)

The genetic links between rift magmatism, crustal growth and reworking, and granitoid petrogenesis are an important issue with respect to supercontinent breakup. A combined study of U-Pb age, Hf and O isotopes in zircons from Neoproterozoic granitoids in South China, including the Jiangnan orogen between the Yangtze and Cathaysia Cratons, the Kangdian rift along the western margin of the Yangtze Craton, and the Dabie-Sulu orogen along the northern margin of the Yangtze Craton. Two generations of magma crystallization are discerned for the granitoids, with double-bimodal features in their zircon Hf and O isotope compositions. Despite consistently high δ18O values of 8.1 to 10.4% for zircons, ~825 Ma S-type granitoids in the Jiangnan orogen show not only positive εHf(t) values of 3.4 to 5.4 with young Hf model ages of 1.17 to 1.25 Ga, but also negative εHf(t) values of ~3.4 to ~1.6 with old model Hf ages of 1.81 to 1.92 Ga. In contrast, 760~750 Ma bimodal I-type intrusives in the Kangdian rift are characterized by positive εHf(t) values of 3.5 to 9.9 with young model Hf ages of 0.94 to 1.18 Ga, and by both low and high δ18O values of 4.2 to 6.2‰ relative to 5.3±0.3‰ for normal mantle zircons. Bimodal protoliths of 780~750 Ma ages for metagneous rocks in the Dabie-Sulu orogen have consistently low δ18O values of ~4.3 to 4.4‰ for igneous zircons, but their Hf isotopes are subdivided into two groups: one has positive εHf(t) values of 5.9 to 12.9 and young Hf model ages of 0.82 to 1.24 Ga, and the other has neutral εHf(t) values of ~2.7 to 2.3 and old Hf model ages of 1.68 to 1.92 Ga.

The zircon Hf-O isotope systematics provides a link of granitoid petrogenesis to orogenic collapse, rift magmatism, water-rock interaction, and the Rodinia collision. Growth and reworking of juvenile and ancient crusts are dated by means of zircon εHf(t) values and model Hf ages in combination with U-Pb ages. While a change in magma source from arc-derived crust to asthenospheric mantle keeps pace with the tectonic advance from supercontinental rifting to breakup, reworking of pre-existing arc-continent collision orogen in either successful or failed rifts plays a basic role on their composition. As a result, the granitoids have principally inherited their source features in element and isotope geochemistry, with additional changes due to partial melting, fractional crystallization or crustal contamination. A plate-rift model is thus proposed to resolve paradoxical interpretations concerning trace element and isotope patterns of both arc-like and rift-like sources in given suites. It also provides a resolution to the controversy between arc-derived and plume-related magmatism for the Neoproterozoic igneous rocks in South China.

Re-Os systematics of lithospheric peridotites from Nushan, east China: Implications for multiple modifications of SCLM

Xia-Chen Zhi, Laurie Reisberg and Xi-Sheng Xu

1CAS Key Laboratory of Crust-Mantle Materials and Environment, School of Earth & Space Sciences, USTC, Hefei 230026, China (xchzhi@ustc.edu.cn)
2CRPG/CNRS, BP20, 54501 Vandoeuvre-les-Nancy Cedex, France, (reisberg@crpg.cnrs-nancy.fr)
3Department of Earth Science, Nanjing University, Nanjing 210093, China, (xsxu@nju.edu.cn)

The Nushan Quaternary volcanic cone in northeast Anhui province, carries abundant mantle xenoliths which including spinel and garnet phase peridotites with or without volatile-bearing minerals such as amphibole, phlogopite and apatite. 12 representative xenoliths were selected for determination of Re and Os concentrations and Os isotope compositions.

Os and Re abundances range from 0.876 to 2.417 ppb and from 0.019 to 0.306 ppb respectively, while 187Os/188Os and 187Re/188Os ratios vary from 0.1149 to 0.3130 and from 0.037 to 0.805 respectively in this sample set. 4 of 12 samples have Os concentrations of <1.0ppb. Such low Os concentrations have usually been attributed to S-undersaturated melt percolation that remove Os-bearing sulfides. 2 of 3 fertile garnet lherzolites have high equilibration temperatures (~1100°C) and the highest 187Os/188Os ratios, similar to the present value of PUM (~0.1296). All spinel lherzolites from fertile to refractory in major chemical compositions, with or without amphibole and/or phlogopite have unradiogenic 187Os/188Os ratios. 6 of 12 samples have 187Re/188Os ratios higher than the PUM ratio of 0.435 that indicating recent Re addition. Nushan mantle xenoliths define a well-correlated linear trend between 187Os/188Os and both Al2O3 and Yb, through the PUM composition and give the model age of primitive melt extraction event (~2.0 Ga).

Previous data indicate that 143Nd/144Nd and 87Sr/86Sr isotope ratios of clinopyroxenes separated from the sample set fall on the mantle array in the depleted quadrant. It is interesting that 187Os/188Os and 143Nd/144Nd ratios have a linear positive correlation for the sample set. The sample with the most depleted 187Os/188Os ratio has the richest 143Nd/144Nd ratio and 2 garnet lherzolites with the highest 187Os/188Os ratio have rather depleted 143Nd/144Nd ratios. The decoupling of Os and Nd isotope compositions of the Nushan mantle xenoliths indicate that SCLM experienced complex multiple modification via modal and/or cryptical mantle metasomatism after primitive melt extraction.

Fluid phase separation from residual intercumulus aluminosilicate liquid of the Merensky Reef

L.M. ZHITOVA¹, I.A. ZHUKOVA¹, A.S. BORISENKO¹ AND A.A. BOROVIKOV²

¹Institute of Geology and Mineralogy, Novosibirsk State University, Novosibirsk, Russia (zhitova@uiggm.nsc.ru, zhukova@uiggm.nsc.ru, borisenko@uiggm.nsc.ru)
²Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (borovik@uiggm.nsc.ru)

Fluid inclusions in both symplectitic and miarolitic quartz of the Merensky Reef of the Bushveld Complex (South Africa) have been studied using cryometry, microthermometry, Raman-spectroscopy, LA ICP-MS, scanning electronic microscopy, gas-chromatography and isotopic methods. This allowed us to obtain principally new information about an order of fluid phase separation from the Merensky Reef crystallizing intercumulus liquid.

We attempted to document at least three generations of fluid separated from boiling residual aluminosilicate intercumulus liquid in the following sequence.

The earliest fluid phase composed of homogenous high dense gas mixture (from CH₄-98.48 and N₂-1.52 to CH₄-73.21, CO₂-24.42 and N₂-2.37 mol.%) was identified in primary gas and co-existing anomalous (combined) fluid inclusions from miarolitic quartz.

The next generation was hetero phase fluid, composed of brines or water-salt solution, containing a free low dense gas phase (CO₂>N₂). This fluid was observed in primary multiphase and coexisting gas-rich inclusions from interior zones of miarolitic quartz.

The latest generation was also heterophase fluid (low salinity water-salt solution and free low dense gas phase) that was found in primary water-salt and syngenetic CH₄-rich gas inclusions from peripheral zones of miarolitic quartz crystals.

The results give us a possibility to suggest that magmatogene fluids that successively separated from aluminosilicate liquid changed from homogenous high dense gas phase to immiscible heterophase oxidized mixture during the crystallization evolution of the Merensky Reef.

Different forms of sulphur in the Lower Cambrian Ni-Mo mineralized black shale in Zunyi, Guizhou Province, southwest China

J. ZHOU, K. HU, S.M. SONG, J. CAO, J. CHEN AND B. HE
Department of Earth Sciences, Nanjing University, Nanjing, 210093, China (kaihu@nju.edu.cn)

A great and famous Ni-Mo polymetallic deposits are developed in the Lower Cambrian Niutitang Formation in South China. As these mineral deposits are all sulfide, we measured different forms of sulfur in the outcrop Zhuliushui section, Zunyi (SW China) and have a preliminary analyses on their distribution.

Analytical results indicate that along the section, in wallrocks around deposits, the sulfur-content is less than 1%; whereas at the deposit seam (ca. 20-cm-thick) the content exceeds 1%, even high up to 23.807%. This implies that the formation of mineral deposits is closely related to sulfur. In order to know what roles do different kinds of sulfur play, three forms of sulfur including sulphate, pyrite sulfur and organic sulfur were further investigated. It is showed that the content of sulphate is mostly lower than 1.0%, while the other two forms ranging from 0.0441-6.233 (pyrite sulfur) and 0.0192-16.822 (organic sulfur), respectively. This likely implies that the sulfur in the mineralization comes relatively low from sulphate and great from pyrite. Futhermore, under microscopic observation, most of the pyrites occur in the formation of crystal granule, which may be ascribed to slow and successive sedimentation during the early diagenesis.

Otherwise, there is not a good relation between the organic and pyrite sulfurs, as the variation of the former was greater than the latter. Thus, it is suggested that the organic sulfur was also not the key factor in the process of pyrite’s formation. In a word, based on the above analyses, we tentatively suggested that both hydrothermal fluid and sulfur produced by biodegradation were responsible for the mineralization here.

Lastly and interestingly, besides the high sulfur content in the presently known Ni-Mo mineralized deposits, we also found another sulfur-peak in the upper 10-cm-thick seam, which located about 5 m on the above. Whether this is an indicative of another mineral deposit needs a more comprehensive investigation in the future.

Climatic and environmental glaciochemical records from a climatic interaction region, East Antarctica over the past 780 years (1215-1996 AD)

L.Y. ZHOU1,2, YSH. LI2 AND J.H. COLE-DAI3

1The Key Laboratory of Coast & Island Development of Ministry of Education, School of Geographic and Oceanographic Sciences, Nanjing University, Nanjing, 210093, China (liayzhou@nju.edu.cn)
2Polar Research Institute of China, Shanghai, 200129
3Department of Chemistry and biochemistry, South Dakota State University, Brookings, SD, 57007, USA

An 82.5-meter ice core was retrieved from marginal area of Dome A, East Antarctica by Chinese Antarctic Scientific Research Expedition in 1998/1999. Previous research shows that the area belongs to a continental-oceanic climatic interaction region.

Based on the ion chromatography analysis, we present the glaciochemical characteristics of the ice core in Antarctica over the past 780 years (1215-1996 AD). Our results show that the climatic and environmental variability during 780 years in this area can be divided into three stages as follows:

Stage I is from 1215 to 1460 AD, with a gradual decrease of the local annual snow accumulation rate and concentrations of most major ions.

Stage II is from 1460 to 1800 AD, reaching the lowest accumulation rate and representing strong cooling. Concentrations of the major cations of Na⁺, Mg²⁺ and the anion of Cl⁻ in sea salt reduce distinctly, with the maximum drop in NO₃⁻ and MSA, indicating the possibility to trace environmental changes by chemical ions. This period coincides with the Little Ice Age in the Northern Hemisphere.

Since 1800, Stage III is characterized by a rapid increase of the annual accumulation and concentrations of the major cations and anions, implying the increase of local temperature, which is consistent with the global warming after the Industrial Revolution.

It seems that in Antarctica, the global climatic and environmental variability is recorded in the climatic interaction region rather better than in the other regions.

Mantle fluids involved in metallogenesis of the gold deposits in the hanging wall of Zhao-ping fault: Evidence of H-O isotopes

YAN ZHOU1, PEI-XI ZHENG 2, YANJIE ZHANG1 AND TIE-FU WANG1

1Center of Analysis and Testing, Jilin University, Changchun 130026
2College of Earth Science, Jilin University, Changchun 130026

The Jiaodong region is located on the eastern margin of the North China Craton and the western Circum-Pacific tectonic belt. It is bounded by the Wulian-Rongcheng fault and the Dabie-Sulu ultrahigh-pressure metamorphic belt in the southeast and the Tanlu fault in the west.

The Jiaodong region is the lage cluster of gold mineralization in China. Zhao-Ye gold zone is one of the major gold mineralization zones in Jiaodong. There is many large and medium-sized gold deposits, such as Linglong gold deposit, Dayingezhuang gold deposit and Xiadian gold deposit. But most of this gold deposits are located under Zhao-Ye gold zone. The gold deposits are located in the hanging wall of the Zhao-Ye gold zone have little people to study except Sun Zhongshi (Jilin University). At present, Lingqueshan gold deposit located in the hanging wall of the Zhao-Ye gold zone have put into production, it is advantage for studying on the material sources.

Fluids are distillation of ore-forming, which origin, movement and matter uninstall reflect the whole process of ore forming. The composing of ore-forming fluids is an important parameter to demonstrating geochemistry character of ore-forming. The paper study on the geochemistry character of H-O isotopic of gold deposit located in the hanging wall of Zhao-Ye gold zone, in order to discussing the origin of fluids of ore forming.

Zhao-Ye gold zon is one of the major gold mineralization zones in Jiaodong. The gold deposits located in the wall of the Zhao-Ye gold zone have little people to study, which occurs mainly in the Jiaodong rock group. The ores are mainly of the auriferous quartz vein type hosted in NE trending fractures and faults. Wall-rock alterations are most potassic alteration, siliconization, quartz-sericitization, pyritization and carbonatization. According to research of geological characteristics of deposit and analysis of fluid inclusion of quartz. The δ¹⁸O value of the the quartz vein ranges from 4.78% to 10.12%, and the average value is 6.22%. The δD of H₂O values of fluid inclusion vary from –73.13% to –100.15%, and the average value is –86.63%. The research shows that this area mineralogenetic heat fruit is mainly curtain fountain, and participated in a certain degree of magma water and atmosphere water, has the same mineralogenetic hear fruit system with the other Zhao-ye gold deposit.
Effects of cave environmental condition on drip-water hydrogeochemical characteristics

YUNCHAO ZHOU AND SHIJIE WANG
Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China 550002 (zhouyunchao@21cn.com, *Corresponding author: sjwang@ms.gyig.ac.cn)

Speleothems contain large amount information of earth paleoenvironment change. Multi-proxies, supported by a series of hypothesis, have been used to interpret paleoenvironment change of karst. However, the records of speleothems are seldom coincident within the same cave and contradictory results have been reported. To clarify high resolution, short time scale information urged to reduce noise. Understanding hydrogeochemical processes happening in cave roof can contribute to interpret paleoenvironment change. Cave systems were monitored in Jiangjun Cave in Anshun county of Guizhou province, China, lasted for a year. NaCl was adopted to trace sources of cave drip water, time scales of drip water responding to precipitation, and processes of water dynamics in the cave. 4 drip points were monitored. The result shows that time scale of drip-water responding to rainfall was very quick (0~9 days). Drip water chemical components were directly originated from soil and greatly affected by the soil thickness. The thinner soil was; the less substances water dissolved. Water passed more quickly, which decreased the possibility of dilution happening in drip water, simultaneously, increased the contribution of rock to drip compositions. Different sources of water affected drip water dynamic process, which led to piston flow for JJD-1#, and increased drip ratio and water head pressure for JJD-2#. As well while water was of much quantity. The process of rock dissolution and calcite precipitation mainly controlled elements variations of 4 drip waters while water transported in the route and acted with soil and rock. Consequently, as an important karst environmental factor, soil decides and controls drip compositions of cave drip waters, which means more attentions must be paid to soil in future study.

Tracing natural CO₂ geological sequestration processes with noble gases

ZHENG ZHOU¹, CHRIS BALLENTINE¹, MARTIN SCHOELL² AND SCOTT STEVENS³

¹SEAES, The University of Manchester, Manchester, UK (zheng.zhou@manchester.ac.uk; chris.ballentine@manchester.ac.uk)
²GasConsult International L.L.C., Danville, USA
³Advanced Resources International, Arlington, USA

Isotopic and elemental fractionation of noble gases can be used, together with other gases, to identify and quantify the origin, migration and sequestration processes of natural CO₂ gas deposits. The Jackson Dome CO₂ reservoir lies north east of the Jackson Dome intrusive in Mississippi, USA. The reservoir occurs between 4270m and 5180m depth and is assumed to have formed by thermal decarbonation reactions associated with the Jackson dome intrusive contact with related carbonate formations. 10 gas samples were collected and analysed for both noble gases and major gas composition. CO₂ ranges from 98.75% to 99.38%. Trace amounts of CH₄ and N₂ are correlated, and both correlate negatively to CO₂, suggesting that CH₄ and N₂ have a different source to that of the CO₂. The highest concentrations of N₂ and CH₄ are found on the crest of the trapping structure.

³He/⁴He ratios range between 4.27Rₐ and 5.01Rₐ (where Rₐ is the atmospheric value of 1.4×10⁹), indicating a strong mantle signature. CO₂/³He ratios vary between 1.07×10⁹ and 4.62×10⁹ and are in the range of the values found in pure magmatic samples (1-7×10⁹). The source of the CO₂ is not due to thermal decomposition of carbonates, but is dominated by magmatic gas.

The relationship among major gases (CO₂ and N₂), ⁴₀Ar, ⁴He and Ne isotopes shows that the gases in Jackson Dome reservoir are a mixture of a fractionated air component, a magmatic end member and a radiogenic/crustal component. ²⁰Ne can be crudely used as a groundwater proxy. Anti-correlation of ²⁰Ne with CO₂/³He shows that groundwater plays a role in CO₂ sequestration and may be responsible for more than 70% of CO₂ loss. This is a common feature seen in other magmatic CO₂ rich natural gas fields (Gillifan et al., 2007)

²⁰Ne/³⁶Ar in the gas phase is higher than the groundwater ratio of ~0.16 with values of 0.798 to 1.35. CO₂/³He ratios correlate with both ²⁰Ne/³⁶Ar and ³¹C (CO₃⁺) values. We explore a variety of models to explain this data including: oil-groundwater partitioning; gas-groundwater partitioning; excess air dissolution and noble gas re-dissolution. A solubility controlled Rayleigh fractionation of groundwater modified by oil interaction appears to account for all correlations.

Redefining feldspar-water interfaces

C. ZHU

Geological Sciences, Indiana University, Bloomington, IN 47405, USA, (chenzhu@indiana.edu).

Currently prevailing theory or hypothesis on kinetics is that feldspar dissolution is controlled by surface reactions. However, recent atomic scale electron microscopy studies of naturally weathered K-feldspars in the Navajo sandstone, Arizona (Zhu et al., 2006), labdorite dissolved in pH 1 solutions in the laboratory at room temperature (Hellmann et al., 2003), and alkali-feldspars dissolved at 200 °C and 300 bars (our unpublished) show that there is an amorphous layer on the dissolving feldspar surfaces. Furthermore, K-feldspars from the Navajo sandstone show tightly adhered coating of kaolinite and a 3-5 micron thick smectite (Zhu et al., 2006). We believe the amorphous layer and secondary coating layers are important characteristics that bear significances on the feldspar dissolution kinetics. We advance two hypotheses for explaining the field-lab discrepancy. First, the secondary minerals rinding on feldspars are not at local equilibrium with groundwater, as traditionally assumed, but their slower precipitation rates can raise the groundwater saturation state with respect to feldspars to very close to equilibrium, and thus retard the feldspar dissolution rates. Feldspar dissolution reaction in aquifers is within a complex web of reactions, in which secondary clay precipitation plays a key role. Second, a thin (~ 10 nm) amorphous layer, possibly leached in origin, is found on feldspars that we examined. The presence of the amorphous layer on naturally weathered feldspars requires reconsideration of the details of surface reaction controlled mechanism.

Stable sufer isotopic composition of H2S and it’s TSR origin in Sichuan basin, China

G.Y. ZHU, S.C. ZHANG, J.X. DAI AND Y.B. LIANG

PetroChina Research Institute of Petroleum Exploration and Development, Beijing (zhuguangyou@petrochina.com.cn)

The natural gas has widely some H2S in Sichuan basin; the contents are from minium to 18.6 percents. The high H2S-bearing natural gas lies in the Feixianguan Formation, Leikoupo Formation and Jialingjiang Formation of Triassic; the Sinian, Carboniferous and Permian reservoir have lower contents H2S, Xujiahe Formation of Triassic and Jurassic have micro or free sulfur in natural gas reservoir. The research shows that the gypsiferous rock of Feixianguan Formation, Leikoupo Formation and Jialingjiang Formation of Triassic, Sinian and Carboniferous reservoirs provide the physical matter for TSR; the Permian lower H2S-bearing natural gas is mainly from the pyrolysis of organic sulfur source rock. The stable isotopic composition of sulfur show that the sulfur isolate of H2S-bearing gas has a short at 7~11‰ of the reservoirs sulfate, and that the sulfur isoltes of lower H2S-bearing have widely distributing and about 15‰ short of most data. The stable isotopes of sulfur have a wide distribution extent and step change in the gypsyiferous rock of Triassic, which are similar to the H2S in the distributed law(Fig.1), the data indicate that the sulfur comes from the sulfate in the H2S and TSR occurs in the respective reservoirs. Otherwise, the temperature conditions are similar as the TSR occurs, which means that the H2S generates in the similar temperature condition and the fractional process of sulfur isotopes have no concern with the sulfur isotopes of sulfate, the temperature and extent of reaction are the key factors in the TSR process.

Investigation on the origin of Se-rich soils and selenosis in Yutangba, China

J.-M. ZHU\(^1\), H.-B. QIN\(^1, 2\), L. LEI\(^1, 2\) AND L. LI\(^1, 2\)

\(^1\)Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China. zhujiianming@vip.skleg.cn
\(^2\)The graduate school of Chinese Academy of Sciences, Beijing, 100049

Yutangba was known as a typical high-selenium (Se) area in China where a sudden incidence of human Se poisoning occurred in 1963. The surface exposed Se-rich carbonaceous cherts and carbonaceous shales (locally known as stone coal) of the Permian Maokou and Wujiaping formations at north part of Yutangba were generally considered as the major source of Se that was enriched soils in Yutangba and other places in Enshi Prefecture. However, little study has been conducted to confirm the source of Se in soils of Yutangba, and the causes of the sudden incidence of human Se poisoning was still in debate so far (Zhu et al. 2004).

161 soil samples were collected from the entire Yutangba area. Abnormal Se content was observed in 11 soil samples with Se concentrations ranging from 346 to 2018 mg/kg with an average of 899±548 mg/kg. Selenium fractionation was investigated in 3 of them based on the sequential extraction protocol described by Kulp et al. (2004), which showed that elemental Se extracted by 1mol/L Na\(_2\)SO\(_3\) was the predominant fraction (>90%) while other fractions are a few percent. These abnormal soil samples were further studied using SEM with EDX for elemental Se. Native Se crystals were discovered and they were surprisingly well preserved mainly as cubic-prismatic in form and more than 20µm in size (ground soil powder). These morphological characteristics are very similar to that of reported native Se crystals derived from natural burning of stone coal on the subsurface of abandoned stone coal spoils, but significantly different from the elemental Se formed by bacterial. This result indicated that the source of Se in cropland soils was different from that of soils which was not cultivated or disturbed by human activities. It provided the strong evidence that local people ever baked soil on the Se-rich stone coal fires and then they dispersed these baked soils containing much more higher dissoluble Se and insoluble native Se over the cropland to fertilize soil. This cultivated practice, ever used by villagers lived in Yutangba and other high-Se areas in Enshi, introduced abruptly a large amount of Se into their cropland, which is further accumulated in local people’s food chain. The occurrence of native Se crystals in Yutangba cropland soils explains the source of Se in soils and the reason for the sudden incidence of human Se poisoning in 1963.

Sn/W-bearing A-type granites in Nanling Range, South China

JINCHU ZHU

Key State Lab for Mineral Deposits Research, Nanjing University, Nanjing 210093, China (jczhu@nju.edu.cn)

There exists an early Yanshanian (J\(_1\)-J\(_2\)) Sn/W-mineralized A-type granite belt in Nanling Range, South China. It extends from Huashan, Guposhan, through Juuyishan, Qitianling, Qianlishan up to Xitian in a NE direction for some 400 km. The total granite exposure area is over 3000 km\(^2\).

These granitic bodies are accompanied with the contemporary dioritic and monzonitic stocks and rhyolitic volcanics. The mafic microgranular enclaves with magma mixing features are very common. In general, the granitic bodies can mostly be divided into two intrusive phases: the coarse-grained major phase (mainly 163~156 Ma) and the fine-grained later stage additional phase (mainly 143~151 Ma).

The granite rocks are very acidic in composition, (SiO\(_2\)=67.89~77.11%), rich in K\(_2\)O (3.99~6.29%) and alkalies (K\(_2\)O+Na\(_2\)O=7.38~9.62 %), slightly meta-aluminous to weakly peraluminous (ACNK=0.92~1.10).

In trace elements, all the major phase granites and the contemporary intermediate stocks and mafic enclaves are enriched in Rb, Cs, U, Th, LREE, Y, Nb, Ta, Zr, Hf, Ga etc LILEs and HFSEs, as well as Sn/W. They belong to aluminous A-type granites. Compared with the major phase granites, the later stage granites are more acidic (SiO\(_2\)>76%), more alumina-saturated (ACNK=1.00~1.21), and more enriched in Rb, Cs, U, Th, Y, Sn, W etc. trace elements, but relatively depleted in LREE, Zr etc. HFSEs. These later stage granites are often Sn/W-mineralized with large even giant tonnage. Chemically these rocks are very close to S-type granites.

The J\(_1\)-J\(_2\) time in Nanling Range region was a post-orogenic extensional geotectonic setting. Upwelling of the asthenospheric mantle along the NE-trending deep faults resulted in melting of lower crust. The mantle fluid/melt may bring in Sn/W etc. ore-forming elements and mobilize them from the basemental rocks. The higher back-ground Sn/W concentration in melted protoliths and well evolved fractionation of granitic melts are also necessary prerequisites for formation of industrial Sn/W deposits.
Fe isotope variations in North Pacific deep water over last 80Ma
X.K. ZHU1, J. Li1, S.H. TANG1 AND H.F LING2
1Lab isotope Geol., MLR, Inst. Geol., CAGS, Beijing, China
(xiangkun@cags.net.cn)
2State Key Lab Mineral Deposits, Nanjing Univ, China
(hf@public1.pitt.js.cn)

Fe-Mn crust has proved to provide excellent records of isotope composition of dissolved Fe in deep seawater. Investigating the variability of Fe isotope composition of Fe-Mn crusts is an important approach to trace Fe cycling in marine environments.

A crust named CLD01 (160°44’24’’E, 21°45’N, water depth = 2210 m) from the central North Pacific has been selected for Fe isotope study. This crust has been subjected to detailed investigation in terms of radiogenic isotopes, and its age has been constrained using multiple approaches extending to ca. 80Ma (Ling et al., 2005). The sub-samples were obtained by micro-milling, and Fe isotope measurements were performed using a Nu Plasma HR MC-ICPMS at high-resolution mode after chemical purification. The results are expressed in ε units which are deviations in parts per 10^4 from the same isotope ratios of the reference material IRMM-14. The overall variations in ε57Fe units are from -8.8 to 0.9, within the range of Fe isotope composition of Fe-Mn crust reported before. In more detail, the Fe isotope compositions of the crust start with -3.6 ε57Fe units at the surface, broadly increase to maxima of 0.9 at ca. 50Ma, then decrease sharply to -8.8 at ca. Ma. Furthermore, the ε57Fe values obtained from the crust are negatively correlated with 206Pb/204Pb and 208Pb/204Pb ratios.

These results illustrate for the first time that the evolution of Fe isotope composition in North Pacific seawater back to latest Cretaceous, and confirms that the average Fe isotope composition in seawater is light relative to the bulk silicate Earth. In general, the main Fe sources for open oceans are terrestrial aerosols and MOR hydrothermal plumes. The crust studied is far away from MOR, and there is no evidence of MOR hydrothermal contribution in terms of Pb- and Nd-isotopes. While the exact reason why the overall Fe isotope composition in seawater as recorded in Fe-Mn crust is lighter than bulk silicate Earth remain to be investigated, it is interesting to note that the Fe isotope compositions of precipitates resulting from Fe(III) hydrolysis are significantly lighter than those of residual solutions. The main turning point in the trend of Fe isotope variation occurs at ca. 50Ma, which is broadly coincident with the switchover of terrestrial inputs from North America to Asia (Ling et al., 2005). The strong linkage between Fe- and Pb-isotope compositions strongly suggests that Fe isotope variation in North Pacific deep water is related with global climate change through source inputs.

He isotope data evidence of crust contamination for mantle melts resulting to the PGE mineralized layered basic intrusions
I.A. ZHUKOVA1, L.M. ZHITOVA2 AND A.S. BORISENKO3
1Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (zhukova@uiggm.nsc.ru)
2Institute of Geology and Mineralogy, Novosibirsk State University, Novosibirsk, Russia (zhitova@uiggm.nsc.ru)
3Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (borisenko@uiggm.nsc.ru)

He isotopic composition of magmatic fluids from various PGE mineralized layered basic intrusions have been studied for understanding the role of mantle-crust interaction in formation of large Pt-Cu-Ni deposits. 3He/4He ratio have been obtained for Noril’sk, Talnakh, and Chineisky PGE mineralized layered basic intrusions (Russia), as well as for the Bushveld Complex (South Africa). All our results have been compared with He isotopic data of Hawaiian and Icelandic basalts and others no mineralized small basic intrusions of the Noril’sk Region (Basu et al., 1995).

3He/4He ratio is a sensitive indicator of crust substance contamination for mantle melts in processes of magmatic ores formation. 3He/4He value >8-10*10^-6 corresponds to mantle He, while <1*10^-6 value is connected with crust source. These ratio values up to 1-8*10^-6 are typical for mixture of mantle and crust He in fluids.

It is important to note, that only basalts and very small basic intrusions with pure ore mineralization contain mantle He, whereas crust He is predominant in all the large Pt-Cu-Ni deposits from layered basic intrusions. This result correlates well with S and C isotopic data (Riabov et al., 2001).

The results obtained give us a possibility to suggest that crust contamination of mantle melts is one of the important factor in formation of large and unique Pt-Cu-Ni deposits for layered basic intrusions.

This work was supported by the Ministry for Russian Science and Education, Grant DSP.2.1.1.702 and by RFBR Grants ## 07-05-00685, 07-05-00803, 05-05-64422.

Geochemical and mineralogical pattern recognition and modelling with Bayesian approach at the hydrothermal gold deposits

M. Ziaii
Faculty of Mining and Geophysics, Shahrood University of Technology; Shahrood, Iran, (mziaii@shahroodut.ac.ir)

The Bayesian approach is an effective method of identifying the certain probability mineralogical and geochemical type mineralization on trace element in galen, pyrite and other distribution or e mineralization. Monomineral samples have been identified using computer upon Bayes method and exploration geochemical techniques of gold deposits for MGT. In order to realize the method, we have used a data bank consisting the results of analysing more than 12000 monomineral samples collected from main hydrothermal gold deposits on territory of CIS. Bayes approach applied to geochemical data such as posteriiori probabilities and discriminate analysis provide a numerical and graphical means through which the relationships of the trace elements and samples can be studied. There methods were used here beside GIS to find MGT that can be used as geochemical indicators of regions with gold mineralization.

The results of analyzing100 monomineral samples of pyrite from Au-Ag Shkolnoe deposit (Tajikistan) reveals multiformalation anomaly of superposition which is a combination of three MGT as:

1. Gold - silver type (85 % and more)
2. Gold- sulfide - polymetalic type (46 %).
3. Gold - sulfide type (40 %).

Mineralogical and geochemical maps (MGM) are results of generalization and analysis of MGT and GIS of different objects. There arises the possibility of quantitative modeling using spatial links of objects and multivariate models helps significantly in making optimal managerial decisions that give maximum economic effect.

Instrumental mass fractionation overcome by total evaporation

A. ZIMMERMAN¹, H.J. STEIN¹,², J.L. HANNAH¹,², D. TUTTAS³, G. YANG¹ and B. BEITSCHER¹

¹AIRIE Program, Department of Geosciences, Colorado State University, USA; (aaron.zimmerman@colostate.edu)
²Geological Survey of Norway, 7491 Trondheim, Norway
³Thermo Fisher Scientific, 28199 Bremen, Germany

A select suite of isotopes, including Li, Cu, V, Lu, and Re, along with isotopic mixtures of unknown isotopic composition, require special analytical techniques to overcome instrumental mass fractionation (IMF). Generally, measurements subject to IMF are corrected using a known ratio either intrinsic to the system or externally added to the sample and measured simultaneously with the sample. For many systems, e.g. Os, and for many types of measurements, e.g. ICP-MS, internal ratios or doping works well. For other cases, e.g. NTIMS Re measurements, neither approach readily works. Therefore, following the work of Suzuki et al [1], an updated total evaporation (TE) technique is employed. In theory, if the entire sample is evaporated until exhaustion and all the ions collected, mass fractionation is overcome, thereby improving accuracy and precision, with less dependence on the analyst.

An experiment was designed to test TE against single-collector peak jumping and multi-collector static measurements using a variety of ¹⁸⁵Re/¹⁸⁷Re ratios (~0.6 standard; ~4 sample; ~37 spike) with the expectation of documenting differences in measured ratios due to variability caused by IMF. Preliminary results demonstrate, within statistical uncertainty, that TE provides equally accurate, equally precise data that is marginally less dependent on the analyst.

While the initial results did not indicate a drastic improvement in accuracy or precision, further optimization of the analytical procedure may result in better data. NBS peak jumping, and to a lesser extent Triton static collection, have undergone multiple filament warm-up, focusing, and centering optimizations during thousands of Re measurements. On the other hand, TE measurements are currently utilizing default parameters. Optimization of procedures and parameters including filament heating; ideal initial, final, and maximum intensities; heatslope (mA/cycle); integration time; and mathematical constants is on-going. Fine-tuning these parameters and procedures should result in higher quality data, surpassing other data collection techniques.

Total evaporation may be extended to other isotopic systems including Li, B, Cu, Ir, V, Br, and Lu. Additionally, total evaporation may provide improved accuracy and precision for artificial isotopic mixtures such as double spikes (e.g. Os, Mo, and Pb). In summary, TE provides an alternate method of data collection for samples subject to, but not internally or externally correctable for, IMF.

Formation of 4.5 Ga continental crust

H. ZOU AND T.M. HARRISON
Dept. of Earth & Space Science & IGPP, UCLA, Los Angeles, CA 90095 USA, (hzou@ess.ucla.edu)

Geochemical models of crustal growth on early Earth have tended to favor mafic over felsic compositions for a variety of reasons including: lack of a mechanism to produce stable continental-type crust from a magma ocean (high P of feldspar w.r.t. hydrous melt, low feldspar growth rate w.r.t. convective vigor), problems reconciling Sm-Nd systematics, apparent inconsistency with Nb/Th/U ratios, and the absence of >4 Ga crust. However, Morse (1987) proposed a model that transcends most of these objections. He invoked a sinking, undercooled, two-phase plume that, upon reaching the base of a magma ocean, rapidly crystallizes olivine. The light, evolved liquid produced (assuming that the fluid in equilibrium with olivine is silica-rich at high P) ascends to shallow depths. Nucleation from sparse centers in the highly polymerized melt results in rapid crystallization of tonalitic rockbergs that coalesce into regions of stable, felsic crust. Recent Lu-Hf results on Hadean zircons tend to support the case for an early continental-type crust. Thus we have re-evaluated this proposal for the case of a ~250 km deep magma ocean using recent experimental data in conjunction with the MELTS program. Melting experiments in the CMAS system at 6.5 GPa and 1850°C (Asahara & Ohtani, 2001) yield liquid compositions characterized by 45-52% SiO₂. We modified the liquid composition by adding Fe to achieve MgO/(MgO+FeO)=0.8 and partitioning pyrolite levels of incompatible elements (e.g. K, Na) into the melt. Upon ascent to 0.2 GPa, the hygroscopic liquid containing 2% H₂O rapidly evolves during cooling to produce a dioritic (57% SiO₂) composition at 950°C. Thus an early felsic crust appears feasible even without the disequilibrium effects of the Morse model. He emphasized that a network-rich liquid would be characterized by a relatively high viscosity enabling the ‘pop-up’ crust to maintain sufficient mechanical integrity to resist remixing with the ultramafic magma ocean until rapid crystallization occurred. At the surface, proto-crust would tend to migrate to down-welling loci and be stabilized by the locally cooler conditions. As the base of the crust heats up in response to shutdown of the descending cell, felsic liquid produced would tend to ascend diapirically to shallow levels creating a feedback that sustains the presence of continental-type crust. Most of the arguments against an early continental-type crust described above lack rigor or have been transcended by recent evidence. Morse’s (1987) model provides a plausible mechanism to produce felsic crust in the earliest stages of Earth evolution. Subsequent re-working and eventual recycling of this proto-continental crust into the mantle provides an explanation for the isotopic characteristics of Hadean zircons and the apparent absence of pre-4 Ga continental crust.
