Influence of coupled diffusion and viscous creep on the composition of metasomatic reaction bands

R. ABART, R. MILKE AND E. PETRISHCHEVA
Institute of Geological Sciences, Free University Berlin, (abart@zedat.fu-berlin.de, milke@zedat.fu-berlin.de, eptris@zedat.fu-berlin.de)

We explore the feedback between reaction induced stress and component diffusion. Rim growth experiments in the system MgO-FeO-SiO$_2$, where orthopyroxene reaction rims were grown between olivine and quartz were made. Two different matrix-inclusion arrangements were used: In a single capsule vol. 10% of olivine grains (150 µm grain size) were immersed in a polycrystalline quartz matrix and, in a second compartemeent, the opposite matrix-inclusion arrangement was chosen using the same starting materials (San Carlos Olivine and synthetic quartz). The orthopyroxene rims that were formed around quartz inclusions in the olivine matrix were 11.6 µm after 80 hours run duration, in contrast, the orthopyroxene rims that formed around olivine inclusions in the quartz matrix were only 6.1 µm thick on average. Provided that run conditions and water fugacities were similar in both compartments of the assembly, this suggests mechanical feedback of the matrix with the rim growth reaction. We present a rate law for diffusion controlled reaction rim growth in spherical geometry and link it to the accommodation of the volume change of reaction by viscouse creep. For the experimental conditions of 1000°C, 1 GPa and a strain rate of $10^{-6}$ s$^{-1}$ we infer a transition from diffusion controlled growth to creep controlled growth for effective bulk viscosities on the order of $10^{16}$ to $10^{17}$ Pas. In the diffusion controlled regime, growth zoning with sharp compositional gradients within the reaction rim may develop due to local equilibrium constraints. If viscouse creep takes over rate control, compositional gradients across the growing rim tend to degrade and the original growth zoning may be obliterated. Pronounced growth zoning observed in many naturally formed reaction rims may thus be taken as an indication of diffusion controlled growth.

Transport, interface and rheological controls on the kinetics of mineral reactions

R. ABART$^1$, R. MILKE$^1$, E. PETRISHCHEVA$^1$, D. SCHMID$^3$, R. WIRTH$^2$ AND D. RHEDE$^2$

$^1$Institute of Geological Sciences, Free University Berlin (abart@zedat.fu-berlin.de, milke@zedat.fu-berlin.de, eptris@zedat.fu-berlin.de)
$^2$GeoForschungsZentrum Potsdam (wirth@gfz-potsdam.de, rhede@gfz-potsdam.de)
$^3$Physics of Geological Processes, University Oslo (schmid@fys.uio.no)

We investigate three examples of reaction microstructures and textures using electron and ion beam techniques with high spatial resolution. In particular we are interested in the role of diffusion, interface energy and rheology during mineral reactions and their influence on microstructure and texture evolution. This is motivated by the notion that the latter determine geo-materials macroscopic properties.

First we discuss findings from natural and synthetic examples that corroborate fast diffusion along grain and phase boundaries. There diffusion may be enhanced by the presence of an amorphous phase even at homologous temperatures well below unity. In the context of reaction rim formation short circuit diffusion along grain and phase boundaries may lead to complex chemical patterns with equilibration domain sizes well below the grain size. In a second example we explore the potential of Cahn-Hilliard theory to describe mineral exsolution. We present numerical models of exsolution in ternary feldspar, which are compared with microstructures and chemical patterns from natural perthites. From this comparison we infer that fractionation of the anorthite component into albite-rich exsolution lamellae may be rate limiting during the coarsening stage, because of slow Al-Si interdiffusion in the silicate framework. The anorthite content of albite-rich lamellae appears to be a sensitive and robust monitor of the cooling history. Finally, we explore the feedback between reaction induced stress and component diffusion. Rim growth experiments in the system MgO-FeO-SiO$_2$ seem to indicate that, provided the materials involved are mechanically strong, reaction induced stress may slow down or even quench net transfer reactions. Our analysis indicates that the rheologies of polycrystalline quartz and olivine are well within the range of mechanical properties required for deformation by creep to take over reaction rate control.
Behavior of water during terrestrial planet formation

YUTAKA ABE

Department of Earth and Planetary Science, The University of Tokyo, Tokyo, Japan (ayutaka@eps.s.u-tokyo.ac.jp)

Recent planetary formation theory suggests two stages of planetary accretion; the stage of runaway growth (e.g., Kokubo and Ida, 1998) followed by the stage of giant impacts (e.g., Chambers and Wetherill, 1998). Here, I discuss the behavior of water during terrestrial planets formation from theoretical points of view.

Usually, the solar nebula is thought to be too warm to form hydrous minerals at 1 AU from the Sun, so hydrated material is not available in planetesimals. However, recent theory suggests cool nebula, so that large amount of water can be trapped in planetesimals. Such water is lost during accretion, but substantial amount of water can be trapped in Mars-sized protoplanets formed during the stage of the runaway growth (Machida and Abe, 2007). Expected water content is size dependent; larger bodies retain water, but smaller bodies are dry. This may imply protoplanets are somewhat wetter than meteorites.

Accretion of water-bearing planetesimals results in many phenomena (Abe et al., 2000). Impact degassing would form a proto-atmosphere. A hydrous magma ocean can form in response to the thermal blanketing effect of an early proto-atmosphere. In addition, a large amount of hydrogen may be partitioned into metallic iron under high pressure, and delivered to the core.

In the stage of giant impacts, addition of material from large bodies beyond the orbit of Mars may transport water to the Earth region (e.g., Lunine et al., 2007). Giant impacts would remove some amount of water, but substantial amount survives them (Genda and Abe, 2003). Moreover, loss rate depends on the surface environment of protoplanets. On protoplanets with oceans, giant impacts result in relative enrichment of water against other gases, because gas species are efficiently blown away by the impact, while water ocean survives (Genda and Abe, 2005). Thus, planets those experienced giant impacts with oceans (Earth?) are likely enriched in water than those without oceans (Venus?) or those experienced no giant impacts (Mars?).

Li isotopes and Li/Ca measured in foraminifera via SIMS and MC-ICP-MS

R. ABELL, T. ELLIOTT, G.L. FOSTER, S.A. KASEMANN AND D.N. SCHMIDT

1Bristol Isotope Group. Department of Earth Science, University of Bristol, Bristol, BS8 1RJ, UK; (richard.abell@bristol.ac.uk)
2Grant Institute of Earth Science Science. Ion Microprobe Unit, The University of Edinburgh, West Main Road, Edinburgh, EH9 3JW

Lithium has a residence time within Earth’s oceans of ~1.5 Ma. Perturbations in the recorded Li isotope composition of seawater beyond this residence time likely reflect changes in competing fluxes of Li derived from continental silicate weathering and hydrothermal circulation. The importance of continental weathering in regulating global climate has led to great interest from several groups in ground-truthing and examining temporal records of lithium archived within foraminiferal tests. In this study we attempt to further our understanding of Li isotopes hosted within foraminiferal carbonate using a combination of in-situ SIMS and MC-ICP-MS analysis with which to measure Li/Ca and δ7Li. We find single specimens of G. truncatulinoides measured by SIMS show, in keeping with other more traditional trace metal concentrations, significant Li/Ca variation throughout the foraminiferal test that cannot be attributed to contaminant phases. Initial in situ lithium isotope ratios also allude to isotopic variation most likely reflecting depth migration during ontogenic stages of biomineralisation.

These observations can be put into context by our high precision MC-ICP-MS study of multiple specimens, sampled from five ocean basins. Deeper dwelling species record decreasing lithium isotope ratios with increasing depth of habitat. Although we document no variation in the lithium isotope composition of modern seawater we observe significant (~2 %) variation between surface dwelling Holocene G. sacculifer and G. ruber from several ocean basins. These lines of evidence are indicative of an environment control on the isotopic fractionation of lithium during biomineralisation, as previously proposed for Li/Ca incorporation.

This characterisation of lithium isotopes makes deconvolving variations in weathering intensity from variations in environmental forcing in Neogene records problematic. Using a multi-proxy approach however, down core variations in the lithium isotopic composition of foraminifera may yield valuable information on past weathering fluxes and climatic conditions.
Lead isotopes on lavas from the different evolution stages of Koolau Volcano—subaerial Makapuu stage, main shield stage lavas from the Koolau Scientific Drilling Project (KSDP) and Honolulu Volcanics (HV)—have identified three end member components in Pb isotope space: Makapuu, Kalihi, and a depleted component unique to the rejuvenated stage HV (Fekiacova et al., 2007). When plotted against SiO₂, the Pb isotope data define two trends consistent with a ternary mixing: a negative correlation defined by shield stage building lavas and a positive correlation defined by the post-erosional HV. Similarly, CaO/Al₂O₃ ratios, a proxy for pyroxene-to-garnet ratio in the source are negatively correlated with Pb isotope ratios and demonstrate the co-existence of peridotite and eclogite in the Koolau source.

The approach was extended to other Hawaiian volcanoes from the two geographic alignments Kea and Loa which have been shown to be compositionally distinct in Pb isotope space (Abouchami et al., 2005). CaO/Al₂O₃ and Pb isotope ratios display a negative correlation at the scale of the whole chain: most Kea-trend lavas cluster at high Ca/Al ratios (0.8) while Loa-trend lavas display a large range (0.6-0.7), overlapping Koolau data, with Makapuu lying at the extreme low end of the correlation. This coupled major-element-Pb isotope variability in Hawaii is interpreted in terms of mixing of pyroxenite and peridotite, in agreement with previous studies (Sobolev et al., 2005; Ren et al., 2005; Herzberg, 2006). Mixing calculations show that most Kea lavas are derived from a mantle peridotite source with small amounts of pyroxenite (10-20%) whereas Loa lavas contain up to 90% of the eclogitic (pyroxenite) component. In addition, the proportion of this component along the Loa track decreases with decreasing age of the volcano (~90% in Koolau to 50-70% in Mauna Loa). This feature might be related to a change in the thickness of the lithosphere along the Hawaiian chain. This suggestion is sustained by seismic data showing a thinning of the lithosphere from 100 km under Big Island to about 50-60 km under Kauai (Li et al., 2004), and also the observation that the amount of recycled component in mantle-derived melts is partly controlled by the thickness of the lithosphere (Sobolev et al., 2007). Alternatively, changes in potential mantle temperature across the Hawaiian plume might produce variations in the composition of the melts (Herzberg, 2006).

The major-element Pb isotope correlation demonstrates that the Pb isotope “bilateral asymmetry” (Abouchami et al., 2005) also extends to the ratio of peridotite to pyroxenite in the source of the Hawaiian mantle plume.

Mars may have formed via runaway growth within ~1 Myr or its accretion may have been more protracted and involved large impacts. Hf-W chronometry ought in principle to be able to distinguish between these two scenarios but reported Hf-W ages for Mars range from <1 Myr to ~12 Myr [1-4]. This range in ages is mainly due to different assumptions regarding the Hf/W ratio of the Martian mantle [5]. Th/W ratios of Martian meteorites are relatively constant and hence can be used to constrain the Hf/W ratio of the Martian mantle [5]. This approach requires knowledge of the Hf/Th ratio of the Martian mantle, which is generally assumed to be chondritic. The chondritic Hf/Th ratio however is not well constrained and potential variations in Hf/Th ratios among different chondrite groups have not been investigated. We developed analytical techniques for the precise determination of Hf/Th ratios by isotope dilution and present an improved determination of Hf/Th ratios in chondrites. This is used to better constrain the Hf/W ratio of the Martian mantle and the age of Mars. Our new Hf and Th concentration data reveal that carbonaceous chondrites have lower Hf/Th ratios than ordinary chondrites. The calculated Hf/W ratio of the Martian mantle therefore depends on assumptions regarding the bulk composition of Mars. For instance, using our new estimate for the Hf/W ratio of the Martian mantle, two-stage W model ages of ~7 Myr and ~4 Myr are calculated for an ordinary and carbonaceous chondrite-like composition of Mars, respectively. These ages change to ~15 Myr and ~13 Myr if one assumes that Mars accreted at an exponentially decreasing accretion rate and complete metal-silicate equilibration was always achieved. These ages would further increase if metal-silicate equilibration was incomplete. In spite of this model-dependence, Hf-W chronometry provides important constraints on the age and origin of Mars because the two-stage model age corresponds to the earliest time when core formation could have been completed [6]. Hence, based on our new estimate for the Hf/W ratio of the Martian mantle, it seems unlikely that Mars had entirely been accreted in less than ~1 Myr. This suggests that Mars is probably not a stranded planetary embryo and that its formation history was similar to that of the larger terrestrial planets.

Re-Os depth profile of the upper mantle beneath Central Europe

L. ACKERMAN1,2, I. S. PUCHTEL3, R. J. WALKER3 AND E. JELÍNEK1

1Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University, Albertov 6, 12843, Prague 2, Czech Republic (ackerman@gli.cas.cz)
2Institute of Geology, Academy of Sciences of the Czech Republic, Rozvojová 269, 16500, Prague 6, Czech Republic
3University of Maryland, College Park, MD 20742, USA

Variations in Re and Os concentrations in upper mantle rocks from various geotectonic environments raise the question of whether they reflect primary or secondary processes. Recent studies have shown that Re can be metasomatically imported from subducting oceanic crust or by basaltic melt metasomatism. Osmium is a compatible element and its concentration mostly remains close to PUM estimates during various mantle processes, although addition of Os from subducting slabs can introduce radiogenic Os.

Rhenium and Os concentrations, and Os isotopic data were determined for a well-characterized suite of upper mantle xenoliths sampled from beneath the Kozákov volcano (5 Ma), of the Bohemian Massif (Czech Republic). This suite of mantle xenoliths represents the upper mantle profile composed of 3 different layers, from 33 to 70 km. The xenoliths underwent 7-15% partial melting and subsequent LILE enrichment by percolation of volatile-rich melt, which was not associated with recent volcanism. These processes were more intensive with increasing depth.

The samples have highly variable, but generally low Re and Os concentrations of 6–28 ppt and 0.2–2.1 ppb, respectively, and relatively uniform 187Os/188Os (0.1219–0.1276). Thus, they have Os isotopic compositions within the range of estimates of the modern convecting upper mantle. The Os concentrations and 187Re/188Os significantly vary with depth with the lowest Os and highest (but subchondritic) 187Re/188Os at the greatest depths (~70 km). Precise age of partial melting could not be determined because of evident perturbation of the Re-Os system. However, Lu-Os “ages” point to ~1.0 Ga depletion event, if the samples affected by perturbation are excluded.

The low Os concentrations and strongly subchondritic Re/Os ratios in some samples imply that Os was removed from the system at some stage of mantle evolution. We suggest that Os was removed during percolation of high-temperature sulphur-undersaturated melt causing sulfide breakdown and Os (and Re) removal. Our data suggest that such processes may affect large proportions of the upper mantle and could significantly modify the Os composition of the Earth’s subcontinental lithospheric mantle.
Antimony speciation in shooting ranges and its association with iron oxides

SONIA ACKERMANN, RETO GIERÉ AND JURAJ MAJZLAN
University of Freiburg, Germany
(sonia.ackermann@minpet.uni-freiburg.de)

Antimony compounds are known as environmental pollutants that may pose a serious threat to human health. The toxicity and bioavailability depends on the speciation of Sb. Antimony salts are known to be more toxic than other Sb compounds, and Sb$^{3+}$ is more toxic than Sb$^{5+}$. Sources of Sb contamination are smelters, emissions from the coal power plants, mining activities, vehicular traffic, and shooting activities. The bullets used for shooting practice contain Pb, Sb and Fe. In Switzerland alone, the estimated annual input of Sb into the environment by these activities is approximately 6 tons. Analyses of the soils at the shooting ranges revealed Sb concentrations of up to 5900 ppm, significantly above the estimated global average concentration in soils of 0.5 ppm (Reimann and De Carritat, 1998). Knowledge about secondary Sb-bearing phases formed during weathering of the bullets is crucial in order to assess the mobility and bioavailability of Sb in these environments.

Our results on weathering crusts around bullets show that various major Sb-bearing phases can be distinguished depending on the soil chemical conditions. Fe-rich phases always represent a major Sb host in the crust irrespective of the sampling site. Element distribution maps and quantitative analyses with an electron microprobe showed a correlation between Sb and Fe. X-ray diffraction analyses revealed that the crystalline Fe oxides are goethite and lepidocrocite. Raman spectroscopy of individual Fe-rich areas confirm the XRD results. The elevated background in the XRD patterns is attributed to ferrihydrite and organic material. In which way Sb is bound to these Fe oxides is not known to date and cannot be solved by the above mentioned techniques.

Knowledge about the geometry and binding behavior of sorbed Sb on different Fe oxide surfaces will help to evaluate the mobility of Sb in this system. Therefore, we collected Sb K edge EXAFS spectra of synthetic goethite, lepidocrocite, and ferrihydrite with different Sb surface loadings relevant to our field samples. The evaluation of these spectra will provide information about the Sb complexes on the surface of the iron oxide minerals. The comparison of these results with the spectra of the natural samples will then allow to describe the behavior of Sb associated with Fe oxides in the weathering crusts of the corroding bullets. The EXAFS studies are also important to numerous other sites polluted by Sb (e.g., acid mine drainage sites) where Fe oxides are known to act as scavengers of pollutants, for example Sb.

Using oxygen isotope and magnetism to reconstruct the paleotemperature framework of ancient travertine deposits in Death Valley, CA

TOMOKO ADACHI$^{1,2}$ AND GUNTHER KLETETSCHE$^{1,2,3}$
$^1$Catholic University of America, Physics Department, Washington DC, USA (astromoko@astromoko.info)
$^2$Goddard Space Flight Center/NASA, Astrochemistry Code 691, Greenbelt, MD, USA (tomoko.adachi@gsfc.nasa.gov)
$^3$Institute of Geology, AS CR, Prague, Czech Republic (kletetschka@gli.cas.cz)

In the light of astrobiology research, studies of modern and ancient hydrothermal systems have illuminated our understanding of the origin and early evolution of the biosphere and highlighted the potential for life to develop in such environments on Mars and beyond. The recent discovery of iron oxides by Mars Rover Mission excited us for existence of water in the past, and possibility to find fossil life form in rocks. Oxygen isotope study may give us important information to interpret the geological history on Mars surface. Comparative studies of the sedimentology magnetism and geochemistry of modern and ancient analog systems are important with the particular goal of evaluating the paleotemperature regime and diagenesis. Such proxies allow better understanding of capture and retention of fossil biosignatures.

We developed a method to reconstruct a paleotemperature regime of fossil (Plio-Pleistocene) hydrothermal system in the Furnace Creek area of Death Valley, CA, USA.

To estimate the formation temperature for each fabric type, we applied the empirical equation of Kim and O’Neil (1997). Results showed that isotopic signatures of the Death Valley travertine sinters were correlated with paleotemperature environment and we show that the qualitative temperature relationships between fabric types were preserved. In addition the fabric type paleotemperature indicators are compared with magnetic paleotemperature indicators.
Ab initio molecular dynamics study of Ca\(^{2+}\) in water: Speciation as a function of P,T, and pH

W. A. Adeagbo and N. L. Doltsinis

Lehrstuhl für Theoretische Chemie, Ruhr-Universität Bochum, D-44780 Bochum, Germany
(waheed.adeagbo@theochem.rub.de, nikos.doltsinis@theochem.rub.de)

Ab initio molecular dynamics (AIMD) simulations of Ca\(^{2+}\) in water have been performed at \(\{T=300 \text{K}, P=0.3 \text{GPa}\}\), \(\{T=500 \text{K}, P=0.5 \text{GPa}\}\), and \(\{T=900 \text{K}, P=0.9 \text{GPa}\}\). The water coordination of the Ca\(^{2+}\) ion is found to increase from 6 at \(\{T=300 \text{K}, P=0.3 \text{GPa}\}\) to an average of 7 at \(\{T=900 \text{K}, P=0.9 \text{GPa}\}\). On the time scale of 20 ps no chemical changes such as the formation of Ca(OH)\(^+\) or Ca(OH)\(_2\) were observed for the periodic Ca\(^{2+}\) + 63 H\(_2\)O system. Coordination constrained AIMD simulations [1-3] have been carried out to determine the free energy barrier for dissociation of a H\(_2\)O molecule in the first solvation shell.

When CaO is introduced into a unit cell containing 62 H\(_2\)O molecules, Ca\(^{2+}\) and 2 OH\(^-\) are formed within femtoseconds. Subsequently, the two species are found to form transient Ca(OH)\(^+\) and Ca(OH)\(_2\) complexes. At \(\{T=500 \text{K}, P=0.5 \text{GPa}\}\) we predict the relative average concentrations 3%, 26%, and 71% for the species Ca\(^{2+}\), Ca(OH)\(^+\), and Ca(OH)\(_2\), respectively, while at \(\{T=900 \text{K}, P=0.9 \text{GPa}\}\) we obtain 4%, 35%, and 62%.

Combining CSIA with ground water dating: A first step toward the determination of in-situ PCE degradation rates

C. Aeppli, H. Amaral, M. Berg and R. Kipfer

Eawag, Swiss Federal Institute of Aquatic Science and Technology, 8600 Dübendorf, Switzerland
(christoph.aeppli@eawag.ch)

Method and field site description
In order to predict the fate of organic pollutants in groundwater systems it is essential to know degradation rates. The combination of compound-specific stable isotope analysis (CSIA) with transient groundwater tracer techniques allows determining degradation rates in situ.

To demonstrate the feasibility of this concept, a former industrial site was investigated. Due to leakage of perchloroethene (PCE) solvent tanks, PCE as well as its transformation products trichloroethene, cis-dichloroethene and vinyl chloride were detected in ground water in concentrations up to 50 mg/L. We measured carbon stable isotopic signatures of these compounds and performed tracer-based ground water dating to determine the efficiency and typical biodegradation rates of these pollutants under natural conditions.

Principle findings and discussion
Along selected flow pathways, the isotopic signature \(\delta^{13}C\) of PCE changed from -24 \% up to -1 \% (vs. VPDB), which was a clear evidence for on-going degradation. Using a simple Rayleigh evaluation scheme and a set of isotopic enrichment factors deriving from literature, a range of degree PCE-biodegradation was calculated. However, since the published enrichment factors differ for more than an order of magnitude, the degree to which amount PCE was degraded could not reliably be determined. If the relevant enrichment factor of the site would be known, the biodegradation could be exactly quantified from isotopic data. Together with the determined local \(^{3}H-^{3}He\) ground water age differences of more than 20 years, PCE degradation rates can be obtained.

As \(^{13}C\) enrichment along with increasing water residence time was also observed in all the transformation products, the total dechlorination of PCE to non-toxic products was evident. However it remains open whether the degradation of the intermediates is complete.

Conclusions and outlook
In order to track and to quantify the degradation of chlorinated ethenes, the site-specific enrichment factor has to be determined. Such work is in progress and will allow us to obtain the effective degradation rates under the natural conditions being characteristic for our contaminated field site.
A noble gas record of groundwater recharge, paleoclimate, and mantle degassing in the North China Plain

W. AESCHBACH-HERTIG1, A. KREUZER1, C. VON ROHDEN1 AND Z. CHEN2

1Institute of Environmental Physics, University of Heidelberg, INF 229, D-69120 Heidelberg, Germany; aeschbach@iup.uni-heidelberg.de
2Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences, 050803 Zhengding, Hebei, China

The North China Plain (NCP) is the largest alluvial plain in East Asia. It is one of the most densely populated areas of the world with great agricultural importance for China. The climate is continental semi-arid, with most of the about 600 mm/yr of precipitation falling during the East Asian monsoon season in summer. Intensive groundwater use for irrigation has led to strong drawdown of the potentiometric surface.

The study of the aquifer system in the NCP, in particular of groundwater recharge and its dependence on climate conditions, is therefore of vital interest. We present noble gas, stable isotope and radiocarbon data from 52 groundwater wells in the NCP that provide information on groundwater recharge in the piedmont plain, paleoclimate in the central plain, and mantle He degassing in the coastal plain.

In the unconfined aquifer of the piedmont area, tritium-bearing waters with 3H-3He ages younger than 40 yr are found down to depths of more than 10 000 m, indicating rapid vertical infiltration. The corresponding recharge rate of about 1 m/yr exceeds precipitation and can only be explained by recycling of groundwater pumped for irrigation. Effects of the anthropogenic modification of the recharge regime are also apparent in Ne excesses and stable isotopes.

Paleowaters with 14C ages up to nearly 40 kyr are found in the deep confined aquifers of the central plain. Noble gas temperatures indicate a glacial cooling of 4 - 5 °C relative to the holocene. However, the coldest period of the last glacial maximum is not represented in the record, presumably because recharge was limited during this extremely arid phase. Depletion of the stable isotopes in the paleowaters can be ascribed to cooling and increased monsoon intensity.

The deep groundwater from the coastal region is near the limit of 14C dating and exhibits the highest He excesses. While the excess He in the central plain has a radiogenic signature (3He/4He = 6·10^{-8}), the 3He/4He ratio increases in the coastal plain by an order of magnitude. This unusual feature clearly indicates the presence of a mantle He component, which can be attributed to known fault zones. Mantle He has also been observed in hydrocarbons from this area.

B isotope study on Tourmalines and Axinites in hydrothermal systems: Insights into fluid circulation

S. AGOSTINI1, T. OYMAN2, S. TONARINI3 AND M.Y. SAVAŞÇIN4

1,3Istituto di Geoscienze e Georisorse-CNR, Via G. Moruzzi, 1, Pisa–Italy (s.agostini@igg.cnr.it; s.tonarini@igg.cnr.it)
2,Dokuz Eylül University, Bornova (Izmir) –Turkey (tolga.oyman@deu.edu.tr; yilmaz.savascin@deu.edu.tr)

Boron isotope compositions were determined in tourmalines and axinites from three different geological contexts in Western Anatolia, linked by the emplacement of granitic intrusion at crustal levels.

In Kadıkalesi (Bodrum), tourmalines in a Late Miocene monzodioritic pluton have low δ11B (-9‰), whereas tourmalines hosted in veins cutting the intrusion and in younger aplitic dikes show higher values of -6 ‰.

In Sinancilar, Menderes Massif, magmatic tourmalines of Early Miocene granitic-granodioritic body, and those belonging to late veinlets cutting the granite, have similar values (δ11B ≈ -4‰), whereas a progressive δ11B lowering is observed in tourmaline veins in host rocks away from the plutonic body (-7‰).

Thus, δ11B increasing in late hydrothermal tourmaline is observed in Bodrum, and the opposite is found in Menderes Massif. This different behavior between magmatic and late magmatic-hydrothermal tourmaline suggests that δ11B variations are mainly controlled by different proportion between magmatic and hydrothermal fluids, more than fluid-mineral isotopic fractionation.

In Maden Adası (Ayvalık), an Early-Middle Miocene volcano-sedimentary complex was subjected to extensive contact metamorphism. Axinites crystallized in Calcsilicate rocks of thermo-metamorphic aureola, from low-T to high-T rocks. The systematic variation of δ11B from -12.6‰ in the lower metamorphic degree samples to -7‰ in the higher temperature rocks, is mainly attributed to B isotope fractionation between circulating fluids and mineral.

Therefore, fluid-mineral boron isotope fractionation seems to play a major role when different B coordination occurs between fluids and crystallizing phases, like trigonal-B in fluids and tetragonal-B in axinites, whereas it is less important in the fluid-tourmaline (both trigonal-B) system.
Evolution of upper mantle in Southern Sanandaj – Sirjan zone of Iran

H. AHMADIPOUR
Dept. of Geology, Shahid Bahonar University, Kerman, Iran
(hahmadi@mail.uk.ac.ir)

In the Southern Sanandaj – Sirjan zone (Iran), there are several ultramafic complexes such as Kuhshah, Soghan and Abdasht. They have many evidences for belonging to the upper mantle and contain dunite, harzburgite and chromitite that in some parts, have been invaded by pyroxenitic intrusions. They show some evidences in various scales for evolution of upper mantle in this part of Iran. In the field, there are many pyroxenite veins and dykes that have been cut ultramafic sections and implies that upper mantle in this area have partially melted and then, resulting melts, have perculated in the other parts of the complexes and impregnated them. In microscopic scale, existence of second generation of orthopyroxene, clinopyroxene, olivine and euhedral chromespinels indicate strong percolation and melt/rock interaction in the upper mantle of the area. First generation minerals are large elongated and deform grains, while second ones have crystallized as small interstitial grains without any deformation. From mineral chemistry point of view, there are also two generation of minerals with different chemical composition. For example, first generation orthopyroxenes (Opx1) rich in compatible and depleted in incompatible elements relative to second generation ones, (NiO in Opx1=0.16 w% and NiO in Opx2=0.07 w%). In clinopyroxenes and olivines, there are similar properties too. Geochemical data on whole rocks indicate harzburgites are depleted mantle rocks that have partially melted and then invaded and impregnated by silicate ascending melts. REE patterns of these harzburgites show depletion relative to primitive mantle, but LREE enrichments relative to MREE are evident. This feature can be produced by entrance of more incompatible REE(LREE) from melts to the harzburgites. All of these evidences indicate upper mantle in Sanandaj-Sirjan zone, have been affected by partial melting and melt/rock interaction so there is strong heterogeneity in various scales in this part. The ultramafic complexes of Sanandaj-Sirjan have ascent and emplaced in the crust tectonically, and textural features show reequilibration in crustal conditions.

Geology, mineralogy, and genesis of the Iwami-Ginzan silver mine, Japan

M. AKASAKA, H. KOMURO AND H. OHIRA
Department of Geoscience, Shimane University, Matue, Japan
(akasaka@riko.shimane-u.ac.jp; komuro@riko.shimane-u.ac.jp; ohira@riko.shimane-u.ac.jp)

The Iwami-ginzan silver mine produced an enormous amount of silver following its discovery in 1309, and thus played a very important role as a major silver producing field, not only in Japan, but also at a global scale. The Iwami-ginzan silver deposit contains two types of ore bodies named the Fukuishi and Eikyu deposits: the former is disseminated type, and the latter vein-type. They are related to the dacite intrusion generated during the Pleistocene epoch of the Quaternary (Sakota et al. 2000).

The ore minerals of the Eikyu deposit are native silver, argentite, electrum, matildite, polybasite, stromeyerite, silver-bearing tetrahedrite, aikinite, Bi-bearing polybasite, wittichenite, tetrahedrite-tennantite, enargite, chalcopyrite, chalcocite, galena, sphalerite, and pyrite. The genetic temperature may be about 200°C. The disseminated Fukuishi deposit contained not only native silver, argentite and hematite but also jalpaite, mackinstyrite, pearceite, stromeyerite, and chlorargyrite. The genetic temperature of the Fukuishi deposit might be about 100°C.

There is a significant gravity anomaly in the Iwami-ginzan area, indicating existence of a cauldron, and the Iwami-ginzan is situated at the rim of the cauldron. During the Neogene, hydrothermal solutions are considered to have repeatedly infiltrated the faults and fractures in and around the cauldron. The hydrothermal solutions which produced the Iwami-ginzan silver mine also passed through these pre-existing faults and fractures. The very high ore grades in the Iwami-ginzan silver mine may have been caused by remobilization of earlier mineralization, and hence are the product of multiple episodes of ore genesis.

Sulphur isotopic composition of volcanic-hosted sulphide deposits at the Neoarchaean greenstone belts and the Belomorian mobile zone (Baltic Shield): A comparative study

A.M. AKHMEDOV AND S.S. SHEVCHENKO
Russian Geological Research Institute (VSEGEI), St.-Petersburg, Russia (anver_ahmedov@vsegei.ru)

In the NE Baltic Shield the Late Archaean (2.81 – 2.76 Ga) greenstone belts and the Belomorian mobile zone (BMZ) comprise massive sulphide deposit associated with host volcanics. Sulphur isotopes in pyrite from the ores have been studied.

Generally the two types of Late Archaean greenstone belts are distinguished in the Baltic Shield: 1 – with prevalence of basic–ultrabasic metavolcanics; 2 – with predominance of felsic volcanic rocks. Within the BMZ the massive sulphide ore is associated with medium to felsic metavolcanics. In all the mentioned structures the sulphide ores constitute thick extensive bodies.

Discussion of results

Sulphur isotope composition in pyrite from the massive sulphide deposit of the 1- type greenstone belts resembles that of meteorite. In the latter $\delta^{34}S$ insignificantly varies within $-2 - +1^{\circ/o}$. In the massive sulphide deposit from the 2- type greenstone belts, dominated by felsic volcanics, the sulphur isotopes range more considerably $\delta^{34}S = -6 - +4^{\circ/o}$. The sulphide ore of the BMZ has even wider span of sulphur isotope composition $\delta^{34}S = -12 - +6^{\circ/o}$.

Conclusions

Pronounced variance of sulphur isotope compositions in the massive sulphide deposits associated with different volcanics of the Neoarchaean greenstone belts has been revealed. This may be explained by divergent depth of ore-producing magmatic chambers, which caused discrepant fractionation of sulphur isotopes.

In the BMZ the widest range of sulphur isotope compositions with evident trend to lighter isotope enrichment is caused by variable sulphur influx from both crustal and upper mantle sources in the spreading zone tectonic setting.

Ghost primordial He and Ne

FRANCIS ALBAREDE1 AND ICHIRO KANEOKA2

1 Ecole Normale Supérieure, 69007 Lyon, France (albarede@ens-lyon.fr)
2 Earthquake Research Institute, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan (ikaneoka@aol.com)

The canonical view of He isotope geochemistry holds that high $^3\text{He}/^4\text{He}$ and solar Ne in oceanic basalts fingerprint hidden undegassed mantle sources. Competing evidence of recycled material processed next to the Earth’s surface being present in the source of Hawaiian basalts is nevertheless very strong, whether it be carried by oxygen or Hf isotopes.

We here discuss the marble-cake paradigm in the light of Shuster et al.’s (2003) diffusion data on olivine. The closure temperature for diffusion of $^3\text{He}$ is $\sim 200^{\circ}C$ and the data show that He moves around remarkably fast, e.g., more than 1 km at 1500 $K$ and more than 5 km at 2000 $K$ within 1 Gy. Ever since the accretion of the Earth, He and Ne originally hosted in primordial material therefore pervaded all the lithologies coexisting on length-scales typical of a marble-cake mantle (1-100 m), and, in particular, contaminated U- and Th-poor refractory residues tightly folded in with streaks of primitive mantle. Dunite and harzburgite residues left by ridge activity, and their high-pressure equivalents, therefore act as long-term sinks for ‘ghost’ rare gases. Conversely, such restites also act as a source of primordial rare gases for whichever recycled material gets subsequently folded in during the rest of the Earth’s history, even long after most of the primordial material has been removed by processing at mid-ocean ridges. A numerical marble-cake diffusion model with suitable parameters can reproduce the uptake of primordial gases initially present in the primordial lower mantle by background refractory residues and its subsequent transfer to younger ‘layers’ of recycled pyroxenite. Both low- and high-$^3\text{He}/^4\text{He}$ hotspots may be produced by changing the duration of the diffusion process and the U and Th contents of refolded pyroxenite layers.

Upwelling beneath mid-ocean ridges happens much too fast (<100 My) for the refractory material to be flushed clean of primordial gases by diffusion. However, once back into the deep mantle, primitive-looking He and solar Ne from these refractory layers have plenty of time to permeate into all sorts of newly neighboring layers, whether recycled or primitive. Decoupling by diffusion certainly explains the lack of coherence between $^3\text{He}/^4\text{He}$ and lithophile isotopic tracers. Although rare gas isotopes require that the upper mantle is more outgassed than the lower mantle as a whole, neither He with high $^3\text{He}/^4\text{He}$ nor solar Ne in basalts are diagnostic of the presence of primordial material in the source itself. Likewise, the missing terrestrial $^{40}\text{Ar}$ is likely to be another ghost rare gas hosted largely by refractory residues, thus essentially voiding a widely used constraint on the proportion of undegassed solid mantle.

Biogeochemistry of plutonium and uranium in intertidal sediments

M. AL-BOKARI1, J. R. LLOYD2, M. J. KEITH-ROACH3 AND F. R. LIVENS4

1Centre for Radiochemistry Research, University of Manchester, UK (albokari2003@hotmail.com)
2School of Earth, Atmospheric and Environmental Sciences, University of Manchester, UK (jon.lloyd@manchester.ac.uk)
3School of Earth, Ocean & Environmental Sciences, University of Plymouth, UK (miranda.keith-roach@plymouth.ac.uk)
4Centre for Radiochemistry Research, University of Manchester, UK (francis.livens@manchester.ac.uk)

Intertidal sediments of the NE Irish Sea basin contain elevated levels of transuranic and other nuclides derived from the authorised low level discharges to sea made by the Sellafield fuel reprocessing plant. The majority of the discharges occurred more than 25 years ago and the radionuclides have now become incorporated in offshore and intertidal sediments. These sediments provide a rare opportunity to explore the behaviour of artificial radionuclides in the natural environment. Microbially-driven redox cycling occurs in the sediments and this has been linked to seasonal variations observed in transuranic element solubilities.

Poised microcosm experiments were established using these sediments, and nitrate-, iron- and sulfate-reducing conditions developed. Radionuclide concentrations were measured by alpha spectrometry (234,238U; 238,239,240Pu) and high resolution ICPMS (235,236U). The microbial communities were characterised by DNA/RNA extraction and PCR amplification, followed by cloning and sequencing.

In the poised microcosms, plutonium solubility is enhanced approximately 6-fold in both nitrate- and iron-reducing conditions, with smaller changes in uranium solubility. Neither uranium nor plutonium are affected by sulfate-reducing conditions. 234U is more soluble than 238U, consistent with the establishment of disequilibrium, but this effect is even greater for the artificial isotope 236U, which can be used as an indicator for technogenic uranium.

The onset of nitrate-, iron- or sulfate-reducing conditions is accompanied by substantial shifts in microbial community structure, and both DNA- and RNA data give similar outcomes. In nitrate- and iron-reducing conditions, the communities are dominated by known nitrate- and iron-reducing organisms respectively. In the sulfate-reducing microcosms, known sulfate-reducers comprise only a small proportion of the community.

Solubility measurements of Neptunium-incorporated soddyite

DANIEL S. ALESSI, JEREMY B. FEIN, TORI Z. FORBES, PETER C. BURNS, JENNIFER E. S. SYMANOWSKI, AND JENALEE U. ALMES

Department of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN, 46556, USA (d Alessi@nd.edu)

Spent nuclear fuel is likely to alter to uranyl minerals under the oxidizing conditions of a geological repository. Radionuclides, such as neptunium, may become incorporated into these secondary uranyl mineral structures, potentially altering the solubility of the phases and hence the mobilities of U and Np in the repository environment. Soddyte ((UO2)2(SiO4)(H2O)2) forms as an alteration product of spent nuclear fuel in laboratory settings (e.g., Finch et al., 1999), and significant concentrations of Np can be incorporated within soddyte (Klingensmith and Burns, 2007). The solubility and thermodynamic properties of pure soddyte have been studied (Gorman-Lewis et al., 2007). It is unclear, however, what effect Np(V) incorporation into the mineral structure of soddyte will have on the mineral solubility or on the extent to which Np is released from the phase.

We synthesized soddyte in the presence of 10 to 600 ppm aqueous Np(V) and measured the release of U, Np, and Si as a function of time under controlled pH conditions. XRD and FTIR analyses demonstrated that soddyte remained the only stable uranyl phase during the course of the experiments. We use the data to constrain the value of the apparent solubility product of soddyte as a function of Np concentration in the mineral. These values can be used to predict the extent of Np release from Np-bearing soddyte phases, and therefore are useful for modelling Np mobility under repository conditions.

Mineralogical, ore-microscopic and geochemical comparative study of Fe-Ni-ores of Lokris area (Central Greece)

G. ALEVIZOS
Dept. of Mineral Resources Engineering, Technical University of Crete, Politechnioupoli, GR-73100 Chania, Greece (alevizos@mred.tuc.gr)

Nickeliferous iron ores (Fe-Ni-ores) located in the area of Lokris (Central Greece) is exploited by Larko A.G. Company. With an annual production of over than 18000 tons of nickel, Larko is ranked as one of the most important European nickel producers. In this study the Fe-Ni-ores of Agios Ioannis, Marmeiko and Tsouka deposits are compared according to their mineralogical, ore-microscopic and geochemical characteristics.

The examined Fe-Ni-ores, formed from lateritic weathering of ophiolithic complexes of the subpelagonian unit of Greece, to which the Lokris area belongs, are oolithe/pisolithe type. They consist of ooids, pisoids, peloids and abrasioliths (fragments of ooliths). Their major mineralogical constituents are hematite, goethite with minor quantities of kaolinite. Additionally in the Fe-Ni-ores chromite, Al-spinels are also present, while Ni-minerals (Nimite, Willemseite, Nepouite, Takovite) and Mn-minerals were found in minor quantities. The Fe-Ni-ores of Agios Ioannis and Marmeiko forms beds, which are placed on the karstificated limestones of Jurassic, while Tsouka ore deposit which also form beds, is placed on ultrabasic rocks. All three deposits are overlaid by transgressive sediments of the Cretaceous. The presence of fragments of ooids, clastics and abrasioliths, in the deposits of Agios Ioannis and Marmeiko, indicates redeposition of the Fe-Ni-ores. Both deposits are considered as secondary heterochthone formations. Contrary in the deposit of Tsouka the occurrence of a limited number of abrasioliths as well as the absence of inclusions of fragments of oolitis, indicates that a small transport and redeposition of the clastic components of the ooliths has occurred. The deposit of Tsouka is considered as a secondary pseudoautochthones deposit, having characteristic underlying laterite units. The correlation of the geochemical data of the deposits of Agios Ioannis and Tsouka showed that the ores formed from ultrabasic parent rocks. The relatively higher contents of Al and Ti as well as the occurrence of, Al-spinels, ilmenite with its replacement products (pseudorutile and leucoxene), anatase and magnetite, in the ores of Marmeiko, are signs for the fact that beside ultrabasic, also basic rocks were involved in the structure of the parent rocks.

Nd isotopes in Archean water masses: The importance of mantle- versus continentally-derived inputs

BRIAN ALEXANDER1, MICHAEL BAU1 AND PER ANDERSSON2

1Jacobs University Bremen, Bremen, Germany (b.alexander@iu-bremen.de, m.bau@iu-bremen.de)
2Laboratory for Isotope Geology, Swedish Museum of Natural History, Stockholm, Sweden (per.andersson@nrm.se)

The 2.9 Ga Pongola Supergroup (South Africa) contains shallow water banded iron-formation (IF) that possesses a primary seawater signature, and displays Nd isotope values indistinguishable from contemporaneous shale (εNd(t) between -2 and -4). The distinctly negative εNd(t) of the Pongola IF is atypical for many Archean IFs. Rare earth element distributions in the Pongola IFs vary as a function of relative water depth (as suggested by a transgressive-regressive cycle of IF deposition), and these observations indicate that shallow seawater along continental margins in the Archean was heavily influenced by inputs from continental weathering.

This scenario for the Pongola Supergroup is examined using data from contemporaneous IFs from the 2.9 Ga Pietersburg Greenstone Belt (South Africa). Whereas the Pongola IFs formed on a stable cratonic margin, the Pietersburg Greenstone Belt is not associated with pre-existing cratonic crust. Pietersburg IF samples display rare earth element distributions indistinguishable from older Isua IFs (3.8 Ga, Greenland) and younger Kuruman IFs (2.5 Ga, South Africa), and are consistent with primary seawater precipitates. Nd isotope signatures for the Pietersburg IFs are less negative (εNd(t) between -1 and 0) than contemporaneous shales and the coeval Pongola IFs. Therefore, it appears that Archean seawater was inhomogeneous with respect to Nd isotopes, similar to modern oceans. These data, and the contrasting depositional environments of the Pongola and Pietersburg IFs, suggests the presence of mantle-derived Nd in Archean open-ocean seawater, whereas coastal waters were dominated by continental Nd.
High-Precision Isotope Acquisition with the NanoSIMS 50L

C. ALEXANDER1, E. H. HAURI1, J. WANG1 AND F. HILLION2

1Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015, USA
2Cameca Instruments, 92622 Gennevilliers, France

The in situ measurement of isotope ratios at high precision has always been a goal of secondary ion mass spectrometry (SIMS). The NanoSIMS 50L is a third-generation ion microprobe developed by Cameca and modified in collaboration with the Carnegie Institution of Washington. This instrument incorporates a number of design and functional improvements over the stock NS50, including precise stepper motor control over all slits, apertures and stage movements, a larger magnet, and a modified multicollector (6 moveable and 1 fixed) capable of holding both Faraday cups and miniature multi-dynelectron multipliers. The instrument is capable of attaining a minimum beam diameter of <50 nanometers with Cs and <200 nanometers with oxygen (O2), a factor of 5-10 improvement over the IMS6F/7F/1280 generation of instruments. The CIW instrument is also the first NanoSIMS to be fitted with multiple Faradays and associated high-precision electrometers.

One year’s experience with the NS50L has disposed of a number of incorrect perceptions with regard to its potential and capabilities for terrestrial geochemistry:

1) "Beam currents are too low to be useful": With Cs, a routine primary beam diameter of 100 nm is obtained with 2-3pA of current, sufficient to yield >1MHz of 32S from pyrite or 16O from silicate glass at >6000 MRP. 250pA of current yields a 350 nm beam that gives an H2O detection limit of 50 ppm on olivine.

2) "You’ll never get enough signal for Faradays": A 2.5 nA Cs beam with a diameter of 700 nm yields 90 pA of 32S from pyrite at >6000 MRP, sufficient to analyze 32S-33S-34S on Faraday cups and 36S in EM @ >10,000 cps. Similar results have been obtained for oxygen from Al2O3.

3) "The instrument is unproven at high precision": In multi-Faraday mode, spot-to-spot reproducibility is 0.4 permil (1sig) or better for 32-33-34S from pyrite, and for 28-29-30Si from a silicon wafer. Reproducibility as good as 0.15 permil (1sig) has been obtained for 32-33-34S from pyrite in different holes of a single sample holder. With multiple EMs, simultaneous measurements of Mg and Si isotopes in silicates achieves a reproducibility of ~1 permil (1sig) for all ratios from multiple craters. All of these measurements were obtained in raster craters at a spatial resolution of 5-10 μm.

Other high-precision and high-resolution applications of the instrument will be presented at the meeting.

Influence of reductive dissolution of iron oxides by S(II) on uranium mobility

V.G. ALEXANDRATOS, T. BEHRENDS AND P. VAN CAPPELLEN

Faculty of Geosciences, Utrecht University, P.O.Box 80021, 3508 TA Utrecht, The Netherlands (vasso@geo.uu.nl, behrends@geo.uu.nl, pvc@geo.uu.nl)

Transient redox conditions can influence the mobility of uranium by inducing changes in iron mineralogy with which uranium may be closely associated. Iron oxides play a critical role in uranium transport by providing reactive surfaces for sorption or by assisting in U(VI) reduction. Iron oxides reductively dissolve when exposed to S(II), produced by microbial sulfate reduction. This might lead to the mobilization of adsorbed U(VI). However, U(VI) might also remain solid-bound due to adsorption onto FeS or reduction by S(II) and precipitation as UO2. This study investigates the fate of sorbed U(VI) in response to reductive dissolution of iron oxides by S(II). In batch experiments, S(II) is incrementally added to a lepidocrocite suspension with preadsorbed U(VI). The S(II) concentration decreases with time due to oxidation by Fe(III), causing an increase in Fe(II) concentration. With every S(II) addition, an instantaneous increase in dissolved uranium concentration is observed. The concentration then gradually decreases for about one hour, but remains at a higher level than before sulfide amendment. This could be due to the competition between U(VI) and Fe(II) for surface sites, or to the transformation of lepidocrocite into FeS and lower affinity of FeS surfaces for U(VI) than lepidocrocite. Preliminary results regarding possible complexation of uranium with S(II) in solution, show that this process is negligible. XANES spectra imply a gradual but partial transformation of U(VI) into U(IV) during of the experiments. Results indicate that most likely the formation of FeS might be required for U reduction.
Maghemite lag: Formation and implication for mineral exploration

SAMAD ALIPOUR
University of Urmia, Department of Geology, Urmia, Iran, (Alipour_Samad@Yahoo.Com)

Maghemite is the cubic form of Fe$_2$O$_3$ and isostructural with magnetite. It is a common mineral in weathered profiles in arid, semi-arid, subtropical and tropical environments but more rare in cooler humid regions (Eagleton, 1988).

The formation of maghemite has been attributed to aerial oxidation of magnetite, dehydration of lepidocrocite (-FeOOH) or goethite and transformation of goethite to maghemite under arid climatic conditions. It is concentrated in the course grains of bedrock remnants or grains formed at weathering profiles by accumulating surface material classified as lag. Lag” was defined by Bates and Jackson (1980) as a general term applied to coarse grained (> 2 mm), hard, but partially weathered rock fragments which concentrated at surface through attrition of finer materials. Studies show that ferruginized and maghematized lag can attract elements from subtle anomalies and reveal the metal sources with elevated contrast compared to ill nature soil and aeolian materials (Alipour et al., 1994 and 1995; Robertson, 1989 and 1995).

Therefore, its unique characteristics such as abundance in arid regions, covered deserts or cultivated lands, converts it to an excellent sampling media. Comparing geochemical behavior of maghematized and non-maghematized materials, maghematized lag can be sampled at first stage of regional exploration to delineate potential targets and non or weakly maghematized lag could be used in follow up stages to locate the source of the anomalies.

Fe-Ti oxide minerals geochemistry of Late Triassic Carpathian Keuper sandstones: Implications for provenance

ALI I. AL-JUBOURY
Research Center for Dams and Water Resources, Mosul University, Iraq (alialjubory@yahoo.com)

Selected Fe-Ti oxides minerals from the Carpathian Keuper sandstones at different localities from Slovakia were analyzed by JEOL-JXA-733 Super probe analyzer and identified as highly altered and fractured Fe-Ti oxide minerals. Iron oxides which form a large portion of the heavy minerals in the samples examined are represented mostly by ilmenite, titaniferous magnetite, leucoxene, and hematite. Chemical analysis of Fe-Ti oxides revealed that the total oxides generally are low and this may be related to the alteration on these grains. Most of Fe-Ti oxide minerals studied are polymineralic grains with mixture of two or more phases. The chemical composition of some grains indicates a coexisting mixture of ilmenite and titano-magnetite. The highly TiO₂ concentrations may indicate the metamorphic source rocks origin of the studied grains (Basu & Molinaroli 1989, 1991).

By comparing the present chemical results with that mentioned by aforementioned authors, it appears that Keuper ilmenites generally were derived from metamorphic and partly from igneous sources. Based on the mineralogical and geochemical indicators, the probable provenance of the Keuper sandstones was mainly the metamorphic and igneous rocks of the crystalline cores of the Western Carpathians and the foreland of the Bohemian Massif which were weathered and deposited in the continental mainly fluvial and littoral environments of deposition of the Keuper Formation.

Open system behaviour and early chronologies in the Solar System

C. J. ALLEGRE, C. GÖPEL, G. MANHES AND M. MOREIRA
Equipe de Geochimie et Cosmochimie, Institut de Physique du Globe de Paris et Université Paris-Diderot, CNRS; 2 Place Jussieu, 75005 Paris, France (allegre@ipgp.jussieu.fr)

The problem of concordant ages between different chronometers in meteorite chronology is discussed since the earliest comparisons between the precise chronologies obtained by ⁸⁷Rb-⁹²Sr and ¹²⁹I-¹²⁹Xe were made. However in recent years the subject became again important since considerable analytical progress has been achieved and allowed one to use a variety of extinct radioactivities: ⁵⁶Al-⁵⁷Mg, ⁵³Mn-⁵⁴Cr, ¹⁸²Hf-¹⁸⁴W, ¹⁴⁶Sm-¹⁴⁴Nd and ¹²⁹I-¹²⁹Xe.

Most “apparent ages” obtained by different chronometers have been calibrated against the set of U-Pb ages obtained on chondritic phosphates (Göpel *et al.* 1994). The older age considered as an absolute reference corresponds to 4567 Myr and was obtained on refractory inclusions of the Allende meteorite by Manhès *et al.*, (1988) and later confirmed by Amelin *et al.* (2002).

When the whole set of apparent ages obtained by various chronometers is considered, no simple pattern is visible. Some chronometers compared to another chronometers may give older ages for a few objects, applied on other objects they result in younger.

These inconsistencies are observed by assuming that each chronometer behaves as a closed system and by using simple chronometric equations for each of them.

We developed a quantitative model in which meteorites behave as open systems. After their initial formation the system has been perturbed by shock events, reheating, metamorphism occurring on planetesimal or meteorite parent bodies. We can compute a model for continuous or episodic perturbations assuming that the perturbations generate a loss of radiogenic isotopes or a change in the parent-daughter ratios.

This model shows how ages obtained by two chronometers can be sometimes older, sometimes younger depending the age of perturbation event and its intensity. We also may obtain concordant ages between a long lived and short lived chronometer which however have no physical significance, concordancy being just an artefact.

We can interpret all the apparent ages obtained on meteorites with this model. The data are compatible with a model in which all primitive solid objects formed around 4567 Myr and were subsequently perturbed by events occurring from few hundred thousands years to 100 Myr.

**In situ crystallisation processes in the Miocene PX1 pyroxenite intrusion (Fuerteventura)**

J. ALLIBON¹, F. BUSSY² and É. LEWIN³

¹(james.allibon@unil.ch)  
²(francois.bussy@unil.ch)  
³(eric.lewin@ujf-grenoble.fr)

The PX1 gabbro-pyroxenite intrusion of Fuerteventura (Canary Islands) displays a remarkable NNE-SSW trending vertical magmatic layering. This layering is strongly dependent on the regional tectonic regime and is expressed by alternating horizons of gabbros and pyroxenites, generated by successive magma injections into a progressively widening dyke system. Multi-scaled compositional variations span from olivine-rich pyroxenite, pure clinopyroxenite and plagioclase bearing pyroxenite to non-cumulative gabbro.

Whole-rock incompatible trace-element contents show large variations and poorly correlate with monotonous major element compositions, these features are typical of in situ crystallisation (Langmuir 1989) with variable amounts of interstitial liquid (L). La-ICPMS analyses of minerals and quantitative modelling based on Langmuir’s equation using REE concentrations in mineral phases show that these underwent re-equilibration with interstitial melts (Hermann et al. 2001).

Calculated REE patterns of mineral phases in samples are adjusted to fit the measured REE plots by playing with the degree of differentiation (F) and the proportion of interstitial liquid (L). L has a stronger influence than F on LREE for low degree of differentiation (F) and the proportion of interstitial adjusted to fit the measured REE plots by playing with the modal proportions of amphibole.

Dcpx were estimated using a predictive model (Wood & Blundy, 1997) on a sample selected for low whole-rock Zr, Nb and ZRE (24,33 ppm), and displaying a Eu/Eu* close to unity (0.96). The bulk rock partition coefficients have been estimated using modal contents of an olivine-gabbro sample.

The calculated amounts of L are 15 to 30% for plagio-pyroxenites and gabbros and correlate well with the proportion of interstitial amphibole in studied samples. The calculated amounts of fractionation (F) relative to a primary magma crystallisation experiment at 200 and 500 MPa. All experiments have been performed in an internally heated pressure vessel at intrinsic oxygen conditions using pure argon as a pressure medium. Three starting basaltic compositions have been chosen so that Ol, Plag or Cpx are crystallizing as a liquidus phase. The H2O concentrations in the glasses were obtained by infrared spectroscopy and Karl-Fischer-Titration.

As a result of the study we parameterized our experimental data in the form of simple equations describing the liquidus of Ol, Plag and Cpx as a function of dissolved H2O content. Finally, these simple equations have been incorporated into the algorithm of the COMAGMAT program [3].

Application of the refined COMAGMAT model is presented for basaltic lavas from the Mid-Atlantic Ridge (MAR) east of Ascension Island (7-11°S). To determine crystallization conditions of the given MORB suite two sets of equilibrium and fractional crystallization calculations have been performed. The results indicate that MORB-magmas beneath different segments of the MAR have crystallized over a wide range of pressures (100 to 900 MPa). Nearly isobaric crystallization conditions (100-300 MPa) were obtained for the geochemically enriched MORB, whereas N-MORB magmas are characterized by polybaric crystallization conditions (200-900 MPa). Our results demonstrate close to anhydrous crystallization conditions of N-MORBs, whereas geochemically enriched MORBs were successfully modeled in the presence of 0.4 to 1 wt % H2O in parentals melts. Our results are in agreement within ±200 MPa with previous approaches used to evaluate pressure estimates in MORB. In addition, our data illustrate that the effect of H2O on pressure estimates is within this uncertainty.

**The effect of minor H2O content on crystallization in MORB: Experiments, model, applications**

R.R. ALMEEV¹, F. HOLTZ¹, J. KOEPEK¹ and A.A. ARISKIN²

¹Institute of Mineralogy, Leibniz University of Hannover, Germany (r.almeev@mineralogie.uni-hannover.de)  
²Vernadsky Institute, Moscow, Russia

The role of H2O on mineral cotectics and petrochemical trends in MORB systems has been thoroughly discussed in the literature (e.g. [1]). However, the quantitative knowledge on the effects of small amounts of H2O on the liquidus of olivine (Ol), plagioclase (Plag) and clinopyroxene (Cpx) is still limited by the lack of experimental data with well-constrained values of water activity. This, probably, results in considerable inconsistency between the available models [1-3] predicting the mineral liquidus depression as a function of the water dissolved in the melt.

To address the problem we conducted a set of crystallization experiments at 200 and 500 MPa. All experiments have been performed in an internally heated pressure vessel at intrinsic oxygen conditions using pure argon as a pressure medium. Three starting basaltic compositions have been chosen so that Ol, Plag or Cpx are crystallizing as a liquidus phase. The H2O concentrations in the glasses were obtained by infrared spectroscopy and Karl-Fischer-Titration.

As a result of the study we parameterized our experimental data in the form of simple equations describing the liquidus of Ol, Plag and Cpx as a function of dissolved H2O content. Finally, these simple equations have been incorporated into the algorithm of the COMAGMAT program [3].

Application of the refined COMAGMAT model is presented for basaltic lavas from the Mid-Atlantic Ridge (MAR) east of Ascension Island (7-11°S). To determine crystallization conditions of the given MORB suite two sets of equilibrium and fractional crystallization calculations have been performed. The results indicate that MORB-magmas beneath different segments of the MAR have crystallized over a wide range of pressures (100 to 900 MPa). Nearly isobaric crystallization conditions (100-300 MPa) were obtained for the geochemically enriched MORB, whereas N-MORB magmas are characterized by polybaric crystallization conditions (200-900 MPa). Our results demonstrate close to anhydrous crystallization conditions of N-MORBs, whereas geochemically enriched MORBs were successfully modeled in the presence of 0.4 to 1 wt % H2O in parentals melts. Our results are in agreement within ±200 MPa with previous approaches used to evaluate pressure estimates in MORB. In addition, our data illustrate that the effect of H2O on pressure estimates is within this uncertainty.

Stone decay in two-mica granite buildings of Northern Portugal

A. ALMEIDA¹ AND A. BEGONHA²

¹GIMEF, CGUP, Faculty of Sciences, Porto University, Portugal (aalmeida@fe.up.pt)
²Civil Engineering Department, Faculty of Engineering, Porto University, Portugal (abegonha@fe.up.pt)

The application of the natural stone as a building material catalyzes the deterioration process due to the reactivity between the rock minerals and industrial mortars and to the exposure to particular environmental conditions. Among the main factors in the origin of stone decay, the intrinsic characteristics of the rock are determinant in the behaviour of its constitutes. Three historical granite monuments from the Oporto region, largely affected by a diversity of stone deterioration types, have been selected in order to illustrate the combination of the intrinsic factors with weathering and environmental agents, responsible for the susceptibility of granite stones to deterioration: a millenarian Xth century Romanic church, a XVIIIth century Baroque church and a XIXth century neoclassical building. The granite the selected monuments are built with is classified as a medium- to coarse-grained leucogranite, syntectonic in relation with the third Hercynian deformation phase. This granite exhibits a non-porphyritic hydridomorphous granular texture and a mineral association of quartz, orthoclase, perthitic microcline, albite, muscovite and biotite. Apatite, zircon, monazite, ilmenite, and scarce tourmaline and garnet are accessory minerals. The granite is affected by late-to post-magmatic alteration as well as by weathering processes to various extents. In some outcrops the potassic feldspar is intensely kaolinized. The A/KCN molar ratio between 1.3 and 1.5 is an evidence of a strong peraluminous character due to the presence of primary muscovite. A U-Pb geochronological study on zircon and monazite indicates a minimum emplacement age of 318±2 Ma (Almeida, 2001). The granite stones applied in the selected monuments display different weathering degrees, as a consequence of different susceptibility to deterioration. Granular disintegration, plates, flakes, black crusts, thin black layers, efflorescences and biological colonization are the main deterioration types. Gypsum, halite, niter, glauberite, calcite, apatite, thomandite, anatase and mirabilite have been detected by X-ray diffraction and SEM analyses and play an important role in the stone decay (Silva, 2005). The main source of salts is rainwater, affected by the proximity with the Atlantic Ocean. Carbon and sulphur rich porous fly ashes and silicon and aluminium rich smooth fly ashes are also present, in the thin black films, produced by air pollution agents.

The CaCO₃ saturation state of Phanerozoic oceans

G. ALOISI

UMR5125 PEPS, CNRS, Université Lyon 1, Villurbanne Cedex, France (Giovanni.Aloisi@univ-lyon1.fr)

Geochemical models suggest that perturbations of the global carbonate cycle in the geologic past resulted in large variations in the CaCO₃ saturation state (Ωₐ) of the ocean (Zeebe and Westbroek, 2003; Ridgwell, 2005). These variations may have influenced the evolution of biocalcifying organisms and global sedimentation patterns. To independently test these ideas, I deduce information on past oceanic Ωₐ from the geological record of calcified cyanobacteria and a numerical model of cyanobacterial mat calcification. A curve of threshold oceanic Ωₐ needed for cyanobacterial calcification is derived and compared to the Phanerozoic distribution of calcified cyanobacteria, providing some constraint on past oceanic Ωₐ levels. To this curve correspond threshold curves of pH and total alkalinity (TA). The emerging picture of considerable oceanic Ωₐ variation through time matches the long-term tectonic, geochemical and biological evolution of the Earth System: Ωₐ maxima at the base of the Cambrian (545 Ma; Ωₐ > 12), most of the Carboniferous (330-300 Ma; Ωₐ > 7), the mid Permian (280-260 Ma; Ωₐ > 9) and the late Triassic (210–200 Ma; Ωₐ > 7) correspond to periods of increased continental weathering or decreased neritic depositional space. A prominent drop in oceanic Ωₐ starting from an early Jurassic high (Ωₐ > 7) to a mid-Cretaceous low (Ωₐ < 3) records the advent of planktic calcifiers during the “mid-Mesozoic revolution”. Low and relatively stable oceanic Ωₐ after this event confirms the efficiency of the carbonate compensation mechanism in stabilising the global carbonate cycle. Both the “Cambrian Explosion” and key moments of the “mid-Mesozoic revolution” took place in highly supersaturated oceans, suggesting a link between these major evolutionary events and changes in ocean chemistry. Global biocalcification crises associated with Mesozoic oceanic anoxic events took place in poorly supersaturated oceans, when short-lived (< 1 Ma) perturbations of the global carbon cycle would have been most effective in inhibiting biocalcification.

Organic matter is mineralized in marine sediments by microbial activity using predominantly oxygen, sulfate, and metal oxides as electron acceptors. Modern euxinic basins as found in the Baltic Sea or the Black Sea are of particular importance because they may serve as type systems for anoxia in Earth’s history.

We present here first results from biogeochemical investigations carried out in the Baltic deeps (Gotland Basin, Landsort Deep) during the first scientific cruise of the new German RV M.S. MERIAN in 2006. Short sediment cores were obtained with a multi-corer and analyzed for particulate and dissolved main, minor and trace elements besides stable carbon isotopes in dissolved inorganic carbon (DIC). Microsensors were applied to analyze steep gradients of oxygen, sulphide and sulphate. Pore water profiles were evaluated in terms of process rates and associated element fluxes. Gross and net anaerobic mineralization rates were additionally obtained from core incubations with \textsuperscript{35}S or bag incubations of sediment sections. Highest SRR were found in the top 5-10 cm. Element fluxes across the sediment-water interface were compared with re-evaluated literature data and show for the Baltic Sea a dependence from bottom water redox conditions, and sediment compositions and formation conditions (e.g., accumulation rates).

Interaction of fluid flow, heat and mass transport, and chemical reactions in oceanic hydrothermal systems: New insights from fully coupled reactive transport simulations

P. ALT-EPPING AND L.W. DIAMOND
Institute of Geological Sciences, RWI-Group, University of Bern, Baltzerstrasse 1, CH-3012, Bern, Switzerland (alt-epping@geo.unibe.ch)

Circulation of seawater through the oceanic crust and the chemical reactions that occur along the flowpath control the composition of vent fluids. We use 1D and 2D fully coupled reactive transport models to explore the evolution of fluid flow, heat transport and chemical reactions in the oceanic crust and the implications for mineral alteration patterns and vent fluid composition.

Fully coupled models are required to assess the complex interaction between chemical alteration, fluid flow and thermal conditions in the oceanic crust. The recharge of seawater into the basaltic crust causes the precipitation of significant volumes of anhydrite and chlorite which reduces the porosity and thus the permeability of the recharge zone. Similarly, cooling of the hydrothermal fluid as it ascends to the seafloor below hydrothermal vents may lead to the precipitation of minerals such as quartz and a reduction in permeability. Alteration reactions in the high-temperature reaction zone also introduce some heterogeneity of the permeability distribution which are, however, somewhat less pronounced than the permeability reduction in the recharge and discharge zones due to lower thermal and/or compositional gradients and closer to equilibrium conditions. Therefore, over time chemical reactions have the potential to modify the flow field and the thermal conditions in oceanic hydrothermal systems which could lead to observable changes in discharge rate, temperature and/or chemical composition of seafloor hydrothermal vents.

It is interesting that, despite this potential for temporal evolution, the composition of vent fluids in oceanic hydrothermal systems (e.g. 21ºN, East Pacific Rise) are observed to remain constant on a decadal time scale. The fluid composition at these vents is consistent with rock buffering at greenschist metamorphic conditions. Our simulations are therefore aimed at incorporating this observational constraint and quantifying the magnitude, spatial distribution, time scales and rates of chemically induced permeability changes and the associated effect on flow and thermal conditions and the impact on the evolution of the vent fluid composition. Critical parameters and aspects that are explored in these simulations are water/rock ratios (which are dependent on the permeability and the reactivity) and the formulation of the porosity / permeability coupling used in the reactive transport code.
‘Geochemical’ research: Key building block for radwaste disposal safety cases in clayrocks

SCOTT ALTMANN
Andra, 1/7 rue Jean-Monnet, Chatenay-Malabry, 92298 FR

Disposal of high-level radioactive waste in deep underground repositories has been chosen as the solution by several countries. Because of the special status that this type waste has in the public mind, national implementation programs typically mobilize massive R&D efforts, last decades and are subject to extremely detailed and critical social-political scrutiny. The culminating argument of each program is a ‘Safety Case’ for a specific disposal concept containing, among other elements, the results of performance assessment (PA) simulations whose object is to model the release of radionuclides (Rn) to the biosphere. Public and political confidence in PA results (which generally show that Rn release will always be at acceptable levels) is based on their confidence in the quality of the scientific understanding in the processes included in the PA model, in particular those governing radionuclide speciation and mass transport in the geological host formation. Geochemistry (obviously) constitutes a core area of research in this regard.

Clay-mineral rich formations are the targets of radwaste programs in several countries (France, Belgium, Switzerland…), principally because of their demonstrated capacities to adsorb many radionuclides and to limit (diffusion-dominated) mass transport. The corresponding key processes in PA models are radioelement chemistry (redox state, speciation, reactions determining Rn solid-solution partitioning) and diffusion-driven transport. These processes take place in solution-filled pore spaces, most of which are bounded by the surfaces (basal, interlayer, edge) of permanently charged clay minerals. In addition, natural rocks always contain other solid phases potentially capable of influencing radionuclide speciation (pyrite, organic matter…) as well as being physically and chemically heterogeneous at space scales ranging from sub-millimetric to hectometric.

In order to gain the detailed scientific understanding needed for constructing those parts of the Safety Case supporting how Rn transfer is represented in the PA model, a wide range of coordinated (and internationally collaborated) research has been carried out. The purpose of this presentation is to illustrate how research results in fields ranging from molecular dynamic calculations of ion distributions and mobility near clay surfaces, to clay surface-catalyzed transformations of the redox state of certain elements (Se…), to the effects of electrical double layers on the composition and ion transport properties of clayrocks, to measurement and model representation of micro-scale mineral-porosity relationships and the effects on diffusion, to use of geochemical modeling to estimate porewater composition, to use of high resolution detection methods to quantify diffusion at sub-millimeter scales…, have contributed to building convincing Radwaste Safety Cases.

Depleted uranium in the environment: A biogeochemical study

R. ALVAREZ1,2, F.R. LIVENS1,2, J.R. LLOYD1 AND D.J. VAUGHAN1

1Williamson Research Centre for Molecular Environmental Science and School of Earth, Atmospheric and Environmental Sciences, The University of Manchester, UK; (rebeca.alvarez@manchester.ac.uk); (david.vaughan@manchester.ac.uk); (jon.lloyd@manchester.ac.uk)
2Centre for Radiochemistry Research, School of Chemistry, The University of Manchester, UK; (francis.livens@manchester.ac.uk)

Geochemical and microbial processes affecting the decomposition and dispersion of military depleted uranium (DU)/titanium alloy penetrators are being investigated. Since the behaviour is unique to this form of uranium, laboratory model systems are being used to define the effects of the chemical and microbial processes involved in decomposition. The effects of DU on bacterial communities are of particular interest and are being studied using both culturing and molecular methods, together with quantification of dissolved, colloidal and macro-particulate fractions of uranium decomposition products.

DU coupons with a mass of ca 8 g have been exposed to aqueous media containing appropriate terminal electron acceptors (TEA: oxygen, nitrate, Fe(III) or sulphate), and indigenous bacteria, either those present in various selected soils, or an inoculum cultured from an estuarine sediment and a loamy clay soil. The concentrations of the added TEA groups were monitored over time. Microcosms were supplied with excess electron donor and sacrificed once TEA reduction was complete. Abiotic control samples were also prepared for comparison.

There was greater degradation of DU by cultured aerobes, including ‘pitting’ of the surface when compared to anaerobes. An example of the pitting is shown in the photograph below taken after only one day of incubation at 15 °C.

The extent of DU corrosion under different conditions can be related to changes in solution geochemistry and microbial community structure.
Phanerozoic crustal growth constrained by zircon U-Pb age and Sr-Nd-Hf isotopic evidence from the granitoid rocks in Mongolia

S. AMAR-AMGALAN, R. TANAKA, K. KOBAYASHI AND E. NAKAMURA

The Pheasant Memorial Laboratory, Institute for Study of the Earth’s Interior, Okayama University at Misasa, Japan

Mongolia is the largest segment of the Central Asian Orogenic Belt which is formed by accretion of island arcs and subdomain Precambrian microcontinents (Badarch et al., 2002). Here we report new U-Pb zircon ages and Sr-Nd-Hf isotopic data of granitoids from four representative areas along one transect from northwestern to southeastern Mongolia (Ider, Erdene, Akhar-Uul and Khanbogd). Zircon U-Pb age data show three distinct age ranges: ca. 538 Ma; 368-290 Ma; and 262–216 Ma, which reveal that: (1) Granitic magmatism in Mongolia was most active during the Carboniferous to Permian; (2) The Cambrian granitoids were emplaced in the Akhar-Uul area in the southern part of Mongolia, although previous studies assumed that the distribution of granitoids young towards the south; (3) The late Permian to Triassic granitoids are mainly located in the central part of the Mongolia (Erdene area). The widespread granitoids indicates accretion and collision processes took place continuously throughout the Phanerozoic. Isotopic data display significant differences along the transects. The Cambrian peraluminous granitoids in the Akhar-Uul area, in the passive continental margin terrane (Badarch et al., 2002) show high initial Sr isotopic compositions (0.7135 to 0.7244), and low εNd (-8.2 to -8.8) and εHf (-12 to -16). These features suggest that they were derived from sediment source and produced by erosion of old continental crust and were likely emplaced in a forearc environment. Granitoids in the Khanbogd area in an island arc terrane (368 to 290 Ma) show high εNd (+5.3 to +9.9) and εHf (+7.5 to +9.8) whereas those in Ider (350 to 290 Ma), Erdene and Akhar-Uul areas (282 to 213 Ma) that were emplaced in the Precambrian cratonic and Ordovician clastic basin terranes lower εNd (-2.7 to +4.7) and εHf (-4.1 to +5.5). The depleted isotopic character in the Khanbogd area corresponds to the upper mantle and lower crustal xenoliths included in Cenozoic volcanic rocks, suggesting these granitoids were formed by melting of mafic lower continental crust that was originally formed by mantle-derived magma. Whereas enriched isotopic signatures those in Ider, Erdene and Akhar-Uul areas may be explained by interactions with preexisting old crust where they were emplaced.

Tracer analyses as a tool to validate the effectiveness of pump-and-treat measures in the field.

HELENA AMARAL AND ROLF KIPFER
Eawag – Swiss Federal Institute of Aquatic Science and Technology – Dübendorf, Switzerland.

We show that the remediation of a contaminated site, by pump-and-treat, disturbed the groundwater dynamics and lead to mixing of different water components. The remediation impacts on groundwater mixing can be traced by the noble gases $^3$He and $^4$He, and by the transient tracers CFCs and SF$_6$. At the site, chlorinated ethenes as DNAPL lay at the bottom of an aquifer of fluvial sediments, that covers the top of a molassic rock of much older age. Before and after remediation the site was sampled for noble gases, CFCs and SF$_6$. All these bio-geological conservative tracers indicate a major change in groundwater dynamics although the contamination levels remain the same.

After the remediation, the observed $^3$He/$^4$He ratios of the local groundwater were lower then the atmospheric value (1.36*10$^{-6}$), whereas before the remediation the $^3$He/$^4$He ratios were considerably larger. Such distinct change of the He isotopic composition indicates the emanation of isotopically heavy He from the molassic hardrock, most probably through fractures. This let us assume that the DNAPL penetrated into the underlying bedrock, through those fractures that allowed the He to emanate. Such DNAPL impregnation of the bedrock may explain why the remediation measures failed, and would further imply that a DNAPL contamination can hardly be removed, under such conditions, by pump-and-treat methods. Moreover, the abrupt change in the $^3$He/$^4$He ratio of the local groundwater clearly prove that the remediation measures severely impacted the natural groundwater flow regime.

Other transient tracers, such as CFCs and SF$_6$, were found to be oversaturated both before and after the remediation. However, the observed change in concentration and relative abundance, again indicate that applied pump-and-treat schemes changed the local hydraulic situation, but did not remove significant amounts of the DNAPL contamination, because the contamination concentration did not decrease in response to the taken measures.

Goldschmidt Conference Abstracts 2007 A19
Lu/Hf ratio and initial $^{176}\text{Hf}/^{177}\text{Hf}$ in the Solar System and the Earth

YURI AMELIN$^{1,2}$

$^1$Geological Survey of Canada, 601 Booth Street, Ottawa, Ontario K1A 0E8, Canada (yamelin@nrcan.gc.ca)
$^2$Research School of Earth Sciences and Planetary Science Institute, The Australian National University, Canberra ACT 0200, Australia (yuri.amelin@anu.edu.au)

The $^{176}\text{Lu}$-$^{176}\text{Hf}$ system is an invaluable tool for studying early differentiation in the Earth and other planets. An accurate knowledge of the initial condition of this isotopic system in the Earth remains elusive, despite the growing amount of Lu-Hf data on early Solar System materials. Determinations of $^{176}\text{Lu}$ decay constant by age comparison on terrestrial minerals and meteoritic phosphates yield consistent results, but two conflicts are still unresolved: 1) Slopes of Lu-Hf isochrons for bulk chondrites and achondrites, and some recently reported internal isochrons for eucrites and angrites are inconsistent with the “terrestrial” $^{176}\text{Lu}$ decay constant value, whereas other eucrite internal isochrons are consistent with it (e.g. Bouvier et al., MetSoc-2006, abstract #5348, Thrane et al., MetSoc-2006, abstract #5125); 2) Lu-Hf and Sm-Nd systems give different images of early mantle differentiation and proto-crust formation in the Earth, if we use the currently accepted $^{176}\text{Lu}$ decay constant value (e.g., Jacobsen (2003), Nature 421, 901-903).

There are several potential complications in determination of Lu/Hf ratio (and ratios of other refractory lithophile elements) from analysis of chondrites. First, Lu/Hf in chondrites can be heterogeneous, as a result of metamorphic phosphate growth, or uneven distribution of chondrules and CAIs. Second, Lu/Hf may vary between the classes of chondrites, and may not be representative of the Solar System value. Third, the bulk Solar System Lu/Hf value is not necessarily identical to the bulk Earth value.

There are several ways to address the first two complications, and to improve our knowledge of the bulk Solar System Lu/Hf. For example, one can study the Lu-Hf system in the least metamorphosed chondrites and chondritic matrices, and explore the correlation between Lu/Hf and the ratios of other refractory lithophile elements in various classes of chondrites and Solar photosphere. In addition, it may be possible to determine the initial $^{176}\text{Hf}/^{177}\text{Hf}$ of the Solar System directly from analyses of minerals with low Lu/Hf from old, well preserved meteorites. An approach to the third problem – precise matching of the Lu/Hf ratio (and other geochemically significant elemental ratios) between the bulk Earth and the bulk Solar System, needs to be developed.

Biogeochemical interactions in soil – Ccontrols through aggregation?

WULF AMELUNG

Institute of Crop Science and Resource Conservation, Soil Science and Soil Ecology, University of Bonn, D-53115 Bonn, Germany

The microbial turnover of natural organic matter (OM) and anthropogenic contaminants in soils depends on both quality and accessibility of the substrates. Agglomeration of soil minerals with plant and microbial remains to soil aggregates of different sizes strongly affects this bioaccessibility. Applied pesticides, for instance, are first caught in-between or at the surface of aggregates. Sequestration occurs after movement into interior parts. Also natural OM turnover is restricted in inner-aggregate pore space, however, when aggregates are broken down by e.g. ploughing, (old) organic C and N sources are made available to microbial growth and can rapidly be degraded.

This keynote aims at elucidating the role of aggregate cycling for compound turnover and sequestration in soil. Case studies presented relate to the tracing of xenobiotics using mass spectrometry after sequential extraction, to the cycling and preservation of natural OM using compound-specific stable isotope techniques of biomarkers and amino acid racemisation assessment.

The results suggested that selective preservation of organic molecules in soil may become insignificant when bioaccessibility is not restricted at the surface of aggregates or after their break-down. In undisturbed and very small pore spaces the pollutants and natural organic nutrient sources are withdrawn from actual biogeochemical cycles for unknown periods of time. Racemization of amino acids indicates that the conserved molecules may even age for centuries, despite N deficiency frequently occurring in living terrestrial environments.
Archaea and Bacteria in an arsenic-rich shallow-sea hydrothermal system, Papua New Guinea

J.P. AMEND1, D.R. MEYER-DOMBARD2, N.H. AKERMAN1, M.R. OSBURN1, E.M. HERNDON1, J.R. GAREY3, H. RUBELMAN3 AND T. WU3

1Dept. Earth & Planet. Sci., Washington University, St. Louis, MO, USA; amend@wustl.edu
2Dept. Earth, Atm., Planet. Sci., MIT, Cambridge, MA, USA
3Dept. Biology, Univ. South Florida, Tampa, FL, USA

The shallow-sea hydrothermal vents off Ambitle Island (Papua New Guinea) discharge hot (98 °C), slightly acidic (pH 6), AsIII-rich (~1,000 µg/L), chemically reduced fluids. Near the vent orifices, rocks and sediment are coated with AsV-rich (up to 7 wt. %) hydrous ferric oxides and green and orange biofilms. Shallow porewater chemistry changes rapidly with increasing lateral distance from the vents, approaching ambient seawater values within a few meters. Interestingly, porewater arsenic concentrations remain elevated even at 300 m lateral distance, predominantly as the oxidized AsV form (Price, R.E. et al., 2007. Appl. Geochem., in press).

Bulk genomic DNA was extracted from the biofilms and from near-surface sediment samples, amplified using standard bacterial and archaeal 16S ribosomal RNA primers, and sequenced. The archaeal communities in the orange and green biofilms consist entirely of uncultured, deeply-branching Crenarchaeota. The corresponding bacterial libraries were surprisingly sparse in thermophilic phyla (e.g., Thermus, Thermotogales, Aquificales), and dominated by several typically aquatic and sedimentary taxa. As an example, Bacteria in the green biofilm were nearly half alpha-Proteobacteria; strict phototrophs were not identified.

The archaeal libraries from sediment samples along a transect were also dominated by uncultured Crenarchaeota, but a few Euryarchaeota and Korarchaeota sequences were identified. Interestingly, a number of clones were >97% similar to Nitrosopumilus maritimus, the first chemolithoautotrophic nitrifying archaeon and the first mesophilic Crenarchaeote in pure culture (Köneke, M. et al., 2005. Nature 437, 543-546). Actinobacteria and gamma- and delta-Proteobacteria were ubiquitous along this same transect, and green sulfur and green non-sulfur Bacteria were found at 7.5 m and at 90 m from the vent, respectively.

In addition to gene surveys, several thermophiles were cultured from this site. Here, we report on a novel Bacterium isolated from the green biofilm on an anoxic, chemolithoautotrophic medium amended with 4,000 µg/L AsIII. The strain, PNG2, grows optimally at ~50 °C, but not above 60 °C. Based on the 16S gene sequence, PNG2 is an alpha-Proteobacterium, but with very low similarity (~90%) to any sequenced environmental clones or cultured strains.

Biogeochemistry of the Salton Sea, California

C. AMRHEIN1, B.K. REESE2 AND M.A. ANDERSON3

University of California, Department of Environmental Sciences, Riverside, CA 92521
1(chrisa@mail.ucr.edu)
2(brandi.reese@email.ucr.edu)
3(michael.anderson@ucr.edu)

The Salton Sea is a saline, closed basin lake 70 meters below sea level in the southern desert of California. It is the largest lake in California with a surface area of 945 km² and an annual inflow of 1,600 million m³. The Sea is hypereutrophic due to nutrient inputs from farm runoff, and the elevated sulfate concentration results in high rates of hydrogen sulfide production. The salinity of the Sea is 47 g/L and rising, with an annual salt load of 4 million metric tons. Construction of a salt repository is being considered to control the rising salinity, improve water quality, and maintain the Sea as a refuge for migratory birds. We estimate 700,000 metric tons of calcite are precipitating in the Sea each year, along with 7,000 tons of iron sulfide minerals. Hydrogen sulfide production rates, reoxidation rates in the water column, and atmospheric releases of H2S have been measured. In addition, we have measured dimethylsulfide concentrations >6 uM in the surface water, which are the highest ever reported. Hydrodynamic modelling of the proposed modified Sea indicates that persistent stratification could occur, with the potential for episodic releases of hydrogen sulfide during fall mixing.
The climatic and biotic thresholds on soil elemental cycling along an arid to hyperarid rainfall gradient

R. AMUNDSON1, S.A.EWING1, G. MICHALSKI2, M THIEMENS3, C. KENDALL4, K. NISHIIZUMI1, C. MCKAY5 AND G. CHONG6

5NASA Ames Research Center, Moffett Field, CA 94035 USA
6Universidad Catholica del Norte, Antofagasta, Chile

Across much of the planet, soil properties and biogeochemical processes vary monotonically with changes in rainfall. The studies that provide these observations have generally been performed in landscapes supporting biota. In this study, we examined soils along a rainfall transition from arid (vegetated) to hyperarid (abiotic) in northern Chile, and find that key geophysical and biogeochemical processes exhibit a sharp non-monotonic response across the transition from biotic to nearly abiotic conditions. All sites are ~ the same age (late Pliocene) and have similar lithologies, so that any chemical differences are due primarily to rainfall. Here we focus on N and S: elements intimately involved in biological processes. Atmospheric deposition is the main input at all locations, but soil retention and in situ biogeochemical alteration is strongly dependent on rainfall and biota. At the arid (vegetated) site, soil N is predominantly organic and exceedingly low (0.03 kg m⁻²), while at the extreme hyperarid endmember, soil N is predominately NO₃⁻ and much higher than at the arid site (5.4 kg m⁻²). Sulfate retention increases with aridity, to 240 kg m⁻². In the driest soil, a large vertical variation in the SO₄ S and O isotope composition indicates inorganic isotope fractionation during dissolution/reprecipitation and downward transport of sulfate. In summary, the removal of water and biota essentially closes the common soil N and S cycles, resulting in soils that passively accumulate these elements as soluble inorganic ions. The long-term absence of biota strongly alters the behavior and fate of elements, highlighting the signature of life on Earth surface geochemistry.

Phosphorus, barium and boron in the deep-sea coral Desmophyllum dianthus: Preliminary calibrations

E. ANAGNOSTOU1, R.M. SHERRELL1, J.F. ADKINS2 AND A.C. GAGNON3

1Institute of Marine and Coastal Sciences/ Dept. of Geological Sciences, Rutgers, New Jersey, USA (eleni@marine.rutgers.edu, sherrell@marine.rutgers.edu)
2Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, USA (jess@gps.caltech.edu)
3Division of Chemistry, California Institute of Technology, Pasadena, USA (gagnon@caltech.edu)

We present new data for element/Ca ratios in modern samples of D. dianthus, with the goal of developing skeletal proxies for subsurface nutrient and carbonate system proxies. The samples were collected from Atlantic and Pacific regions (~350-1400m) representing a wide range of nutrient and carbonate system concentrations. Mean element/Ca ratios for each coral were obtained for lines along the exterior surfaces of septa using 193nm laser ablation HR-ICP-MS. To test the relationship to seawater chemistry, means for each sample were regressed against hydrographic data from nearby stations. The P/Ca values showed reasonable correlation with seawater phosphate (D-PO₄~1.0, where D=El/Ca-coral divided by El/Ca-seawater; R²~0.7). When a single high point is ignored, D-PO₄ decreases to ~0.3 and the correlation improves (R²~0.78), supporting the potential for a direct seawater nutrient proxy. However, this D value is far lower than the D-PO₄~7.0 reported by Montagna et al. (2006) for the same species, and more consistent with inorganic incorporation of an oxyanion. The Ba/Ca values are strongly correlated to seawater Ba/Ca (R²~0.95) with D~1.7, close to that of surface corals. Skeletal B/Ca values were examined for relationships to carbonate system variables. We found a positive correlation with seawater carbonate ion concentration (R²~0.77), and a weaker one with pH (R²~0.51). These new findings provide a preliminary context for exploring the potential for reconstruction of past nutrient and carbonate system distributions using deep-sea corals.

Fe isotopic composition of inner solar system materials: The fit of Martian basalts and minerals

M. ANAND1,2, F. POITRASSON3 AND M.M. GRADY1,2
1Centre for Earth Planetary Space and Astronomical Research (CEPSAR), The Open University, Milton Keynes, MK7 6AA, UK (M.Anand@open.ac.uk)
2Dept. of Mineralogy, The Natural History Museum, London, SW7 5BD, UK
3LMTG-CNRS, 14, av. E. Belin, 31400, Toulouse, France

Currently, there is a debate about the Fe isotopic signature of inner solar system materials and whether Fe isotopes could be fractionated during planetary differentiation processes [1]. Large variations have been found among terrestrial mantle xenoliths, in sharp contrast to the homogeneous isotopic composition of terrestrial basalts. Previous Fe isotope work on lunar, Martian, HED and terrestrial basalts have shown that although the Fe isotopic compositions of these materials were relatively homogeneous for each planetary body, there were significant interplanetary differences [2]. This has been interpreted as a signature of the accretion history experienced by each planetary body. Martian mantle-derived samples, directly accessible for lab-based studies, are only available as Martian meteorites. They represent a variety of lithological types ranging from melt rocks to basaltic cumulates that formed during different episodes of Martian magmatic history. We present the most comprehensive bulk (>10) and major silicate minerals (>5) Fe isotope data from Martian basaltic rocks using a high-resolution MC-ICP-MS and compare our results with previously published data. At the level of precision obtained in our preliminary study (± 0.05‰ for δ57/54FeIRMM-14), all Martian meteorites and their dominant silicate phases appear to have an indistinguishable Fe isotopic composition. In addition, our data agree remarkably well with silicate phases appear to have an indistinguishable Fe isotopic composition compared to terrestrial and lunar igneous samples.

Rb-Sr and Sm-Nd isotope studies on the metabasalts of the Late Archean Hutti Greenstone Belt, Dharwar Craton, south India

R. ANAND AND S. BALAKRISHNAN
Department of Earth Sciences, Pondicherry University, Puducherry, India (anand_pu@yahoo.com)

The Late Archean Hutti Greenstone Belt in the Eastern Dharwar Craton consists of predominantly tholeiites and felsic volcanic rocks and is surrounded by granitoid rocks. Based on distinctly different metamorphic mineral assemblages the belt can be divided into east-west and north-south trending arms.

Rb-Sr and Sm-Nd isotope studies were carried out on the metabasalts from both the arms of the Hutti Greenstone Belt. The samples of the N-S arm define a collinear array in the Rb-Sr isotope evolution diagram which corresponds to an age of 2674 ± 120 Ma (MSWD = 8). The samples of the E-W arm define a collinear array in the Sm-Nd isotope evolution diagram which corresponds to an age of 2664 ± 86 Ma (MSWD = 0.94). The above ages for the metabasalts are interpreted to represent time of metamorphism which occurred soon after formation of their igneous precursors. The granitoid intrusives and gneisses surrounding the belt with U-Pb titanite and zircon ages ranging from 2574 ± 8 Ma to 2531 ± 3 Ma are younger than the metabasalts.

Neither the E-W nor the N-S arm metabasalts show any correlation in εSr vs. εNd plot (Figure 1) and hence, it is inferred that their precursor magmas were not contaminated by continental crust. Based on the εNd values it is suggested that the E-W arm metabasalts were derived from a source relatively more Rb-depleted than that for the N-S arm metabasalts. The sources for the magmas represented by both the E-W and N-S arm metabasalts were depleted in LREE > 600 Ma ago before melting as they all have positive εNd values. Two felsic volcanics from the Hutti Schist Belt have both negative εNd and negative fSm/Nd values and they could have been derived from LREE enriched sources. The felsic volcanic from the E-W arm of the Hutti Schist Belt has negative εSr value indicating that its magma must have derived from Rb-depleted sources while the magma representing the felsic volcanic of N-S arm was either derived from sources or interacted with continental crust having high Rb/Sr ratio.

Natural water

River and spring water samples were collected from an andesitic volcano, Norikura, central Japan and a region covered in “Shirasu” ignimbrite on Kyushu Island. The statistical analysis showed that the water chemistry of those areas is only slightly influenced by hot springs or anthropogenic pollution, but is highly controlled by weathering of silicate rocks or ignimbrite. On the basis of the thermodynamic and stoichiometric calculation based on water–rock interaction, the water chemistry was successfully demonstrated by the following simple theoretical equation:

\[ [\text{Si}] = 2[\text{Na}^+] + (2[\text{K}^+]) + [\text{Mg}^{2+}] \]

Experiment of water-rock interaction

Rock dissolution experiments in a batch system were performed on andesite and “Shirasu” ignimbrite. The reactors were filled with 100 gram of rock powder and 2L of water, of which pH were adjusted with sulfuric acid and were left for over one year. The experimental results successfully demonstrated the above relations between silicon and cations.

![Graph showing measured and estimated silicon concentrations.](image)

**Figure 1:** Measured and estimated silicon concentrations. [Si] estimated is given by \((2[\text{Na}^+]+[\text{Mg}^{2+}])\). Open circles are the river water samples taken from Shirasu ignimbrite region, and solid squares are the experimental water samples of batch system.

Many lines of evidence point to a rapid rise of atmospheric \(\text{O}_2(\text{P}_{\text{O}_2})\) between 2.45 - 2.22 Ga, a transition often referred to as the Great Oxidation Event (GOE). Before this time non-mass-dependent S isotope data (NMD-S) indicate that \(\text{P}_{\text{O}_2}\) was \(<10^{-5}\) times the present atmospheric level (PAL). The cause of the GOE is unknown. It could have been an immediate consequence of the evolution of oxygenic photosynthesis. Alternatively, \(\text{P}_{\text{O}_2}\) may have been controlled by a balance between oxidants and reductants at the Earth’s surface that crossed a critical threshold at that time. In the latter case, oxygenic photosynthesis could have evolved long before the GOE. This debate can be addressed by looking for evidence of trace \(\text{O}_2\) in the geologic record before 2.45 Ga.

The abundances of some redox-sensitive transition elements, such as Mo and Re, in ancient sediments can help address this problem because their weathering fluxes and global ocean budgets are sensitive to the availability of \(\text{O}_2\). The rates of weathering of sulfide minerals which are major carriers of these elements in igneous rocks are geologically rapid even when \(\text{P}_{\text{O}_2} \approx 10^{-5}\) PAL.

High-resolution chemostratigraphy in a newly-obtained late-Archean drill core reveals an episode of enrichment of these elements in the late Archean Mt. McRae Shale, Western Australia. Mo and Re concentrations in a pyritic black shale unit reach ~ 40 ppm and ~ 35 ppb, respectively. These enrichments are superimposed on a background of < 5 ppm and < 10 ppb, respectively, in underlying pyritic black shales. Re-Os geochronology demonstrates that the enrichment is a primary sedimentary feature dating to 2501 ± 8 Ma. Correlations with organic carbon indicate these metals were derived from contemporaneous seawater, providing convincing evidence that these metals were dissolved in late Archean oceans. The enrichment episode may record a change in local or global ocean Mo and Re inventories in response to changing \(\text{P}_{\text{O}_2}\). These findings point to the presence of small amounts of \(\text{O}_2\) in the environment > 50 Ma before the start of the GOE.
Sm-Nd and Lu-Hf garnet geochronology offers a quantitative link between isotopic ages and metamorphic conditions. Most commonly, the link is established on the basis of major element study of a peak metamorphic assemblage. Such an approach is valid only for low to medium grade metamorphism, where both major and trace elements preserve garnet growth conditions. At high temperatures major elements show diffusive profiles and hence are of very limited use for interpreting the dating results, which imposes a necessity for in situ studies of trace element distribution. In this study we present Sm-Nd and Lu-Hf garnet dating results along with laser ablation ICPMS trace element data obtained for high and ultra-high temperature rocks.

Migmatitic gneisses from N-Vietnam metamorphosed at ca. 800 °C show high quality Sm-Nd isochron ages spread between 50 and 30 Ma. Lu-Hf data obtained for the same samples failed to deliver tight age constraints but clearly point to much older dates. Both Sm and Nd tend to show decreasing from core to rim concentration gradient with decreasing crystal size, which is interpreted as reflecting variable degree of resetting. Indeed, the youngest Sm-Nd age was obtained for the sample with the smallest garnet crystals. Additionally, the youngest age is associated with the highest strain, which shows that not only temperature but also deformation is a significant factor facilitating resetting of the Sm-Nd, and potentially, Lu-Hf clocks in garnet. Lutetium in most analysed garnets shows Rayleigh-like patterns pointing to the preservation of prograde growth conditions. However, minor resetting of the heavy REE in the smallest crystals is observed.

In ultra high temperature granulites from the Bohemian Massif, Sm-Nd and Lu-Hf systems were decoupled and recorded distinct episodes separated in time by as much as 40 to 70 Ma. The oldest Lu-Hf age correlates with the steep Rayleigh-type Lu zonation profile, which indicates that under dry conditions, garnet can withstand temperature even in excess of 900 °C and preserve the time of prograde growth. In granulite which underwent hydration under amphibolite facies conditions, a younger Lu-Hf age correlates with the partially homogenized Lu zonation trend. In the case of Sm-Nd system in the studied UHT granulites, much younger ages do not reveal any obvious correlations with spatial distribution with these elements in garnet.

Weathering of rock minerals has great importance for the natural cycles of elements and other processes on the Earth surface. Lately, several isotopic systems have been employed to study rock weathering. The daughter 234U to the parent 238U ratio can be expressed as an activity ratio (234U/238U) equal to one at secular equilibrium. The (234U/238U) ratio often deviates from one due to recoil effects of 234U: it is either directly ejected (through 234Th) from a mineral or preferential leached from damaged mineral lattices. These effects result in natural waters mostly having (234U/238U) >1 whereas the outer rims of minerals have (234U/238U) <1, the latter depending on time, grain size and α-recoil distance. Thus, (234U/238U) should be a useful monitor to compare between physical or chemical weathering rates.

Two progressively flow-through laboratory leaching experiments on bulk crushed granite samples were conducted over 1200 hours. Input solutions were kept at pH 1 and output solutions were measured for their (234U/238U) and U concentrations. Both experiments show a similar three-step development:

1. 0-400 hours; (234U/238U) above 1 (1.00-1.15)
2. 400-700 hours; a gradual decrease in (234U/238U) reaching <1 (0.90-0.95)
3. 700-1200 hours; relative constant (234U/238U) at ~0.95

The initial U concentrations in the output solutions were of 800-400 ppt U with a continuous decrease in U concentration below <100 ppt after 1200 hours of leaching.

The observed behavior of (234U/238U) in the flow-through experiments suggests that continuous chemical weathering of a granite rock, yields waters with (234U/238U) >1 followed by (234U/238U) <1. As these experiments are short relative to the 238U decay rate, the initial high (234U/238U) cannot stem from in situ 238U decay and suggest that the excess 234U are released from damaged lattice sites due to preferential leaching. When the source of the excess 234U has been exhausted, direct dissolution of minerals from rim inwards starts to dominate the U signal and yields output solutions with a surprising 234U deficit. This suggests that under natural high chemical weathering rates, granitic rocks should yield natural waters with (234U/238U) <1. However this is rarely observed in nature and suggests that the release rates of (234U/238U) during natural chemical weathering, are not fast enough relative to the rates of physical denudation, thereby the 234U/238U system is useful in constraining the relative rates of the chemical and physical weathering.
**3500 Ma of crustal evolution in Fennoscandia as seen from Hf isotopes in zircons from granitoids**

T. Andersen¹, L.S. Lauri² and U.B. Andersson³

¹Department of Geosciences, University of Oslo, Norway (tom.andersen@geo.uio.no)
²Department of Geology, University of Helsinki, Finland (laura.lauri@helsinki.fi)
³Naturhistoriska Riksmuseet, Stockholm, Sweden (Ulf.Andersson@nrm.se)

The Fennoscandian shield shows a generally younging trend from NE to SW, with regionally important crustal growth events in the late Archaean, late Palaeoproterozoic and early Mesoproterozoic. Zircons separated from granitoids (s.l.) ranging from Archaean to Permian age have been dated by U-Pb and analysed for their Hf isotope composition by laser ablation ICPMS. The crystallisation age of the oldest rock so far recognized is ca. 3.5 Ga, with $\varepsilon_{\text{Hf}} \leq +2$, but the rock contains ca. 3.7 Ga old inherited zircons with $\varepsilon_{\text{Hf}} < 0$, indicating a crustal prehistory up to >3.9 Ga. Both depleted mantle and Meso- to Palaeoarchaean crust contributed to crust-forming events at ca. 3.2, 2.9 and 2.7 Ga. At 1.86-1.67 Ga, the juvenile Palaeoproterozoic Svecofennian crust was remobilized at a large scale to form $>10^6$ km³ of Transscandinavian Igneous Belt (TIB) granitoids with relatively uniform $\varepsilon_{\text{Hf}} = +3\pm 3$. The TIB granites did not contain new mantle-derived material, and coeval mafic magmas must have acted mainly as a heat source. In the early Mesoproterozoic, the western margin of the shield grew along a long-lived subduction system. Hf isotopes indicate a significant juvenile input in the western, distal part of the continental arc system ($\varepsilon_{\text{Hf}} \approx +12$), and less so in the eastern, proximal part ($\varepsilon_{\text{Hf}} \approx +8$). At ca. 1.3 Ga and 1.22-1.21 Ga, the western part of the shield was underplated by depleted mantle material ($\varepsilon_{\text{Hf}} \approx +13$). This juvenile component contributed significantly to subsequent granitic magmatism, but its relative influence decreased with time. The late Palaeozoic alkaline magmas of the Oslo Rift are the youngest additions to the Fennoscandian crust. These seem to be mainly derived from a lithospheric mantle source with $\varepsilon_{\text{Hf}} = +2$ to +6, but with contributions from local Proterozoic crust.

**The alteration of zircon and its role in the remobilization of high field strength elements in the Georgeville granite, Nova Scotia**

A.J. Anderson¹ R. Wirth² and R. Thomas²

¹Department of Earth Sciences, St. Francis Xavier University, Antigonish, N.S., Canada, B2G 2W5 aanderso@stfx.ca
²GFZ-Potsdam, Telegrafenberg, 14473, Potsdam, Germany

The structure and composition of metamict zircon from an epizonal A-type granite in the Antigonish highlands, Nova Scotia, was investigated using transmission electron microscopy (TEM), electron microprobe analysis (EMPA), laser ablation-inductively coupled plasma mass spectrometry (LA-ICPMS), and Raman micro-spectroscopy. Individual zircon crystals within the granite are variably altered and are comprised of up to four domains, designated A, B, C and D. Each domain is readily distinguished on the basis of texture and composition. Domain A consists of trace element-enriched zircon and zirconium oxide nanocrystals in an amorphous matrix. Coupled dissolution and reprecipitation of zircon A in proximity to microfractures produced a relatively trace element-poor zircon (domain B), and Th, U, Y, Yb-enriched inclusions (domain C). Domain D is composed of Hf-enriched, amorphous zirconium silicate that is depleted in Y, Yb, Th and U. Domain D occurs within microfractures together with lesser amounts of thorite and thorianite. Alteration of zircon, which is the dominant accessory phase in the Georgeville granite, resulted in preferential hydrothermal transport and precipitation of the lanthanides. Perturbation of the initial high field strength element and isotopic signature of zircon accounts, in part, for the anomalous chondrite normalized rare earth element patterns and Nd isotopic values reported previously for the Georgeville granite (Murphy and Nance, 2002).

Ti substitution in zircon

B. E. ANDERSON¹, E.J. ESSENE² AND U. BECKER³

¹University of Michigan, Ann Arbor, MI (beliza@umich.edu)
²(essene@umich.edu)
³(ubecker@umich.edu)

A recently proposed geothermometer (Watson et al., 2006) assumes that the Ti content of zircon is buffered in equilibrium with rutile. However, Ti may substitute into either the Si or Zr site of zircon, and as a result, the concentration of Ti in zircon will change with pressure and with SiO₂ activity as well as temperature. Understanding how Ti partitions between the two sites is therefore crucial to developing this new geothermometer. Based on ionic radius arguments and recent experiments, it was suggested that substitution of Ti for Si dominates (Harrison et al., 2005; Ferry and Watson, 2006).

Gaining a more quantitative understanding of the energetics of Ti substitution in zircon requires the use of computational methods. Therefore, quantum mechanical calculations (CASTEP, Dmol, Crystal) were used as a basis for Monte-Carlo calculations to derive the enthalpy and free energy of mixing for the binary ZrSiO₄ – ZrTiO₄ (assuming that all compositions have the zircon structure) at various temperatures.

Similar calculations are being carried out for the binary ZrSiO₄ – TiSiO₄, again assuming a zircon structure. Preliminary quantum mechanical calculations suggest that substitution of Ti into the Zr site requires a similar amount of energy as substitution into the Si site for low Ti content (x=0.0625 in Zr(Si₁₋ₓTiₓ)O₄ compared with (Zr₁₋ₓTiₓ)SiO₄). Excess volume is also calculated for both solid solutions in order to estimate the effect of increasing pressure.

In contrast to terrestrial plants, carbon isotopic results from wetland plants, such as pond cypress, have a positive relationship with rainfall amount. One important plant in the greater Everglades ecosystems is sawgrass (Cladium jamaicense), which comprises an important part of the regional ecosystem. To calibrate and understand the isotopic changes that may potentially be related to changes in water level, which corresponds to hydroperiod in a temporal manner, mesocosm experiments were used to grow these plants at different water levels. 24 mesocosms were randomly assigned 4 different water treatments to simulate changes in hydroperiod and water depth, similar to the typical Everglades wet season and dry season cycle. Our initial results from this work show a strong correlation between variations in water depth and plant carbon isotope values in the shallow water treatments vs. the deeper water treatments (Fig.1). Further analyses are presently underway to compare assimilation with the collected carbon isotopic data. These results confirm the observations from the cypress work, and set the stage for using carbon isotopes from preserved OM and/or biomarkers to reconstruct changes in water level from wetland settings.

Figure 1: Carbon isotope values compared to water depth in young (A) and mature sawgrass leaves (B).
The sources of Nd isotopes in Arctic Ocean water

P. S. ANDERSSON¹, D. PORCELLI², M. FRANK³, G. BJÖRKEN, R. DAHLQVIST⁴ AND Ö. GUSTAFSSON⁵

⁵ITM, Stockholm Univ, orjan.gustafsson@itm.su.se

The Arctic Ocean connects the Pacific and Atlantic Oceans and it also receives a significant freshwater input equivalent to 10% of the global river run-off. The most important exchange of Arctic Ocean water masses occurs through the Barents Sea and Fram Strait with the Nordic Seas (Norwegian, Greenland and Iceland Seas) and this exchange is crucial for the formation of North Atlantic Deep Water. The Nd isotopic composition, εNd(0), of the northern North Atlantic is well characterised but it is not clear how the signal is acquired and how it relates to the Arctic Ocean.

We have determined the Nd concentration, CNd, and εNd(0) of the major inflow areas to the Arctic Ocean through the Barents Sea and the Fram Strait, as well as the dominant Arctic outflow through the Fram Strait.

The Barents Sea inflow has a CNd of 15 pmol/kg and an εNd(0) of -10.7, which is similar to waters from the northeastern Nordic Seas and demonstrates that Nd from the Atlantic dominates the Arctic inflow. In contrast to the inflow, the Nd in the major Arctic Ocean outflow, the Fram Strait, is isotopically different with a higher εNd(0) of -9.8 throughout the entire water column, down to 1300m depth. This reflects addition of Nd derived from sources that include Pacific water, shelf sediments and rivers within the Arctic Ocean basin. River water inflow is a possible source for the added Nd to the surface waters, but it is also likely that Nd from Pacific waters modified by addition from shelf sediments in the Canada Basin is an important component in the Fram Strait surface outflow. The isotopic shift in the deeper water of the Fram Strait outflow is probably not directly related to river- or Pacific water input but rather to exchange with sediments along the shelf of the Canadian archipelago. It is likely that different sources contribute to the Nd at different depths in the water column. The influence of these sources on the isotopic composition of the northern North Atlantic will be discussed.

Reactivity of nitrates in the near field of type-B nuclear waste cells

L. ANDRE¹, M. AZAROUAL¹, H. PAUWELS¹, A. ALBRECHT² AND M.-A. ROMERO²

¹BRGM, 3 Avenue Claude Guillemin, Boîte Postale 6009, F-45060 Orléans Cedex 2 (l.andre@brgm.fr; m.azaroual@brgm.fr; h.pauwels@brgm.fr)
²Andra, Parc de la Croix Blanche, 1/7 Rue Jean Monnet, F-92298 Chatenay-Malabry Cedex (achim.albrecht@andra.fr; ma.romeo@andra.fr)

Introduction

B2-type nuclear waste consisting of a dry mixture of bitumen and a mineral phase (mainly NaNO₃ and BaSO₄ salts mixed with radionuclides) is proposed for deep geological storage. After closure the waste cell will progressively resaturate leading to the dissolution of soluble salts and the diffusion of dissolved species within the compartments of the storage cell (cement engineered barrier and argillite host rock in the French case). Chemical modifications, such as denitrification, catalysed by possibly existing bacterial activity, will affect the system equilibrium. This study is intended to gain a better comprehension of the redox reactions involving nitrates and bacteria and their possible impact on the long term evolution of the B2 waste cells.

Modelling concept

Denitrification processes are modelled with the Phreeqc code, which couples geochemical reactions with dispersive and diffusive transport. Calculations were performed on a 1D column with a nitrate source on one side followed by two major zones in which only diffusion of dissolved species (nitrates, organic matter...) is allowed.

A particular attention is paid to the role of nitrate as an electron acceptor in the presence of micro-organisms and different electron donors (i.e. iron, pyrite, organic matter or hydrogen gas). The consideration of these different redox reactions allows description of the overall denitrification process. The mathematical tool for estimation of the impact of bacterial activity on reaction kinetics proposed by Jin and Bethke (2005) has been implemented in Phreeqc to model microbial controlled kinetics in reactive chemical transport.

Discussion and conclusions

Different denitrification scenarios were modelled showing important nitrate reduction in the first centimeters within the cement barrier. Modifications of gas phase composition and mineralogical assemblages of cement and argillite barriers are also predicted. Results emphasize the lack of experimental data to constrain the model, but help to guide future laboratory experiments, to define the role played by the electron donors and to better estimate nitrate concentrations and microbial implications.

Trace element analysis and dating of monazite single grains by XRF milliprobe: Quick, cheap, simple

ALEXEY A. ANDREEV, ALEXANDER V. ANDREEV AND SERGEY P. SAVENOK

Kiev National Shevchenko University, Geological faculty (andreev@univ.kiev.ua)

Single grains (crystals) of monazite (Ce,La...)PO₄ are micro objects with size varying from 0.05 mm to 0.5 mm and mass from n-0.1 mkg to n-100 µg. Monazite are known as relatively stable in sedimentary environments and their detrital population could reflect the provenance. Such techniques as LA-ICP-MS, EMPA and SIMPS have good analytical characteristics (low detection limits, high precision and spatial resolution) and usually are applied. But they require expensive hardware and time-consuming sample preparation. This paper presents a new promising technique - XRF milliprobe of single grains (XRF MP/SG) for analysis of monazite trace elements (Sr, Y, Pb, Th, U), and chemical U-Th-Pb dating obtaining in a great number of such grains within a real time. It was designed with two thin X-Ray beams from two independent X-ray tubes, which irradiate the sample by turns. The beam of first tube (Mo anode) is monochromatic by cylindrical crystal-monochromator (LiF, plane 200) for MoKa line, the beam of second tube (Fe anode) is filtered by different changing filters. Both of beams are collimated to diameter 0.5 mm. Characteristic X-ray of a sample is detected by energy-dispersive spectrometer with Si(Li) detector cooled by liquid nitrogen. Detection limits in zircon, monazite for grains with masses 1-10 mg are as follows: Sr,Y – 5-10 ppm, Pb,Th,U – 10-20 ppm. The statistical uncertainty is defined by counting statistics in peak of element analytical line. In the fixed conditions of measurements it depends on weight of grain, concentration of the elements and analyses time.

Figure 1: Experimental statistic uncertainty of fluorescence intensity for monazite grain (mass 0.46 mkg, ball diameter 0.054 mm).

The systematic dependence between intensity of fluorescence being registered from the grain and mass, form of the grain is calculated.

The method is absolutely non-destructive, small grain can be repeatedly measured for improved statistics (and improved age precision), thus providing a possibility of analysis by other method.

Trees and weathering: Insights from root-mineral contacts

M.Y. ANDREWS, J.J. AGUE AND R.A. BERNER

Department of Geology and Geophysics, Yale University, New Haven, CT, USA (megan.andrews@yale.edu)

Over geologic time scales atmospheric CO₂ levels are controlled by the feedbacks and processes of the long-term carbon cycle. One poorly understood aspect of this cycle is the impact of the evolution of large vascular plants (trees) and their role in accelerating silicate weathering. In particular, differences in weathering between gymnosperms (Paleozoic origin) and angiosperms (Mesozoic origin) still need to be unravelled as they may play a critical role in the regulation of atmospheric CO₂ over geologic time scales. Differences in nutritional requirements, seasonal shedding of biomass, extent of association with ectomycorrhizal fungi and associated microbial and terrestrial burrowing organisms are potentially responsible for these differences in weathering on soil and bedrock silicate minerals. However, the actual impact of the different trees and associated ecologies remains to be elucidated. Sensitivity analysis of the the GEOCARB model of Phanerozoic atmospheric CO₂ (Berner and Kothavala, 2001) indicates that even small differences in rates of weathering between the two tree types may have a significant impact on the evolution of Mesozoic CO₂.

To address this issue, this study focuses on soil cores collected along transects of small groves containing both angiosperms and gymnosperms in the Cascade Mountains of Washington State. These cores were carefully collected and preserved in epoxy with minimal disturbance to the samples. Root-mineral contacts and the spatial geometry of roots and soil particles were successfully captured in the epoxied core sections. Qualitative differences in these cores are observed both along the transect (corresponding to nearest tree type) and with depth in individual cores. Weathering intensity is greatest both near the surface (all cores), with soil particles coarsening with depth, and in proximity to the gymnosperms. Quantitative differences in the root-rock reaction zones will be directly evaluated using the electron microprobe to observe any mineral alteration near roots, as well as overall chemistry and petrology of the soils on a fine scale. This unique snapshot of the complex interactions between tree roots and their host soil mineralogy provides insight into the impacts of different tree types on silicate weathering.

Monazite single grain trace element analysis and dating by XRF milliprobe

ALEXANDER V. ANDREYEV, ALEXEY A. ANDREIEV, SERGEY P. SAVENOK, ALEXEY L. BUNKEVICH AND ELENA V. MESHCHERYAKOVA

Kiev National Taras Shevchenko University, Geological faculty (andreev@univ.kiev.ua)

Monazite is stable in sedimentary environments and its detrital populations could reflect provenance. Such techniques as LA-ICP-MS, EMP and SIMS commonly are applied to study a monazite composition. They have good analytical characteristics but require expensive hardware and time-consuming sample preparation. Single-grain milliprobe XRF analysis (XRF-MP/SG) is a new promising technique for trace elements (Sr, Y, Pb, Th, U) determination and chemical U-Th-Pb dating of monazite. This technique was designed on a base of original XRF installation with two thin X-ray beams (collimated to 0.5 mm) from two independent X-ray tubes with Mo and Fe anodes and energy-dispersive spectrometer with Si(Li) detector. Detection limits for grains with masses 1-10 µg are: Sr, Y – 5-10, Pb, Th, U – 10-20 ppm. The fluorescence intensity of elements vs. shape and mass of grains as well as their matrix effect were calculated to calibrate the quantitative element analysis. The statistical uncertainty is defined by counting statistics in spectrum peaks. It depends on grain mass, element concentrations and measurement time (Fig. 1).

Figure 1: Experimental statistic uncertainty of fluorescence intensity for spherical monazite grain (m≈1.1 µg, Ø≈0.07 mm).

Up to then unknown ‘young’ stage of significant formation of monazite within the East European Platform has been discovered as a result of XRF-MP/SG application (Fig. 2).

Study of the copper reactivity in organic soils

J. ANTELO, P. VILLAVERDE-DIOS, F. ARCE, S. FIOL, R. LÓPEZ AND D. GONDAR

Physical-Chemistry Department. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain (qfjam25@usc.es)

The accumulation of heavy metals in soils can cause adverse effects in natural systems due to their mobility and bioavailability. The study of heavy metals speciation in such systems can be controlled by the presence of different types of sorbent materials. Until now, several studies have deal with the interaction of heavy metals with isolated soil fractions such as natural organic matter which has been proved to bind strongly to metal cations. In the present work a comparative study was carried out between the copper binding on a peat sample and on a peat humic acid. A widely used model for describing the metal binding to humic substances is the NICA-Donnan. We have checked the possibility of using this model with the peat sample which is expected to exhibit a similar behaviour to that observed for humic substances in solution.

The effect of pH and ionic strength observed for the peat sample shows the same trend as in the peat humic acid. In both cases the copper binding is enhanced by an increase in pH or decrease in ionic strength. The main difference between both samples could be attributed to different binding sites content. The peat shows higher complexation capacity than its humic fraction.

An acceptable prediction of the experimental results for the peat sample was achieved with the NICA-Donnan model. The fitted parameters were quite similar to those obtained for the peat humic acid (Gondar et al., 2006) and also to the generic NICA-Donnan parameters for copper-humic acids binding published by other authors (Milne et al., 2003)

1Polytechnic Institute of Castelo Branco. 6001-909 Castelo Branco. Portugal (imanutes@esa.ipcb.pt)
2Department of Earth Sciences, University of Coimbra. 3000-272 Coimbra, Portugal (neiva@ci.uc.pt; mmvsilva@ci.uc.pt)

The Iberian massif corresponds to the southwestern extension of the European Variscan Belt. The Ordovician magmatism is rare in the Central Iberian Zone of this massif. A medium-grained biotite granodiorite from Lower Ordovician of 479-480 Ma crops out at the Oledo-Idanha-a-Nova pluton. It intruded the Cambrian schist-metagreywacke complex, is deformed and contains fine-grained biotite tonalitic and biotite granodioritic microgranular enclaves, which are darker and richer in mafic minerals than the host granodiorite. The microgranular enclaves show rounded or ovoid shapes, some of them irregular, having sharp, occasionally crenulated and diffuse contacts. Microgranular enclaves and host biotite granodiorite are peraluminous (A/CNK=1.00 to 1.13) and contain quartz, K-feldspar, albite-labradorite, amphibole, biotite, sphene, allanite, zircon, monazite, apatite, ilmenite and magnetite. Variation diagrams of the rocks and their biotite, sphene, allanite and ilmenite show trends of fractionation from tonalitic enclaves to host granodiorite. The rare earth element (REE) patterns are sub-parallel and show fractionation of REE from tonalitic enclaves to host biotite granodiorite. Biotite increases and anorthite content of plagioclase decreases from tonalitic enclaves towards the host granodiorite. Biotite composition shows fractionation with increase in deformation of host granodiorite. The least squares analysis of major elements and modelling of trace elements indicate that granodioritic enclaves and host biotite granodiorite were derived from the tonalitic magma by fractional crystallization of plagioclase, amphibole, biotite and ilmenite. The ($^{87}$Sr/$^{86}$Sr)$_{i}$ ratio (0.7050-0.7067), εNd$_{i}$ (1.56-3.46) and δ^{18}O (6.00-8.92‰) values indicate that they are I-type granitic rocks and contain a mantle component. The decrease in ($^{87}$Sr/$^{86}$Sr)$_{i}$, regular variation of εNd$_{i}$ and increase in δ^{18}O from tonalitic enclaves to host biotite granodiorite suggest that another mechanism has also occurred, probably mixing with other magmas or are related to deformation.

An integrated in-situ O, U-Pb and Hf isotope approach to decipher the petrogenetic evolution of granites

The combination of in-situ O, U-Pb and Hf isotope analyses of zircon provides very powerful constraints on the sources, ages and evolution of granitoid magmas. This robust zircon record has been accessed at the intra- and inter-grain scale by combining SEM imaging with SIMS ($^{18}$O and U-Pb) and LA-MC-ICP-MS (Lu-Hf) micro-analysis. The combined information has been used to constrain crystallisation and crustal residence ages, magma sources and relative mantle and crustal contributions of late Caledonian ‘I-type’ granites of the Scottish Grampian Highlands, which were emplaced between 430 and 400 Ma following the c. 470 Ma Grampian Orogeny. These comprise two main suites based on whole-rock geochemical and isotopic data. This study focuses on granites and diorites of the 420 Ma Lochnagar and the 425-400 Ma Etive plutons (U-Pb ages), representing the Cairngorm and Argyll suites respectively. In both plutons high-precision SIMS oxygen isotope analyses have enabled us to recognise statistically distinct zircon populations (e.g. Lochnagar diorite: population 1: 6.6±0.4‰ (2σ), population 2: 7.4±0.4‰ (2σ)) that indicate the entrainment and mixing of distinct mafic and felsic lower crustal source components. The absence of pure mantle zircon populations ($^{18}$O (Zrc) = 5.3±0.3‰) indicates that none of the granites and diorites contain an identifiable unmodified mantle component.

In-situ Hf isotope data also show a large spread in both plutons (Lochnagar: εHf = +4 to -4; Etive: εHf = -2 to -8 (±0.7-1.0 εHf (2σ)). This variation is caused by mixing of several felsic crustal components of differing residence ages in the range ~1.2 – 2.0 Ga. Thus, this approach is able to distinguish several different mixing events and provides insights into the nature and ages of the sources involved. It also shows that formation of the 430-400 Ma Caledonian granites in Scotland is dominated by crustal recycling rather than crustal growth.
Very high exhumation rates in the central Swiss Alps, revealed by the (U-Th)/He and fission track analyses

A. ARAMOWICZ1, M.A. COSCA1, K.A. FARLEY2, D. SEWARD3 AND D.F. STOCKLI4

4Department of Geology, University of Kansas, Lawrence, USA.

Apatite and zircon (U-Th)/He thermochronological data together with apatite fission track analyses from near the Lötschen valley and subsurface samples from the NEAT tunnel are used to constrain the exhumation and thermal history of the western part of the Aar crystalline massif in the central Swiss Alps. This region is undergoing active deformation as geodetic measurements indicate current uplift at a rate of 1 mm/a. Samples for this study have been collected over an overall elevation range of 3 km. Exhumation rates calculated from both age-elevation profiles and from cooling curves constructed using multiple systems agree with each other and suggest that a geothermal gradient of ~30°C/km has likely remained stable over the last 7 Ma. Zircon (U-Th)/He and apatite fission track data indicate that a period of relatively fast exhumation (~3 mm/a) occurred at 5.5-6.5 Ma. This episode of rapid exhumation, previously undetected in past studies, correlates well with a contemporaneous, high erosional flux in the internal parts of the Alps (Messinian salinity crisis). The rate of exhumation in the western Aar massif, although relatively high, is in agreement with Pliocene exhumation rates described recently from the nearby Mt. Blanc massif. Because of high spatial resolution and three dimensional sampling in this area we have identified a significant role of localized heat advection by hot fluid circulation in the crystalline rocks, postdating initial cooling registered by the applied methods. The northern part of our study area appears to have been severely affected, as evidenced by young apatite (U-Th)/He ages. Similarly, some zircon (U-Th)/He ages suggest considerable resetting in the lowest elevation, axial part of the valley. The average exhumation rate calculated for the period between closure to helium diffusion in apatite (U-Th)/He and the present day from the tunnel samples is ~0.3 mm/a while current surface uplift is 2-3 times faster. This discordance can be explained by either recent acceleration in uplift of the Aar massif or, more likely, by transient changes in the thermal structure within the massif due to fluid circulation and associated heat advection. Exhumation rates calculated with the reset ages represent minimum values. These results underscore the caution that must be taken when interpreting low temperature geochronological data from Alpine regions.

Magma generation and transport in subduction zones: Numerical simulations of chemical, thermal and mechanical coupling during magma ascent by porous flow

D. ARCAY, T. GERYA AND P. TACKLEY

ETH-Zürich, Swiss Federal Institute of Technology, Institute of Geophysics, Hönggerberg, Schaffmatstr. 30, CH-8093 Zürich, Switzerland (diane.arcay@erdw.ethz.ch, taras.gerya@erdw.ethz.ch, ptackley@ethz.ch)

Most subduction zones are characterized by significant magmatic activity responsible for building trench-parallel volcanic arcs above descending slabs. High magma production rates observed within the arcs result from infiltration of water-reach fluids released by slab dehydration. The released water triggers hydrous melting of hot mantle wedges located above the cold slabs. However, the process of magma transport from the melt generation region located above the hydrated slab surface at 100-300 km depth to the magma extraction zone at the volcanic arc surface, and its influence on mantle wedge deformation, are not well known. In particular, during basaltic liquid ascent through the mantle wedge, decreasing pressure and temperature changes are likely to induce significant compositional variations, especially in terms of dissolved water content. Relationships between melt transport and mantle wedge deformation are also not clearly understood. We present a numerical model of magma generation and transport in subduction zones, that simulates chemical, thermal, and mechanical interactions between fluids and solid rocks along the magma ascent pathway. Magma migration is modelled by a porous flow across a constant permeability matrix, while the solid downward current associated with subduction in the mantle wedge, is included. The heat advected by the percolating liquid phase as well as latent heat effect associated with melting will be included. Water exchanges between the molten rock and the solid matrix are computed as a function of pressure, temperature, and solubilities laws in melt. We will first present benchmark results to validate the porous flow modelling as well as the emnery equation resolution for a two-phase flow. The aqueous and magmatic fluid repartition within the mantle wedge will then be presented. Magma productivity rates, varying along the magma ascent pathway, will be discussed as a function of magma viscosity.
The Mo isotopic composition of rivers suggests complete euxinia in the Proterozoic ocean

COREY ARCHER AND DEREK VANCE
Bristol Isotope Group, Dept. of Earth Sciences Wills Memorial Building, University of Bristol, UK.
(c.archer@bristol.ac.uk; d.vance@bristol.ac.uk)

Quantifying the extent of past marine anoxia has become a key research goal in recent years [e.g. 1, 2]. Placing firm constraints on the oxygenation history of the ocean is essential for our understanding of the interaction between ocean and atmospheric chemistry, biological evolution, and nutrient controls on primary productivity. Recently, the isotopic record of the marine geochemistry of molybdenum has shown promise as such a palaeoredox indicator [1]. However the use of Mo isotopes in this way has been hampered by the fact that the isotopic composition of rivers, the dominant input of Mo to the oceans, is unknown and has been assumed to be that of average continental Mo isotopic composition.

We report here the isotopic composition of the dissolved Mo content from a selection of global rivers. In contrast to the expected value of 0‰ for the continental source to the oceans, the rivers sampled exhibit a range of Mo isotope compositions with δ97/95Mo always positive and ranging from 0.1 to 1.5‰. Further, there is a general relationship between δ97/95Mo and the reciprocal dissolved Mo concentration, defining an average δ97/95Mo input to the oceans of +0.7±0.2‰. Ancillary data, as well as published constraints on riverine Mo geochemistry, demonstrate that the mechanism for the observed isotopic fractionation is adsorption onto Fe-Mn oxides.

This process must occur wherever Mo exists as an oxidised aqueous species, therefore providing a mechanism for Mo isotopic fractionation in rivers since the onset of oxidative weathering on the continents ca. 2.2 billion years ago [3]. The estimated value for the δ97/95Mo input of Mo from rivers has profound implications for recent Mo isotope data from Mid-Proterozoic [1] and Mesozoic OAE [4] black shales [4]. Reported oceanic δ97/95Mo from these periods approach of the value we find in modern rivers suggesting perhaps a lower limit of riverine and oceanic δ97/95Mo after the onset of oxidative continental weathering and further implies near complete euxinia in the global ocean during these periods.

The hydrogeochemical role played by clay-based barriers in a high-level nuclear waste (HLNW) repository is twofold: (1) the retardation of the groundwater inflow to the waste canisters, and (2) the retention of radionuclides in case of canister failure. The latter is especially relevant taking into account that parameters such as pH and redox state will control the solubility and sorption of radionuclides. The long-term evolution of the porewater chemistry of the barrier system depends mainly on the nature of the inflow groundwater and on the composition of clay material. On one hand, groundwater chemistry may undergo sharp changes due to the climatic evolution, mainly linked to glaciation / deglaciation cycles. On the other hand, the buffering response of barrier to these changes will intimately be associated with the composition and content of some accessory minerals in the clay (dissolution/precipitation of carbonate, sulphate and iron-bearing minerals).

In this work, the long term response of bentonite barrier due to the interaction with groundwater is evaluated by using reactive transport calculations. We considered a granitic groundwater and two commercial bentonites, MX-80 Wyoming-type and Deponit CA-N Milos-type. Moreover, a temperature gradient has also been considered.

The results indicate that the interaction of a granitic groundwater with the bentonite buffer has minor effects on the pH evolution of the system, buffered by carbonate minerals. The redox state seems to be controlled by the regional groundwater, in equilibrium with pyrite and siderite. Composition of the surface sites in montmorillonite in bentonite significantly change since an increase of calcium occupancy is predicted by the model, related to calcium sulphate dissolution.

Finally, temperature gradient caused by heat generation in the canister leads to a general decrease of pH. In addition, it affects the content and distribution of some accessory minerals such as gypsum or silica.

Recent experiments with high-density unsaturated bentonite performed in the frame of NF-PRO European project give support to the results obtained with the model.
Modelling the biospheric influence on the weathering rate of silicate rocks in an EMIC

SUSANNE ARENS AND AXEL KLEIDON
Max-Planck-Institute for Biogeochemistry, Postfach 100164, 07701 Jena, Germany
(sarens@bgc-jena.mpg.de)
(akleidon@bgc-jena.mpg.de)

On geological time scales the main agent for removal of CO₂ from the atmosphere is the formation of carbonate rocks in the oceans. The rate of formation is dependent on the input of products of weathering of silicate rocks from river runoff [1]. Weathering rates depend on climatic conditions such as the strength of the hydrological cycle but also on biospheric processes such as soil genesis, which in turn depend on the climate [2]. These fluxes of the global carbon cycle are usually modelled with global geochemical box models on geological time scales. In order to get spatial scale resolutions of weathering rates a geochemical model can be combined with an Earth System Models of Intermediate Complexity (EMIC) as previously done in [3], by using the EMIC’s climatic output as input to the geochemical model. The study clearly illustrates the importance of spatial detail, which is not resolved in box models. In order to model weathering fluxes in a more direct way and quantify the importance of other spatially variable drivers, we develop a soil weathering module in connection with the SIMBA (SIMulation for Biospheric Aspects) vegetation model [4] for implementation into an EMIC. SIMBA simulates spatially explicit vegetation productivity and biomass as a function of temperature and soil moisture. With the soil module we simulate a) biospheric influence on soil water pH values through heterotrophic and root respiration of CO₂ [5] and b) potential soil water cation concentration by dissolution towards chemical equilibrium between soil water and generic silicate rock fragments corresponding to feldspars such as anorthite. The weathering or dissolution of cations from silicate rocks becomes a direct function of rainfall, runoff and soil water pH values and thus both directly and indirectly of biospheric productivity. In this talk we will present model results of spatial variability of pH and cation fluxes within the scope of long term climate variability.

Detecting core-mantle interactions with W

R. AREVALO JR. AND W.F. MCDONOUGH
Department of Geology, University of Maryland, USA
(gatorick@umd.edu; mcdonough@geol.umd.edu)

Whether or not chemical interactions occur between the core and lowermost mantle has been a controversial issue. The unambiguous identification of core-mantle exchange yields major implications for constraining mantle circulation patterns, the timing of inner-core crystallization, conditions at the core-mantle boundary, and the existence of an early enriched reservoir at the base of the mantle. Recently, core-mantle interactions have been inferred on the basis of coupled 186Os-187Os enrichments and elevated Fe/Mn ratios in Hawaiian lavas (Brandon et al., EPSL 1999; Humayun et al., Sci 2004). Tungsten (W), however, provides a powerful, dual approach to the detection of core-mantle interactions through the use of both W isotopic signatures and concentration ratios.

We have analyzed a global suite of 86 mantle-derived lavas via LA-ICP-MS. The samples, which are primarily basaltic glasses representative of MORB, arc, and intraplate sources, show little variation in W/Ba (0.00136 ± 3, 2n). This value, which is concordant with previously published data for continental crust (Newsom et al., GCA 1996), is taken to represent the ratio of the silicate Earth. Assuming 6600 ± 1320 ng/g Ba in the silicate Earth, the abundance of W in this reservoir is 9.0 ± 5.8 ng/g. Accounting for the 1000 ± 300 ng/g W in the continental crust, the mean W concentration in the modern mantle is 4.1 ± 2.9 ng/g, with MORB and OIB representing more depleted and enriched source regions, respectively. Following mass balance, the core contains 516 ± 116 ng/g W. The relative abundance of W in the core and silicate Earth, coupled with the unique W isotopic signatures of these reservoirs (silicate Earth εW ≈ 0; core εW ~ 2.1), demonstrate that no core-mantle interaction is recorded in previously analyzed Hawaiian picrites (Schersten et al., Nat 2004), assuming a source of undifferentiated mantle.

As the W/Ba ratio of the core exceeds 10⁴, minor enrichments in W/Ba in plume-derived magmas provide a sensitive tracer of outer core additions to a deep mantle source. The restricted range of W/Ba in modern-mantle sources indicates that 1 wt% addition of outer core material to a model Hawaiian plume source (with ~9 ng/g W) would result in a detectable increase in W/Ba by > 50%, as compared to an ~ 10% change in Fe/Mn.
Mg-Fe\textsuperscript{2+}-Fe\textsuperscript{3+}-Al-Si-O phase relations at lower mantle conditions: Lack of evidence for Fe-disproportionation

LORA S. ARMSTRONG AND MICHAEL J. WALTER
Department of Earth Sciences, University of Bristol, UK
(L.Armstrong@bristol.ac.uk; M.J.Walter@bristol.ac.uk)

Experiment and theory show that the charge-coupled substitution Fe\textsuperscript{3+}Al\textsuperscript{3+} ↔ Mg\textsuperscript{2+}Si\textsuperscript{4+} is highly favored in Mg-perovskite, with Fe\textsuperscript{3+} on the large Mg-site and Al\textsuperscript{3+} on the smaller octahedral site [1-3]. This substitution is postulated to be so favourable that in the presence of (Mg,Al) perovskite, Fe\textsuperscript{3+} will form by the disproportionation reaction 3FeO ↔ Fe\textsubscript{2}O\textsubscript{3} + Fe\textsuperscript{0} [1]. This reaction would produce coexisting (Fe\textsuperscript{3+}, Al\textsuperscript{3+})-rich perovskite and iron metal in the lower mantle. If correct, FeO disproportionation provides a mechanism for the ‘self-oxidation’ of the mantle during core formation, and may help explain the siderophile element geochemistry of the mantle [1, 3]. Here, we investigate perovskite phase relations in the system Mg-Fe\textsuperscript{2+}-Fe\textsuperscript{3+}-Al-Si-O and report on laser-heated diamond anvil cell experiments at 30-100 GPa and 1500-2500 K. Run products were analyzed using synchrotron X-ray powder diffraction.

Experiments along the join MgSiO\textsubscript{3}-FeO\textsubscript{3} up to ~70 GPa show a considerable solubility (>25 mol\%) of Fe\textsuperscript{3+} into perovskite via the substitution 2Fe\textsuperscript{3+} ↔ MgSi, requiring that Fe\textsuperscript{3+} occupies the octahedral site in Al-free systems. Unit cell volumes increase slightly with increasing FeO, and the perovskite structure distorts mildly compared to distortion caused by Al\textsuperscript{3+} or coupled Fe\textsuperscript{3+}Al\textsuperscript{3+} substitution. New experiments along the join MgSiO\textsubscript{3}-FeAlO\textsubscript{3} show a maximum FeAl\textsubscript{2}O\textsubscript{4} solubility between 25 and 50 mol\% at 70 GPa.

We made compositions in which enough FeO was added on a molar basis to MgSiO\textsubscript{3}-Al\textsubscript{2}O\textsubscript{3} glasses for complete substitution via Fe\textsuperscript{3+}Al\textsuperscript{3+} ↔ MgSi should all the FeO disproportionate. Perovskite, ferropericlase and stishovite coexist in a composition with ~23 mol\% Fe\textsuperscript{3+}Al\textsuperscript{3+} at 35 – 60 GPa (~ 2000 K). In a composition with ~50 mol\% Fe\textsuperscript{3+}Al\textsuperscript{3+}, perovskite coexists with a ferrite-structured phase (± stish. or ferroper.) at similar P-T conditions. These results are explicable by quaternary phase relations in the reduced system MgO-FeO-Al\textsubscript{2}O\textsubscript{3}-SiO\textsubscript{2}. In contrast, if iron disproportionation were occurring then a Fe\textsuperscript{3+}-Al\textsuperscript{3+}-rich perovskite would coexist with pure iron. Calculations show that even 1 mol\% iron metal should be detectable by diffraction, yet we see no clear evidence of metallic iron in any diffraction pattern. Our results indicate that above the maximum solubility of Fe\textsuperscript{3+} in aluminous perovskite, stishovite + ferropericlase are stabilised and phase relations remain quaternary.

**Black Sea shelf microbial reefs**

**J. ARNDS, K. KNITTEL, A. BOETIUS AND R. AMANN**  
Max Planck Institute for Marine Microbiology, Bremen, Germany (contact@mpi-bremen.de)

**Introduction**  
Microbial reefs, fuelled by the anaerobic oxidation of methane, grow in anoxic waters at the Black Sea shelf (Figure a). The key methanotrophic microbes were identified, but little is known about the structures of reef-forming microbial communities.

In order to follow the reefs growth, we analysed sediment surrounding an active gas seepage (Figure b), a supposably initial reef stage (Figure c), as well as different parts of one reef (top, exterior and center) from the Danube Canyon by using molecular tools. Further reef samples from three different locations along the northwestern shelf (Metrol Cruise POS317/3: Danube Canyon, Northwestern Shelf and Paleo-Dnepr Area) were characterised to address the question whether the reefs are comparable structures.

**Figure:** Supposed stages of forming reefs

**Discussion of results**  
A major fraction of the reef-forming communities consisted of anaerobic methane oxidising archaea (ANME) of which either ANME-1 or ANME-2 dominated certain reef parts. Key bacterial players were members of the sulphate-reducing *Desulfosarcina* / *Desulfococcus*, as well as *Planctomycetes* and *Verrucomicrobia*. The reef’s top was characterised by the abundance of huge, apparently active ANME-2 aggregates whereas the center comprised mostly single, probably inactive cells. Most ANME-1 were found in the center, however including numerous dead cells. The exterior of the reef was highly heterogeneous with respect to ANME distribution and bacterial diversity. The comparison of reefs showed a high variability between activity and abundance of different groups, but most key players appeared in all samples.

**Conclusions**  
We hypothesize, that the most active microbial growth area of the reef is the top, whereas the center seems to be the oldest part. The reef’s exterior provides heterogeneous microniches and might grow more or less radially. Reefs along the northwestern shelf differed remarkably. Certain groups seem to represent typical reef-forming microbes, but the variable community structures suggest various environmental conditions or reef ages.

**Scientific drilling in the Barberton Greenstone Belt**

**NICHOLAS ARNDT AND THE BARBERTON DRILLING TEAM**  
LGCA, Université de Grenoble, 38400 Grenoble France (ardt@ujf-grenoble.fr)

The Barberton Greenstone Belt in South Africa is a remarkable natural laboratory where conditions at the surface of the Archean Earth can be investigated. Shallow (100-1000m) diamond cores will be drilled in selected volcano-sedimentary successions in order to reconstruct the geodynamics of Archean sedimentation and volcanism, how these processes interacted at the interface between lithosphere-hydrosphere-atmosphere-biosphere, and the environments at the Earth’s surface where life first emerged and subsequently evolved.

Despite generally good outcrop, nowhere in the Barberton belt are complete sections preserved, and crucial features such as the contacts of lava flows and critical sedimentary rock sequences are not exposed. Drilling is needed to obtain such sections and relatively unaltered samples. Two main targets have been identified. (1) Sedimentary sequences will provide information about erosion and sedimentation on the early Earth, the composition and temperature of Archean seawater, and one site where life may have emerged and evolved. Tidal sequences will inform us about the dynamics of the Earth-Moon system, and spherule layers and impact debris provide information about the nature and magnitude of meteorite impacts. (2) Successions of ultramafic to felsic volcanic rocks will provide new insights into volcanic processes, mantle dynamics, and interaction between oceanic volcanic crust and the hydrosphere and biosphere. The sources of hydrothermal fluids on the ocean floor, driven by circulation of seawater through the volcanic pile, constitute a second habitat of early life.

The project is supported by scientists from 13 countries in five continents and by the mineral exploration industry. Planning meetings have been held in Johannesburg (Oct 2006), San Francisco (Dec 2006) and Berlin (March 2007). Proposals for funding have or will be submitted to agencies in Europe, America and Asia and to the ICDP.
Diagenesis in deep-seated Cretaceous black shales: Inverse modeling and transient model simulations

S. ARNDT¹, H.-J. BRUMSACK², K.W. WIRTZ³ AND P. REGNIER⁴

¹Utrecht University, Utrecht, The Netherlands (armdt@geo.uu.nl)
²Institute for Biology and Chemistry of the Marine Environment, Oldenburg, Germany (brumsack@icbm.de)
³Institute for Coastal Research, Geesthacht, Germany (wirtz@gkss.de)
⁴Utrecht University, Utrecht, The Netherlands (regnier@geo.uu.nl)

A transport-reaction model was designed to identify the importance and specific rates of diagenetic processes operating in four sites drilled during ODP Leg 207 (Demerara Rise, Equatorial Atlantic). Model results reveal that almost 100 Ma after their deposition, deeply buried (200-500 mbsf) Cretaceous black shales still act as active bioreactors at great sediment depths. Methanogenesis in the black shales is identified as a key process, which dominates not only organic matter degradation but also the sulfate availability through the anaerobic oxidation of methane above the black shale sequences. The complete depletion of sulfate in the methane-rich black shale sequences promotes the dissolution of biogenic barites. The released barium reprecipitates as authigenic barite at the top of the sulfate depletion zone and serves as an indicator for the location of the sulfate-methane interface.

Reaction rate constants were determined by inverse modeling techniques. Due to the low metabolic activity in the deep biosphere, estimated rate constants are orders of magnitudes lower than those observed in the shallow subsurface. Model-determined methanogenic rate constants (1-3.5 10⁻⁹ a⁻¹) compare well with those estimated by the empirical power law (Middelburg, 1989). In addition, methanotrophic reaction rates (10⁻² μM a⁻¹) are similar to experimentally determined rates at other deep biosphere sites (ODP Leg 201). Transient model simulations indicate that the initial reactivity of the black shale organic matter must have been already low (ca. 1.1 10⁻⁸ a⁻¹) during its deposition 100 Ma ago. The decrease of organic matter reactivity and the associated decrease in methanogenic rates, as well as changing sedimentation rates lead to significant shifts of the sulfate methane interface over the past 100 Ma. The associated vertical migration of the barite precipitation zone is well recorded in the barite depth profile and supports our transient model results.

Phosphogenesis in recent upwelling areas: The importance of microbial communities indicated by lipid biomarkers

E.T. ARNING¹, D. BIRGEL¹, H.N. SCHULZ-VOGT², B.B. JORGENSEN³ AND J. PECKMANN¹

¹DFG-Forschungszentrum Ozeanränder, Universität Bremen, D-28334 Bremen, Germany (arning@uni-bremen.de, dbirgel@uni-bremen.de, peckmann@uni-bremen.de)
²Institut für Mikrobiologie, Universität Hannover, D-30167 Hannover, Germany (schulz@ifmb.uni-hannover.de)
³Max-Planck-Institut für Marine Mikrobiologie, D-28359 Bremen, Germany (bjoergen@mpi-bremen.de)

The burial of phosphorus and the formation of phosphorites (phosphogenesis) in marine sediments represent an important sink in the global phosphorus cycle. Numerous basin-scale phosphorite deposits were formed in the geological past (e.g., Trappe 1998). Phosphogenesis is not only found in ancient settings, it is reported in recent sediments of upwelling regions as for example off Namibia, Peru, and Chile (Föllmi 1996).

These sediments contain dense populations of large nitrate-storing sulfate-oxidizing bacteria *Thiomargarita*, *Beggiaota*, and *Thioploca*, respectively. Due to metabolic activities of the thiophots generating sulfate, a close spatial connection to sulfate-reducing bacteria is established. Differences in the motility of the thiophots at the three study sites lead to different distributions of sulfate reducers in sediments off Namibia, Peru, and Chile. Profiles of lipid biomarkers attributed to sulfate reducers (10MeC₁₆:₀ fatty acid, ai-C₁₅:₀ fatty acid, and mono-O-alkyl glycerol ethers) document the close association to thiophots. Depth profiles of mono-O-alkyl glycerol ethers have been found to correlate best with the occurrence of large sulfur bacteria. This suggests a particularly close link between mono-O-alkyl glycerol ether-synthesizing sulfate reducers and thiophots. Lipid biomarker profiles indicate that the interaction between thiophots and sulfate-reducing bacteria favors phosphate enrichment, triggering phosphorite formation in upwelling areas.

Studying recent phosphogenic environments provides a basis to better understand microbial influence on phosphogenesis and to better constrain the role of microorganisms in the formation of ancient phosphorites.

**The role of cations versus anions in the dissolution of ionic crystals**

R. S. ARVIDSON¹ AND A. LÜTTGE²

¹Department of Earth Science, Rice University, Houston TX 77005 (rsa4046@ruf.rice.edu)
²Department of Chemistry, Rice University, Houston TX 77005 (aluttge@rice.edu)

In growth and dissolution of binary ionic crystals, a common assumption is that the cation plays a more fundamental kinetic role than the anion. This thinking derives from the recognition that a key step in ion transfer between solid and solution involves hydration (dissolution) or dehydration (crystallization). In the case of carbonate growth, the energetic penalty of removing water from the hydration shell may impose the limiting step, particularly if the metal involved is strongly hydrated (e.g., Fe²⁺, Mg²⁺). Surface complexation models [e.g., 1,2] are consistent with this thinking. However, to explore this process accurately requires knowledge of the interaction of these species with particular surface sites.

We can test these ideas with parameterized Monte Carlo calculations of dissolution reactions involving various carbonates. These models involve the full crystal lattice and are parameterized by ab initio and DFT calculations. This approach allows us to study the problem of how a given ion (Ca²⁺, CO₃²⁻) interacts at individual surface kink sites. In addition, we can investigate the role of specific metal inhibitors (Mn²⁺, Sr²⁺, Mg²⁺). We will present several examples, including (1) the influence of an impurity metal on dissolution in terms of dehydration versus carbonation reactions, and (2) differences in reaction pathway during anion versus cation attachment and detachment. The tested model generates a predictive tool for dissolution kinetics of carbonate minerals.

Tertiary aged post-collisional volcanics show stratigraphic, petrographic and age differences in the northern and southern zones of the eastern Pontides. The Eocene sequences in E-W direction are exposed as basin fillings in the southern zone and overlay the Upper Cretaceous and Paleocene aged units. The volcanic rocks in the Gümüşhane and Alucra areas are mainly basalt, basaltic andesite, andesite, trachyandesite and rare rhyolite-obsidien.

Petrochemically, the Gümüşhane area volcanics vary from basalt to dacite with low alkali tendency, whereas the Alucra area volcanics from basalt to basaltic-trachyandesite with high alkali tendency. The differences on the element variations of the tholeiitic-alkaline transition and calc-alkaline rocks can be explained by fractionation of clinopyroxene + hornblende + plagioclase ± magnetite ± apatite. The trace element variations show some similarities with enrichment of LILE and negative Nb, Ta and Ti anomalies. Particularly, the enrichments in LILE and a lesser extent in LREE, but the depletions in HFSE indicate that the rocks evolved from a parental magma derived from an enriched source formed by mixing of slab and asthenospheric melts. The chondrite-normalized-REE patterns of these volcanics resemble to each other and spoon-shaped with low to medium enrichment (LaN/LuN=2-35), indicating similar source area for the Gümüşhane and Alucra area volcanics.

The ⁴⁰Ar/³⁹Ar dating of the studied volcanics are between 37.7±0.2 and 44.5±0.2 Ma. The (⁶⁰Sr/⁸⁶Sr) values of the rocks are between 0.70457 and 0.70556, and their ²⁰⁶Pb/²⁰⁴Pb, ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁴Pb/²⁰⁶Pb isotopic ratios range 18.59 to 18.73, 15.62 to 15.64 and 38.65 to 38.86, respectively. Pb- and Sr-isotopic ratios may imply that the rocks derived from a source region at the boundary of the mantle-crust, but the samples with low (⁶⁰Sr/⁸⁶Sr) values (<0.705) reflect the mantle source in their origin. The increasing values of SiO₂ (wt.%), Sr (ppm) ve (1/Sr)x10⁷ ppm⁻¹ versus (⁶⁰Sr/⁸⁶Sr) values suggest fractionational crystallisation (FC) rather than assimilation (AFC) in their evolution. Based on volcanic variety and distributions together with field and petrological data, volcanic activity in the Eocene time of the eastern Pontide is closely related to extensional tectonic regime with transtensional faults.
Post-collisional transition from orogenic to within-plate type volcanism in the Kulu-Haymana area (Central Anatolia, Türkiye)

K. ASAN AND H. KURT

Selçuk Üniversitesi, Jeoloji Mühendisliği Bölümü, Konya, Türkiye (kasan@selcuk.edu.tr, hkurt@selcuk.edu.tr)

Introduction

Orogenic type calc-alkaline and continental within-plate type mildly alkaline volcanic rocks occur together in the Kulu-Haymana area (Central Anatolia, Türkiye). The former are represented by voluminous andesitic-dacitic lavas and their pyroclastites whereas the latter include alkali basalt, hawaiite, mugearite, bnenmoreite and trachydacite. Ar-Ar age data indicate that the volcanic activity was formed during Early Miocene (21.3-18.0 Ma) in the area. Also, a transition from the calc-alkaline to the mildly alkaline volcanism was formed in this period.

Geochemistry

The calc-alkaline volcanic rocks are medium-K in composition (K2O: 1.0-2.2 wt.%) and exhibit enrichment in large ion lithophile elements (LILE) and light rare earth elements (LREE) and depletion in high field strength elements (HFSE). 87Sr/86Sr(t) ratios and ε(Nd) values of the calc-alkaline rocks are 0.704452-0.705264 and 0.73-3.86 respectively.

In contrast, mildly alkaline volcanic rocks have a sodic tendency (Na2O/K2O: 1.5-3.2) and exhibit enrichment in LILEs, LREEs and HFSEs. The mildly alkaline rocks have relatively lower δ87Sr/86Sr ratios (0.703809-0.705159) and higher ε(Nd) values (2.32-4.50) than the calc-alkaline rocks.

Discussion and conclusions

According to geochemical features of the calcalkaline rocks, it can be deduced that the source of these rocks was a subduction-modified lithospheric mantle. High LILE contents and 87Sr/86Sr ratios (up to 0.705264) of the rocks raise possibility of crustal contamination. However, AFC modelling based on equations of De Paolo (1981) shows that the crustal contamination did not play an important role in the genesis of the calc-alkaline rocks (r: 0.2).

In contrast, alkali basalts show no evidence of subduction signature in their mantle source. The mantle source of the alkali basalts was heterogeneous. Two mantle sources were recognized for the alkali basalt samples: 1) depleted mantle (low 87Sr/86Sr and intermediate 143Nd/144Nd ratios) and 2) enriched mantle (high 87Sr/86Sr and low 143Nd/144Nd). Geochemical variations indicate that fractional crystallization played an important role in the evolution of evolved rocks.

The stratigraphic, petrologic and geohemical features of the volcanic rocks suggest the volcanism occurred in a post-collisional tectonic setting.

4NKMK, Novokusnetsk (vishnyakova_ev@nkkm.ru)

Model for magmatic source and lithosphere structure

The kimberlite magma evolving at the lithosphere base form polybaric magmatic system chambers and melting regions in peridotites at 80 -60 kbar according to thermobarometry of minerals (Ashchepkov et al., 2006) from mineral separates and diamond inclusions (DI) (Logvinova and DI, 2006). At their top the magma-rich mantle diapir intrude the lithosphere. The evolved protokimberlite melts create a magma feeding system producing megacrystalline Ilm – Gar – Ol – CrDi aggregates up to 40 kbar (pyroxenite lens) or upper and heat the surrounding peridotite and eclogites followed by Ti–metasomatism. The submelting forms uprising polymeric musch column. Geotherms splits to hot and low-T branches. Relic subduction geotherms refer to dunite– harzburgites and Gar, Opx inclusions in diamonds. Several pulses of melt ascend from the basement beneath satellite pipes like for Ozernaya near Yubileynaya produce strong heating. Magmatic sources may shift to 40 kbar forming diamond- free kimberlites and carbonatites. Geochemical features of mantle peridotites are affected to melt-fluid flows from base and intermediate magma sources.

Heterogeneity in mid-ocean ridge sources
PAUL D. ASIMOW
Division of Geological and Planetary Sciences 170-25, California Institute of Technology, Pasadena CA 91125 USA (asimow@gps.caltech.edu)

This talk will review some theoretical considerations concerning the melting of heterogeneous sources and the implications for interpretation of melt inclusion data, particularly olivine-hosted inclusions from mid-ocean ridge environments. We have apparently adequate models that assume a locally or globally homogenous source and can explain major and trace element chemistry of basalts and correlations with physical variables like melt flux and axial depth. Such models are the basis of the consensus view of the average thermal and compositional state of the upper mantle and the range of their variability. However, a variety of data (most notably from melt inclusion diversity within samples and suites) and lines of reasoning (such as the need for recycling to maintain fertility of the source) require that heterogeneity exists within particular melting regimes as well as among them. We can classify heterogeneity by scale. There is some small scale (perhaps ~10 cm) below which the source melts as if it were effectively homogeneous and some large scale (perhaps ~ 1 km) above which the source components can be treated as chemically and thermally independent and their melts simply mixed; these scales may be different for different elements and lithologies. The challenge is to develop tools that predict behavior at intermediate scales where incomplete thermal and/or chemical interaction occur and hence standard mixing theory is confounded by complex feedbacks between composition and melting behavior and between melting and equilibration. Additional challenges center on the kinetics of interactions during melt migration through heterogeneous media.

I will review some of the reasons this problem defeats the current generation of melting models, the efforts that have been published by various authors, the theoretical progress that is needed, and the prospects for success.

Magmatism and the evolution of the Earth’s interior
PAUL D. ASIMOW
Division of Geological and Planetary Sciences 170-25, California Institute of Technology, Pasadena CA 91125 USA (asimow@gps.caltech.edu)

The flow of liquids relative to solids or other liquids is the only efficient mechanism for obtaining physical separation of chemical components of an initially homogenous material at high pressure. Hence the history of differentiation of the Earth’s interior is essentially the history of magmatic phenomena: core formation involving molten metal, formation and freezing of a silicate magma ocean, and ongoing partial melting of silicate solids. In early history much of this activity took place at very high pressure, in the lower mantle (plausibly, silicate magmatic activity continues today at the core-mantle boundary). In order to define possible evolutionary paths of the young Earth and to learn what evidence might remain today of such early processes we must build well-constrained models of igneous processes at appropriate pressures, temperatures, and compositions. This remains difficult because experimental study of lower mantle igneous petrology lies mostly beyond the pressure capability of multi-anvil devices and beyond the size and homogeneity capability of diamond anvil cells. We must rely on indirect tools: construction of phase diagrams and thermodynamic models from thermochemical and equation of state data contributed by mineral physics and the emerging field of high-pressure melt physics. There are roles in this enterprise for quantum and molecular dynamics computation, shock wave experiments, and a variety of in situ applications of synchrotron radiation. Once the major element phase equilibria are well-defined, then it is appropriate to turn to trace elements and the determination of partition coefficients at appropriate pressure, temperature, and major element compositions.

This plenary lecture will review the times and depths in Earth history where magmatic differentiation has determined planetary evolution, some basic thermodynamic tools for defining and understanding behavior in adiabatic environments like convecting mantles and magma oceans, progress in constructing appropriate phase diagrams, and areas of continuing uncertainty.
Petrography and geochemistry characteristics of the calc-alkaline Tertiary (?) tuffs in the Gumushane area, NE Turkey

Z. ASLAN, A. KAYGUSUZ, M.A. GUCER AND E. AYDINCARKIR
KTU, GMF, Department of Geological Engineering, Gumushane/Turkey
(aslan@ktu.edu.tr; abdullah@ktu.edu.tr)

The study area is in the southern zone of the eastern Pontides, which is characterised by Liassic, Upper Cretaceous and Eocene volcanism [1]. Eocene volcanism consists of acidic, notr and basic volcanic and pyroclastic rocks in Gumushane and surrounding area [2]. In this study, mineralogical, petrographical and geochemical properties of the Gumushane region tuffs were investigated. These rocks are consisting of andesite, dacite, lapilli, vitric and silicification tuffs. Tuffs contain plagioclase (An 28-50), amphibole, glass shards, lesser pyroxene and K-feldspar, opaque oxides, secondary clay, sericite, calcite, chlorite, and devitrified glass. It is excessively weathering and silicification, and cut by dolerite.

Tuffs have a composition of contents 52-67% SiO₂, 0.55-0.74% TiO₂, 14-18% Al₂O₃, 0.5-6% FeO₄, 0.2-2.2% MgO, 1.5-2.9% Na₂O and 1.5-6% K₂O. Geochemically, these rocks change from andesite to dacite in composition and exhibit medium-high K calcalkaline characteristics. In variation diagrams show two different trends. Dacitic tuff is characterized high K₂O, Na₂O and Al₂O₃ and low CaO, Fe₂O₃, MgO and P₂O₅, but andesitic tuff is of inverse value. In addition, generally Na₂O, Fe₂O₃, Al₂O₃, CaO and MgO decrease whereas Zr, Ba, Rb, Th, U and Nb increase with increasing SiO₂. Rare earth element patterns pronounced Eu anomalies indicating plagioclase fractionation. All samples are characterised by significant flattening of REE patterns from Dy to Lu relative to the LREE. (Lu/La)N value is change from 3.3 to 7.7.

The investigated tuffs differ from the Eocene volcanics in the southern zone by their field, petrographical and geochemical characteristics. Probably these tuffs may be related to post Eocene volcanism.

Critical crater diameter and the impact response of asteroids

ERIK ASPHAUG
Earth and Planetary Sciences Dept., University of California, 1156 High St., Santa Cruz CA 95064, USA (asphaug@pmc.ucsc.edu)

Asteroid surface morphologies are expressions of the seismic properties of their interiors. They allow us to measure, to first order, how an asteroid responds to collisions and other high energy events through a quick examination of its largest craters.

The critical crater diameter Dcrit is defined as the minimum crater diameter on an asteroid whose formation disrupts, through distal shock and seismic effects, all previous craters ≤ Dcrit. This threshold is computed by applying crater scaling relations and peak particle velocity attenuation relations. If the largest distinct crater observed on an asteroid is typically at or near this threshold size, it follows from this analysis that small asteroids (e.g. 25143 Itokawa) can have no sizable craters, relative to their diameter, while large asteroids (e.g. 253 Mathilde) are likely to have hemisphere-spanning craters.

Because Dcrit can approach or even exceed the size of the target, the largest asteroids like Mathilde are likely to be saturated with hemisphere-spanning craters – up until the size that the asteroid is a geologically active and gravitationally relaxing planet. This is because craters smaller than Dcrit, however gigantic they might appear, do not broadcast globally.

Stress wave velocities on known asteroids, as parameterized by the model, are found to decay with the ~1.3 power of distance for most asteroids (circles plot the largest identified crater on each asteroid). This is much less attenuative than strong shocks. This is expected, because disturbances capable or destroying crater rims on asteroids are of very low particle velocity, and thus require stress waves lower in amplitude than typical lunar regolith cohesion. Models for asteroid catastrophic disruption, which rely upon stronger attenuation or upon hydrocodes tuned to energetic blast events, consequently over-estimate particle velocity attenuation and over-estimate the threshold for catastrophic disruption QD.
Interaction of gypsum with Pb-bearing aqueous solutions

J.M. ASTILLEROS1, J.D. RODRIGUEZ-BLANCO2, A. GODELITSAS3, L. FERNÁNDEZ-DÍAZ1 AND M. PRIETO2

1Dpto. Cristalográfia y Mineralogía. Universidad Complutense de Madrid. E-28040 Madrid, Spain [jmastill@geo.ucm.es, lfdiaz@geo.ucm.es]
2Dpto. de Geología. Universidad de Oviedo, E-30005 Oviedo, Spain [juandiegorodriguez@gmail.com, mprieto@geol.uniovi.es]
3University of Athens, Faculty of Geology and Geoenvironment, Athens, Greece [agodel@geol.uoa.gr]

Sorption of heavy metals on mineral surfaces plays an important role in controlling both the dispersion and accumulation of these pollutants as well their geoavailability and bioavailability in near-surface environments. Among sedimentary rocks-forming minerals, gypsum arises as potentially useful to uptake a broad spectrum of dissolved metals because of the high reactivity of its surfaces and its abundance in nature.

With the aim of investigating the effectiveness of gypsum (CaSO4·2H2O) as a Pb-sequester, we have carried out macroscopic experiments in which 2 g of pure gypsum fragments (selenite variety) millimetre-sized (1.00-1.40 mm) were put in contact with 100 cm³ of Pb-bearing aqueous solutions. The initial concentrations of Pb in the solution were in the range between 10 and 1000 mg/l). Experiments were conducted at room temperature under atmospheric CO₂ pressure in a closed batch type experimental set-up. Independent experimental runs were carried out for each Pb(NO₃)₂ aqueous solution concentration. After specific reaction periods (ranging from 1 minute to a week), crystals were separated from the solution. The evolution of the aqueous solution composition was monitored using AAS, Ion Chromatography, and occasionally ICP-OES. Our experimental results show that the concentration of Pb²⁺ in the solution rapidly decreases during the first minutes of the interaction. The uptaking process takes place by the rapid dissolution of gypsum (pKsp = 4.58) and the simultaneous formation of an anglesite (PbSO₄, pKsp = 7.79) precipitate (identified by XRD and SEM-EDX) on the gypsum surface. Speciation calculations using PHREEQC (Parkhurst and Appelo, 2000) demonstrate that solutions tend to reach equilibrium with respect to both gypsum and anglesite phases after long interaction periods. The behaviour observed can be interpreted as a result of the coupling between gypsum dissolution and anglesite precipitation. The kinetics and effectiveness of this process is discussed. The macroscopic study is completed with some AFM observations.

Toxic metals in runoff from acid sulphate soils

MATS E. ÅSTRÖM

Kalmar University, School of Pure and Applied Natural Sciences, 39182 Kalmar, Sweden (mats.astrom@hik.se)

A massive supplier of toxic metals

A largely unrecognised geogenic source delivering massive amounts of toxic metals to the aquatic environment is presented. The source is a soil type – acid sulphate (a.s.) soil – that cover more than 17 million ha worldwide. This soil is located mainly on coastal plains and is developed when sulphide-rich sediments once formed under anoxic conditions in lakes or oceans are exposed to atmospheric oxygen. The pH of this soil is between 2 and 4.

The awareness of the problem

It is well known that from a.s. soils large amounts of acidity is leached, in particular during heavy rains or snow melting, causing severe acidification of downstream waters and inner estuaries. Associated fish kills have been reported from a variety of regions, including northern Europe, eastern Australia and south-east Asia. The metal problem associated with these soils is, however, largely unrecognised and unknown.

The mechanisms and extent of metal release

The behaviour of chemical elements, including potentially toxic trace metals, in a.s. soil landscapes has been sparsely studied. One exception is the largest a.s. soil occurrences in Europe, found on the coastal plains of western Finland, where a number of hydrogeochemical studies have been carried out. These have shown that the Finnish a.s. soils deliver to the aquatic environment large amounts of highly toxic metals such as Be, Tl and Cd, produces in low order streams concentrations of Al up to 300 mg/L and Mn 20 mg/L, and supplies much larger amounts of metals to the aquatic environment than the entire Finnish industry. Preliminary studies in Asia and others in Australia have indicated similar patterns in tropical and subtropical areas. The mechanisms and extent of the metal release from these nasty but also socioeconomically valuable soils are presented.
DIC concentration and $\delta^{13}$C in thermal springs of La Soufrière volcano (Guadeloupe, FWI): Implications for volcanic surveillance

Cyril Aubaud, Céline Dessert, Pierre Agrinier, Olivier Crisp, François Beauducel

La Soufrière volcano (Guadeloupe, FWI) is an arc volcano representing high risks of future eruptions. It is among the best surveyed volcano in the world, thermal springs and fumaroles being sampled and analyzed since 1979, providing a continuous data record over 28 yr [1]. The increase in seismic and fumarolic activity since 1992 and HCl degassing since 1998 prompted the observatory to intensify the surveillance of the volcano. Since CO$_2$ is the least soluble volatile species in magmas, it is the first to be degassed from a rising magma. As a consequence, carbon and its stable isotopes in fumaroles and magmas, it is the first to be degassed from a rising magma. It can be expected that future intrusions would result in an increase in DIC and $\delta^{13}$C-value in the springs. Therefore, DIC and $\delta^{13}$C may represent valuable tools for volcanic surveillance.

The role of fluid immiscibility in the formation of magmatic-hydrothermal ore deposits

Andreas Audétat, Thomas Pettke, Christoph A. Heinrich

Experimental studies suggest that large immiscibility gaps exist in H$_2$O-salt (±CO$_2$, CH$_4$) fluids at the P/T-conditions prevailing in subvolcanic to plutonic environments. Not surprisingly, therefore, samples recording the former coexistence of two types of fluids are rather common in the magmatic-hydrothermal systems. One major consequence of fluid immiscibility is chemical fractionation. PIXE, SXRF and LA-ICP-MS analyses of individual fluid inclusions have shown that Cu, Au, B, As, Sb and Li are often systematically enriched in vapor inclusions relative to coexisting brine inclusions (e.g., Williams-Jones and Heinrich, 2005). In the case of Cu and Au it is believed that this behavior is caused by the formation of stable sulfur complexes in the vapor phase, although definitive experimental proof is lacking so far. Another major consequence of fluid immiscibility is that differences in density and/or wetting properties lead to physical separation of the two fluid phases. This, together with chemical fractionation, can result in chemical zonations at various scales, e.g., the formation of epithermal gold deposits above porphyry-Cu deposits.

Fluid inclusion studies and experimental data suggest that intermediate to felsic magmas crystallizing at depths relevant for magmatic-hydrothermal ore deposits first exsolve a single-phase fluid of intermediate density and low salinity (2-10 wt% NaCl eq.) upon cooling (e.g., Audétat and Pettke, 2003). Fluid immiscibility commonly does not occur until the magma has approached its solidus, where pressure starts to change from lithostatic to hydrostatic. Due to the pressure decrease and the low salinity of the bulk fluid, the mass of vapor generated may often exceed that of the coexisting brine, such that the bulk fluid can be thought of a vapor plume at that stage. However, in view of the high metal content and relatively low mobility of brines it is nevertheless feasible that some deposits formed predominantly from brines rather than from vapors, and that the condensation of brine out of a low-density bulk fluid helped to concentrate the metals in a small rock volume. Element partitioning between coexisting fluid phases combined with quantitative fluid flow models will advance our understanding on how elements are separated, distributed and concentrated up to ore grade in magmatic-hydrothermal environments.

References

Provenance studies of sedimentary rocks can play an important role for palaeogeographic reconstructions. Such reconstructions are aided by varietal studies of detrital heavy minerals. In an ongoing varietal study of detrital zircons from sedimentary rocks of the Palaeozoic Gondwana margin of NW Argentina and N Chile, the detrital sources are traced. We will present the first morphology, zoning and U-Pb age data of zircon grains of the Middle Ordovician Lower Turbidite System of the Puna Turbidite Complex in NW Argentina (ca. 23°S, 66°30’W). The zircon analyses from two samples indicate a dominance of grains 100-150 µm in length that are euhedral or slightly abraded. Cathodoluminescence images reveal that most analysed zircons in the two samples are oscillatorily zoned, which is indicative of a magmatic origin. Less than 10 % of the grains are metamorphic. Zircons with only one visible growth phase are common. In situ U-Pb dating was applied to 50-60 grains from each of the two samples. The outer zoning was preferably dated in grains with several growth phases. Concordant preliminary U-Pb ages (uncorrected for common Pb) are mostly < 600 Ma. The morphology, zoning and U-Pb data make it probable that most analysed zircons in the two samples are of local origin, which also can be expected, because the Lower Turbidite System was deposited in a retroarc foreland basin position with a magmatic arc to the (present-day) west, and the Gondwana mainland to the east. The zircon age distribution make it possible that western sources dominated, but that also minor transport took place from the Gondwana mainland.

Proterozoic diamond formation at the Kaapvaal craton edge: Re-Os of Jagersfontein sulfide inclusions

SONJA AULBACH1, STEVEN B. SHIREY2, THOMAS STACHEL1, JEFFREY W. HARRIS3
1 Earth & Atmospheric Sciences, University of Alberta, Edmonton AB, Canada (aulbach@ualberta.ca, tstachel@ualberta.ca)
2 Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington DC, USA (shirey@ciw.edu)
3 Department of Geographical and Earth Sciences, University of Glasgow, Glasgow, UK (Jeff.Harris@ges.gla.ac.uk)

The mantle sampled by the ~90 Ma Jagersfontein kimberlite, near the southern edge of the Kaapvaal craton block in South Africa, is unusual as the diamonds contain asthenospheric, transition zone and a preponderance of eclogitic inclusions. This unusual depth range of diamond provenance may indicate that the multiple episodes of diamond formation seen in other Kaapvaal kimberlites (3.4 to 1 Ga; Richardson et al. 1993; Shirey et al. 2004) are distinct at Jagersfontein.

Sixteen diamonds, examined for N levels and aggregation states, hosted Fe-sulfide inclusions that were analyzed for composition and Re-Os isotopes. Eleven stones have low N contents (15 – 57 ppm) similar to, but not exclusive of, sublithospheric diamonds (Tappert et al. 2005), N contents in four stones range from 62 to 94 ppm, one stone contains 756 ppm. Based on N aggregation state, two diamond groups exist (<20 % vs. >33 % Ninal as B centers) suggesting different mantle residence temperatures and/or ages. The majority of the sulfide Re/Os ratios lie between >0.5-46, typical of eclogite with komatiitic to basaltic precursors.

Sulfides from crack-free diamonds fall on two arrays in the Re-Os isotope diagram: one with a 1.7 +/- 0.11 Ga age and a highly radiogenic initial 187Os/188Os (0.45 +/- 0.07), the other with an overlapping age of 1.42 +/- 0.40 Ga and a less radiogenic initial 187Os/188Os of 0.11 +/- 0.13. The former may indicate Proterozoic diamond growth by remobilisation of Archaean mafic components in the lithosphere, whilst the latter may represent growth from new fluids added to the lithosphere. N aggregation states and inferred temperature of provenance suggest diamond crystallization at multiple depths. In stark contrast to all other Kaapvaal eclogitic sulfide suites studied to date, Archaean ages are absent in the present suite. This result may relate to unique aspects of the Jagersfontein kimberlite, which has transported and preserved very deep diamonds, or be a consequence of its location on the craton edge.

Tracing metasomatic reactions using inert zircon coronas around ilmenite

H. AUSTRHEIM1,2, C.V. PUTNIS2, A.K. ENGVIK3 AND A. PUTNIS2

1PGP, Universitetet i Oslo, 0316 Oslo, Norway
(h.o.austrheim@geo.uio.no)
2Institut für Mineralogie, 48149 Münster, Germany
(putnisc@uni-muenster.de)
3Geological Survey of Norway, 7491 Trondheim, Norway
(ane.engvik@ngu.no)

Thin (typically ≤ 10 µm wide) coronas of zircons are commonly found around Fe-Ti oxides in mafic granulites and gabbroic rocks (Bingen et al. 2001; Søderlund et al. 2004). The zircons may remain inert during subsequent metamorphic and metasomatic alteration and outline former grain boundaries allowing to quantify mass transfer and to constrain the mechanism of replacement reactions. We use microtextures and zircon coronas to obtain information on the metasomatic alteration related to scapolitization and albitization of two gabbros (Ødegården and Langoya gabbros) from Kragerø, Southern Norway. During scapolitization ilmenite is completely replaced by silicates and rutile. The scapolitized Ødegården gabbro contains trails of tiny zircons in talc (after enstatite) documenting a complete replacement of the Fe-Ti phase with a Mg-silicate (mg# = 0.95). In addition to Ca-rich scapolite and apatite, Mg-rich minerals phlogopite (mg# = 0.95) amphibole (mg# = 0.85) and sapphirine (mg# = 0.98) are formed during this alteration. The ilmenite in the scapolitized Langoya olivine gabbro is replaced by phlogopite and amphibole. Additional phases are prehnite and tourmaline. While Fe in both cases leaves the system, Ti remains as rutile in the scapolitized Ødegarden gabbro. However the rutile is located outside the zircon coronas suggesting local scale mobilization of Ti. The nearby Langoya magnetite mines are the likely sink for the leached Fe and indicate transport on the scale of km.

Trails of ca 10 µm sized zircons are also present in the albitite-rock of the Ødegården area. Here the zircons trails are located in albite spatially associated with rutile suggesting the albitite formed from an ilmenite bearing gabbro possibly via a stage of scapolitization.

Iron partitioning and the self-oxidation of the lower mantle

A-L. AUZENDE1, J. BADRO1,2 AND F.J. RYERSON2

1IPGP-IMPMC, Dpt of Mineralogy, Paris, France
(auzende@impmc.jussieu.fr, badro@impmc.jussieu.fr)
2LLNL, University of California, Livermore, USA
(ryerson@llnl.gov)

Magnesium silicate perovskite (Mg,Fe)SiO3 (Mg-pv) and ferropericlase (Mg,Fe)O (fp) are the dominant phases in the lower-mantle. Their physical and chemical properties determine the dynamics of the deep Earth. It is thus of prime importance to constrain element partitioning at high pressure for improving the geochemical models of the Earth. We investigated iron partitioning between Mg-pv and fp synthetised under lower-mantle conditions (up to 115 GPa and 2200 K) in a laser heated diamond anvil cell (LH-DAC). Recovered samples were thinned to electron transparency by focussed ion beam (FIB) and characterized by analytical transmission electron microscopy (ATEM) and nanometer scale ion probe (nanoSIMS). Iron concentrations in both phases were obtained from EDX measurements and nanoSIMS. Our results are the first to show that recently reported transitions in the lower-mantle (Badro et al., 2003; Murakami et al., 2004) directly affect the evolution of Fe-Mg partitioning between both phases. Mg-pv is increasingly iron-depleted above 70-80 GPa possibly due to the high spin-low spin transition of iron in fp. Conversely, the perovskite to post-perovskite transition is accompanied by a strong iron enrichment of the silicate phase. Iron concentrations determined by ATEM and nanoSIMS are in excellent agreement. Nanoparticles of metallic iron were observed in the Mg-pv bearing runs (figure), suggesting the disproportionation of ferrous iron and the self-oxidation of the mantle, but were not observed when the post-perovskite (ppv) phase was present. Implications on the oxidation state of the Earth and core segregation will be discussed.

Metasomatism and melting in subduction–related volcanics: U-Th-Pa constraints from Vesuvius

R. AVANZINELLI1, J. PRYTULAK1, T. ELLIOTT1, M. MATTEI2 AND S. CONTICELLI3

1Bristol Isotope Group, Depart. Earth Sciences, University of Bristol, UK (r.avanzinelli@bris.ac.uk)
2Dipartimento di Scienze Geologiche, University of Roma III, Italy
3Dipartimento di Scienze della Terra, University of Florence, Italy.

We argue that the highly undersaturated, incompatible element enriched lavas of southern Italy reflect the influence of a metasomatic component from subducted carbonate-rich sediments. Vesuvius in particular, provides a natural laboratory to study this process, located on an active margin where abundant clay-carbonate rich lithologies are currently subducting. Here we present new trace element and U-Th-Pa isotope data on historic potassic to ultrapotassic Vesuvius samples in order to constrain melting and metasomatic processes responsible for such petrologically distinctive rocks.

The samples display ubiquitous $^{238}$U excess (up to 27%) at relatively constant $^{230}$Th/$^{232}$Th. This combination of significant $^{238}$U excesses in enriched arc lavas is extremely unusual and we attribute this to the influence of carbonate component. In striking contrast to the $^{238}$U excess, our new $^{231}$Pa/$^{235}$U are among the highest reported for arc rocks. This further emphasises the decoupled U-Th and U-Pa systems on historic potassic to ultrapotassic Vesuvius samples in order to constrain melting and metasomatic processes responsible for such petrologically distinctive rocks.

More generally we try to relate the case study of Vesuvius to the array of highly alkalic Italian magmatism. We suggest two distinct episodes of melting and metasomatism occurring at different depths and timescales in the down-going slab beneath Vesuvius. Firstly, an episode of sediment melting below the solidus of carbonate phases at shallow depths which can generally explain the K-rich magmatism of the Italian volcanoes. Secondly, a recent episode of U-rich hydrous melts from carbonate- and clay-rich subducted metasediments, generated at the current depth of the slab beneath Vesuvius (>350km), can explain the observed $^{238}$U excesses.

Pyrite oxidation at seafloor conditions: Inorganic mechanisms

ELLEN R. AVERY AND LIANE G. BENNING

School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK; (ellen@earth.leeds.ac.uk, liane@earth.leeds.ac.uk)

Sulfide oxidation and weathering are important processes that govern the global iron and sulfur cycles both in terrestrial habitats, where sulfide oxidation gives rise to acid rock drainage (ARD), and at deep sea hydrothermal vents, where sulfide oxidation provides the necessary energy source to a large variety of biological processes. There have been many studies investigating the ARD related inorganic and biogenic mechanisms of sulfide oxidation and recently some studies also followed pyrite oxidation processes in deep sea environments. However, experimental studies of pyrite oxidation typically used changes in bulk solution chemistry normalized to the surface area of pyrite in equilibrium with the solution to evaluate the reaction kinetics and mechanisms. Yet the changes at the surface of the pyrite grains have so far been difficult to evaluate. We will present here for the first time rate and mechanism data for the inorganic oxidation of pyrite in synthetic hydrothermal vent fluid and in seawater from experiments that combined the bulk changes in solution chemistry with a quantitative 3D volume loss evaluation via vertical scanning interferometry (VSI). With this approach we could directly determine the mass of pyrite lost over the course of the reactions (mol/cm$^2$/min).

Single pyrite grains (~1mm$^2$) were reacted for 1 to 12 weeks with a synthetic hydrothermal vent fluid or a seawater solution, both under anaerobic conditions at ~25°C under gently stirred, dark conditions. The bulk chemical changes in the solution composition (e.g., SO$_4$, Fe$^{2+}$/Fe$^{3+}$) were evaluated using ion chromatography and spectrophotometric techniques, while volume loss was measured directly using VSI. For each pyrite grain, 3D surface topographic maps were obtained prior and after each time step, with a 1/3 or the pyrite grain being masked prior to the experiment in order to obtain a reference surface. After the experiment, the mask was removed and a second VSI scan obtained, which was subtracted from the original VSI scan of the unreacted pyrite surface. Using a specially developed Matlab code, the 3D volume loss during the reaction could be calculated from this direct measurement and this could be used to derive rates.

Preliminary VSI results yielded rates of 3x 10$^{-15}$ mol/cm$^2$/min in the vent fluid and 6x 10$^{-16}$ mol/cm$^2$/min in the seawater experiments. This data will be discussed and compared with previous literature data of bulk dissolution/oxidation of pyrite.
Petrographic and petrological characteristics of Dagbasi (Arakli-Trabzon) volcanites, NE Turkey

E. AYDINCAKIR1, A. KAYGUSUZ1, C. SEN2 and Z. ASLAN1

1KTU, GMF Department of Geological Engineering, Gumushane/Turkey (emre@ktu.edu.tr, abdullah@ktu.edu.tr)
2KTU, Department of Geological Engineering, Trabzon/Turkey (csen@ktu.edu.tr)

Mineralogical, petrographical and geochemical characteristics of Liassic and Upper Cretaceous volcanic rocks in the Dagbasi area, which are situated in the northern zones of Eastern Pontides, are investigated.

Liassic volcanic rocks are basalt, andesite and pyroclastics (volcanic breccia, vitric and crystal tuff) in composition. Basalts contain labrador, augite and hornblende, while andesites contain oligoclase, biotite and hornblende. These volcanics are calc-alkaline to tholeitic transitional in character, and generally have low to high K2O contents. Major and trace element variation plots show that plagioclase, pyroxene, hornblende and Fe-Ti oxides played an important role in fractionation during evolution. The volcanic rocks are enriched in LILE (Sr, Ba, Th) and LREE, depleted in HFSE (Nb and Ti). (La/Lu)N values are between 4.6 and 9.8, show negative Eu anomalies (Eu/Eu*)=0.7-1.0. Based on trace element tectonic discriminations, all samples show volcanic arc signature.

Upper Cretaceous volcanites are dacite and rhyolite in composition. As phenocrysts, contain plagioclase, quartz, orthoclase, biotite and hornblende. This volcanics have calc-alkaline in character, and low-medium K2O contents. Increasing in SiO2 versus Fe2O3*, Al2O3, P2O5, MgO, TiO2, Y and Zr contents show negative correlation, suggesting significant plagioclase, hornblende, biotite and Fe-Ti oxide fractionation during the evolution of Upper Cretaceous volcanites. These volcanites enriched LIL elements and depleted HFS elements at the N-type MORB normalized trace element diagrams. Negative Nb and Ti anomalies indicate that subduction component and/or crustal contamination in their generation. (La/Lu)N values are between 3.20 and 6.75, show negative Eu anomalies (Eu/Eu*)=0.59-0.66. The concave REE patterns show hornblende fractional crystallizations.

Disequilibrium textures showing magma mixing such as oscillatory zoning, sieve textured and resorbed plagioclase phenocrysts, embayed quartz, breakdown of hornblendes and biotites are commonly observed in these rocks. In addition, basic enclaves observing in Upper Cretaceous dacites shows significant role of magma mingling during the evolution of Dagbasi Volcanics.

The whole data indicate that the Dagbasi (Trabzon) volcanics evolved by the fractional crystallization and magma mixing-contamination of a parental magma derived from lower crust and/or upper mantle, and the sources of those volcanics are enriched-MORB mantle in Liassic, and metasomatized MORB mantle in Upper Cretaceous.

Palaeonutrition of Prehistoric sites of Ghaleh Khan and Valeran: A case study

TAHEREH AZIZIPOOR, FARHANG KHADEMI NADOOSHAN AND MOHAMMAD SAFARI

1Educational member, Islamic Azad University, Marvdasht, Fars state, Iran
2Associate Prof, Dept of Archaeology, Tarbiat Modares University, Tehran, Iran
3Head of XRF lab, Faculty of Basic Science, Tarbiat Modares University, Tehran, Iran

Palaeodietary study of the prehistoric sites has been done for the first time in Iran. This study has supplied information about the nutritional habits of Prehistoric man. Chemical composition of bones and teeth gave some information about the nutrition of prehistoric people. These two sites which from ecological condition situated in two different places gave not only through the light on two different dietary system but different geological conditions provide different environments for the buried dead bodies.

In this paper we discuss result of spectroscopy obtained from XRF instrument and compare the result between these two sites.
Silica metasomatism of oceanic serpentinites

W. Bach and F. Klein

Geoscience Department, University of Bremen, Germany
(wbach@uni-bremen.de, fklein@uni-bremen.de)

Both dynamic and static recrystallization of serpentinite to soapstone have been reported from ultramafic masses in the oceans. While the development of talcous schists is common in detachment faults that are loci of large time-integrated fluid fluxes, static replacement of serpentinite by talc is more difficult to explain. We report on observations made in ODP drill core from Leg 209, Hole 1268, at the Mid-Atlantic Ridge (MAR) 15°N, where soapstone is abundant. Talc appears in blackwalls at the contact to small (<10 m) gabbroic units, but the majority of soapstone is not formed diffusively at mafic/ultramafic contacts. Static replacement of serpentinite by talc starts along anastomosing vein networks and continues to pervasive steatitization, during which the serpentinite hourglass texture is preserved. To transform magnesian serpentinite to talc (Mg/Si=0.75) massive removal of Mg or addition of Si is required. As the solubility of Mg is very low in fluids with pH>3, metasomatic enrichment of Mg or addition of Si is required. In fluids with pH>3 the majority of soapstone is not formed diffusively at mafic/ultramafic contacts. Static replacement of serpentinite by talc starts along anastomosing vein networks and continues to pervasive steatitization, during which the serpentinite hourglass texture is preserved. To transform magnesian serpentinite (Mg/Si=1.5) to talc (Mg/Si=0.75) massive removal of Mg or addition of Si is required. As the solubility of Mg is very low in fluids with pH>3, metasomatic enrichment of silica seems the most likely explanation. It appears that, except for obvious blackwalls, this metasomatism was facilitated by ingress of aqueous fluids. Serpentinite in Hole 1268 does not contain any brucite, suggesting that even the serpentinite has undergone silica metasomatism, as the precursor harzburgites and dunites had <15-20% orthopyroxene so that brucite would be expected to form during isochemical serpentinization. Gabbros in Hole 1268 do also show evidence for interactions with fluids with high silica activities since they are not rodingitized but instead show common greenschist alteration to chlorite, albite, and actinolite. This is unlike other drill holes in the MAR 15°N area and elsewhere, where brucite-bearing serpentinites host rodingitized gabbroic dikes.

We propose two possible explanations for the variability in aqueous fluid silica activity suggested by the phase assemblages of oceanic metaperidotites. (1) They are a result of the variable distribution of mafic units in a composite mafic/ultramafic crust, or (2) they are a consequence of the temperature-dependent reaction sequences taking place along the fluid flow path. To further explore the second possibility, we conducted isobaric (500 bar) geochemical model calculation. At temperatures >350°C, olivine is stable and hydration of pyroxenes imposes high silica activities to the fluids. Low aqueous silica activities can only develop at temperatures <350°C, in particular when fluid pH is high due to the hydrolysis of olivine. Brucite-bearing serpentinite as well as rodingite are expected to form under those conditions. Steatitization, in contrast, requires two conditions: high fluid flux and high silica activities. Sulfide assemblages in Hole 1268 suggest that oxygen and sulfur fugacities were high during silica metasomatism, which is consistent with our geochemical model predictions of coupled decreases in H₂ fugacity and pH with increasing fluid flux.

Hydrothermal systems in the eastern Manus Basin: Effects of phase separation and fluid mixing

W. Bach¹,², J.S. Seewald³, M.A. Tivey⁴, M.K. Tivey, Dana Yoerger², P.R. Craddock² and the Scientific Party of MGLN06MV

¹University of Bremen, Dept. of Geosciences, Klagenfurter Str., 28359 Bremen (wbach@uni-bremen.de)
²Woods Hole Oceanographic Institution, Woods Hole, MA02543, USA

The number of factors affecting metal fluxes within hydrothermal systems is large and the evolution of magmatic-hydrothermal system is complex and often difficult to reconstruct from the fossil record. Studying active submarine hydrothermal systems has a tremendous advantage: one can directly link fluid chemistry with deposits composition and rock alteration. Hydrothermal vents in arc/backarc settings are particularly intriguing as these systems are considered modern analogues for VHMS deposits.

The eastern Manus Basin reveals variable basement composition, ranging from depleted mid-ocean ridge basalt to basaltic andesite to rhyodacite with pronounced island-arc geochemical affinity. In August 2006, hydrothermal activity in the eastern Manus Basin was investigated using a combination of mapping and sampling (using AUV ABE and ROV Jason2). Objectives included identifying geological settings, examining interactions of seawater with felsic rocks, and determining the extent of volatile magmatic inputs into these systems. At the PACMANUS area five previously discovered vent fields were mapped and sampled, and a new very active field, Fenway, was located. The core of the Fenway field is a 40 m diameter two-tiered mound with active black smokers. The mound features exposures of anhydrite-sulfide stockwork. At the DESMOS caldera and at North Su vent field within the SuSu Knolls area acidic, sulfate-rich sulfide stockwork. At the DESMOS caldera and at North Su vent field within the SuSu Knolls area acidic, sulfate-rich white smoker fluids were sampled. North Su also features black smoker activity with anhydrite stockwork. The abundance of massive anhydrite at Fenway and presence of anhydrite cement at North Su is consistent with significant local entrainment and heating of seawater.

Fluids sampled from felsic-hosted hydrothermal systems in the eastern Manus Basin exhibit great compositional variability within an individual vent field. Degassing of magmatic volatiles is evident in almost every vent field. Degassing of CO₂ is ubiquitous, while SO₂ degassing is obvious only in the Desmos and North Su hydrothermal fields. Excess fluorine in vent fluids is another indication of magma degassing. Evidence for past SO₄ degassing, in the form of native sulfur and advanced argillic rock alteration, exists in the South Su and PACMANUS areas. The majority of fluids exhibit salinities lower or higher than seawater, consistent with phase separation below the seafloor. Fluid boiling at the seafloor is evident in parts of the PACMANUS area (356°C, 1710 mbsl) and at North Su (325°C, 1180 mbsl).
Carbon dioxide sequestration based on alkaline residues

M. BACK1, M. KÜHN2 AND S. PEIFFER1

1Hydrology, University of Bayreuth, Germany (martin.back@uni-bayreuth.de; s.peiffer@uni-bayreuth.de)
2Applied Geophysics, RWTH Aachen, Germany (m.kuehn@geophysik.rwth-aachen.de)

Amongst various CO₂ sequestration scenarios, mineral trapping is regarded as one promising technique because it warrants a permanent and inherently safe storage of CO₂ (Lackner et al., 1995, Zevenhoven et al., 2006). The carbonation of Ca- and Mg-bound minerals is fairly simple in process even so fast reaction kinetics are required for a technical realization. The energy input for the technical process is dependend on different materials and therefore the net amount of CO₂ sequestered (Huijgen et al., 2006). Alkaline residues from combustion processes are favorable for CO₂-binding because they are cheap, highly reactive and are generated as byproduct from the process of power generation.

In the present work, the reaction of alkaline brown coal fly ashes with CO₂ was studied in aqueous suspension in order to 1) develop a technical process for carbonation that removes CO₂ from flue gas of a powerplant sufficiently fast and 2) to generate an alkalinity-containing solution ready for the injection into deep aquifers. Laboratory experiments were performed in an autoclave system to measure the CO₂ transfer as a function of solid-liquid ratios, CO₂ partial pressure and stirring rates. Mild process conditions (25-50° C, atmospheric gas pressures) were chosen in order to evaluate the storage capacity under low economic and energy costs.

We could achieve an uptake of more than 2 mol CO₂ per kg of the used fly ash. Considering the average amount of fly ash accumulated within combustion process this corresponds to a reduction of about 1 percent of the CO₂ emissions from a brown coal power plant.

In alkaline residues, such as steel slags or waste concrete, CaO and MgO are suspected to be the most important phases. In addition to the fly ash experiments we present first results of the CO₂ reaction with CaO and MgO in order to estimate the CO₂ binding potential of other feedstock materials and to get a more-detailed process understanding.

Effusive and subeffusive rocks in the area of rare-metal ore fields of Phanerozic and their petrogenetic significance

E.V. BADANINA1, L.F. SYRITSO2, V.S. ABUSHKEVICH2 AND E.V. VOLKOVA2

1State University of St.-Petersburg, St.-Petersburg, Russia (elena_badanian@mail.ru)
2Institut of the Earth Crust, SPbSU, St.-Petersburg, Russia (laboratory_mgre@mail.ru)

Results of studying of composition and isotopic-geochemical data (Rb-Sr and Sm-Nd isotope systems) allow sharing out among effusive and subeffusive formations in the Transbaikalian region (Russia) three steady groups of rocks. These groups differ with time and place of separation of melt from uniform crustal source of magma: ongonites – surface F-rich extreme differentiations of granite magmas, on composition analogues of rare-metal granites; rhyolites, ongorhyolites, felsite-porphyries of potassium specializations - result of separation of melt from homogeneous still not differentiated hypabyssal magmatic sources; trachyrhyodacites and trachyrhyolites - have the common substratum of melting with granites, however removal at earlier stage at formation from the magma source. First two groups of rocks close age among themselves and rare-metal granites while formation of trachyrhyodacites can fix appreciable break in time with them. The geochemical relationship of all set of these rocks consists in enrichment lithophile rare elements, in the similar character of distribution of display rare elements that confirms representation about the common substratum of melting. Distinction is shown in levels of concentration of these elements, specialization and contents of volatile components (F, Cl, B), degrees mantel-crust interactions. Studying of melt inclusions has shown the magmatic nature of high potassium concentration in trachyrhyolite melt, its primary geochemical specialization on lithophile elements and chlorine. Concentration of chlorine attain here limiting saturation for haplogranitic system - 0,34 wt. % Cl.
Mineral chemistry and Os isotope systematics of Os-bearing alloys from the Guli massif (Russia): New data

I.YU. BADANINA1,2, K.N. MALITCH2 and I.N. KAPITONOV2

1NATI Research JSC, St. Petersburg, Russia (guli@online.ru)
2All-Russia Geological Research Institute, St. Petersburg, Russia (Kreshimir_Malich@vsegei.ru)

The Guli clinopyroxenite-dunite massif, like other clinopyroxenite-dunite massifs, e.g. Kondyor and Inagli, is situated at the periphery of the Siberian Craton (Russia). The unique features of the Au-PGE placers at Guli are (1) the dominance of Os-rich alloys over other platinum-group minerals (PGMs) and Au, and (2) the considerable predicted values of noble metals, particularly osmium (Malitch et al., 2002). This report presents for the first time results on mineral chemistry and Os isotope compositions of bedrock and detrital Os-rich alloy grains derived from three localities within southern part of the Guli massif. The Os isotope composition of PGMs was determined by laser ablation (LA) attached to multiple collector inductively coupled plasma mass spectrometry (MC-ICP-MS) at All-Russia Geological Research Institute.

The PGM assemblage in chromitite is dominated by iridian osmium (5-100 microns in size); subordinate PGMs are laurite, osmian iridium, tetraferroplatinum, an unnamed RhNiAs and Ni-Ir sulphide. The majority of Os-rich nuggets from placer deposits (i.e. Ingaringda and Burlakovskiy), both single crystals and crystal aggregates, subdivided into six morphological types, are dominated by Os-rich alloys with considerable inter-nugget variation of Ir and Ru. Os-rich alloy nuggets are controlled by their chemical composition (type 1, 2, 5 and 6 correspond to osmium, with Os content > 80 at. %; type 3 and 4 are iridian osmium) and partly by the Os isotope composition. At Ingaringda, average $^{187}$Os/$^{188}$Os value for Os-rich alloys vary from 0.12443 ± 0.00010 (type 6) to 0.12475 ± 0.00053 (type 3), whereas at Burlakovskiy those are less pronounced. The Os isotope composition of type 3 and 4 nuggets slightly differs from that of other types. This variability supported by mineralogical evidence can be attributed to different source rocks (chromitite vs dunite).

The $^{187}$Os/$^{188}$Os values of the Os-rich alloys studied are close to those from a former N-TIMS study (Malitch, 2004), which showed mean value of 0.12463 ± 0.00034. The similar range of $^{187}$Os/$^{188}$Os values for Os-rich alloys, exemplified by both LA MC-ICP-MS and N-TIMS, is consistent with that for PGMs from Kondyor, and likely indicates a highly productive single-stage formation of PGMs in clinopyroxenite-dunite complexes. Finally, $^{187}$Os/$^{188}$Os model ages of osmium and iridium osmium constrain the age of ultramafic protoliths indicating that this event took place in Late Proterozoic, which corresponds to a stage of active tectonism in the development of the Siberian Craton.

Geo-electric investigation of Igbonla Geothermal Sources, South Western Nigeria

B.S. BADMUS1, E.A.A YOLABI2 and A.A. ADEBOWALE2

1Department of Physics, University of Agriculture, Abeokuta, Nigeria.
2Department of Physics, University of Lagos, Akoka, Lagos, Nigeria

Abstract

Twelve Schlumberger Vertical electrical Soundings were carried out Igbonla geothermal source, Epe, South Western Nigeria to investigate the geothermal source located within this area using current electrode separation (AB) of 1,500.0m. The interpreted result revealed a maximum of seven geo-electric layers composing of topsoil, sandy clay, clayey sand, clay, limestone and sand. The geothermal source was penetrated beneath three VES point at depth between 160 to 418m.

Introduction

Geothermal energy is produced from the heat of earth’s interior. Volcanoes, geysers, hot springs and boiling mud spot are visible evidence of great reservoir of heat that are located within and beneath the earth’s natural heat associated with active volcanoes or geologically young inactive volcanoes still giving off heat at depth. It has its origin in the molten core of the earth, where temperatures are 400°C. The geothermal field has been the subject of numerous geologic, geophysical and geo-chemical investigations by both the geothermal industries and various governmental organisations, therefore advances in this field will improve commercial development for economic reliability and commercial safety.

Several boreholes have been drilled in the past within the southwestern Nigeria, where this study was carried; and hot water has been located within the aquifer at a depth ranging from 600.0m with temperature ranging between 29°C to over 72°C where several attributes make geothermal energy a good source of energy. It can be exploited without burning fossil fuel (coal, gas or oil) and it produces only one-sixth of the carbon dioxide that a natural gas fuelled power plant or sulphur-bearing gases.

Conclusion

The geo-electric investigation carried out at Igbonla Epe South western Nigeria revealed the hot water reservoir to be characterized by low resistivity sand bed with resistivity varying from 6.5 to 30.0Ωm at depth of 160 to 418m. The boundaries of the geothermal field as obtained by the qualitative interpretation of the VES curves gave a reasonable result as inferred from the lithological data at Igbonla. On a general note, Abeokuta formation show geothermal activity from Igbonla eastwards to Ikeja and has derived its heat from the earth’s interior.
LA-ICP-MS geochronology of
detrital zircons in Late Paleozoic
sediment units of northern Chile:
Implications for terrane processes

HEINRICH BAHLBURG\(^1\) AND JEFFREY D. VERVOORT\(^2\)
\(^1\)Geologisch-Paläontologisches Institut, Münster University,
48149 Münster, Germany (bahlbur@uni-muenster.de)
\(^2\)School of Earth & Environmental Sciences, Washington State
University, Pullman, Washington 99164-2812, USA
(vervoort@wsu.edu)

Late Devonian to Permian turbidite units are widely
exposed along the coast of northern Chile and represent parts
of an accretionary wedge at Gondwana’s Late Paleozoic active
margin in the present Central Andes. The units overstep the
boundary between the somewhat enigmatic Ordovician to
Devonian Chilenia terrane of alleged Laurentian origin in the
south and coeval autochthonous regions of Gondwana to the
north. Zircon populations of overstepping units deposited on
and derived from Chilenia should ideally demonstrate the
Laurentian heritage of the terrane by an absence of
geochronologic events typical of Gondwana and absent from
Laurentia, i.e. the Brasiliano orogenic cycle.

Using LA-ICP-MS we analysed populations of detrital
zircons in 6 samples, 2 each pertaining to the El Toco and Las
Tórtolas Formations in the northern, autochthonous part of the
study area, and 2 samples from the Huasco and Huentelauquen
Formations on Chilenia. Of each sample we analysed 140 to
145 grains. In this study we only considered grains falling
within 10% of concordia. This number of grains varies
between 99 and 118 between samples.

Concerning the Precambrian and Early Paleozoic, all
samples show essentially the same distribution of main events,
the “Grenvillian” orogenic cycle between 1400 and 900 Ma,
the Brasiliano cycle between 800 and 550, and the Early
Paleozoic Famatinian active margin cycle between 550 and
420 Ma. The younger, Late Carboniferous-Permian samples
also register a cluster of ages between 330 and 290 Ma
marking the re-initiation of subduction magmatism at this
margin after a period of magmatic, tectonic and metamorphic
quiescence in the Late Silurian and Devonian.

Considering the variable Late Paleozoic ages of the
studied samples we find that all record a very similar
distribution and succession of geochronologic events,
including evidence of the Gondwanan Brasiliano cycle in all
samples. Even though margin parallel sediment transport
could account for some of these grains, the size of Chilenia
(>1000 km N-S) should have kept this influence small. In
conclusion we find that our data cast doubt on a Laurentian
origin of the Chilenia terrane in northern and central Chile.

The effect of organic compounds on
the dissolution of amorphous silica-
Pyrochatechol, Salicylate, Hydrogen
Phthalate

SHUQIN BAI, KIYOKO MATSUBAYASHI,
YOSHIHIRO OKAUE AND TAKUSHI YOKOYAMA
Department of Chemistry, Faculty of Sciences, Kyushu
University, Ropponmatsu, Chuo-ku, Fukuoka 810-8560,
Japan (yokotscc@mbox.nc.kyushu-u.ac.jp)

Silicon (Si) is one of the most common elements
constructing the earth’s crust and much of it is present in
different kinds of silica minerals (SiO\(_2\)). Information on the
mobility and transport of Si from minerals to water as silicic
acid (Si(OH)\(_4\)) is important to estimate the chemical
weathering of rocks. The dissolution of silica has been
investigated vigorously in inorganic salt solution included in
natural waters. On the other hand, a lot of organic
compounds (from simple organic compounds with low
molecular weight to polymer with high molecular weight) are
also present in natural waters. Only a few investigations
have been conducted on the effect of organic compounds on
the dissolution of silica and the interaction between silica and
organic compounds is still uncertain. In an oil field, the
groundwater with higher Si concentration than the solubility
of quartz was found and the Si concentration increased with
increasing the total organic carbon in the ground water,
suggesting that organic compounds may accelerate the
dissolution of quartz. A phenolic hydroxyl group and a
carboxyl group are often contained in main functional groups
in natural organic compounds such as humic acid.

In order to search functional groups that can strongly
interact with silica, in this study, we investigated the effect of
pyrochatechol with two hydroxyl groups, salicylate ion with
one hydroxyl group and one carboxyl group and phthalate ion
with two carboxyl groups on the dissolution of amorphous
silica. In conclusion, salicylate and phthalate ions inhibited
the dissolution of silica due to adsorption on the surface of
silica through hydrogen bonds, whereas pyrochatechol
accelerated the dissolution due to formation of silicic acid-
pyrochatechol complexes.

The freshwater pearl mussel: one species – several proxies
S.M. BAIER¹, B.R. SCHÖNE¹ AND J. FIEBIG²
¹Department of Applied and Analytical Palaeontology and INCREMENTS Research Group, Institute of Geosciences, University of Mainz, Germany (baiers@uni-mainz.de and schoeneb@uni-mainz.de)
²Institute of Geosciences, Section Palaeontology, University of Frankfurt, Germany

Recently, bivalves became a powerful tool to supplement climate proxy data gathered from trees, stalagmites or lake sediments. Riverine bivalves provide an ideal junction between terrestrial, freshwater and marine proxy archives. Here, we studied shells of freshwater pearl mussels from Northern Sweden using a combination of sclerochronology (growth rate analyses) and isotope geochemistry (δ¹³C, δ¹⁸O). Valves were cut perpendicular to the direction of growth. After grinding and polishing, one of two “mirroring” thick sections was immersed in Mutvei’s solution. Sections were digitized and growth increment widths measured. Inherent age-related growth trends were extracted from the chronologies by estimating ontogenetic trends with cubic splines. Age trend removal was performed by dividing measured by predicted growth. Standardized growth records of different individuals were combined to a single master chronology and overall growth patterns and cycles were analyzed.

In addition, the remaining cross-sectioned shell portion was micromilled for stable carbon and oxygen isotope analyses. Following the shape of the growth increments, aragonite powder samples of annual resolution were milled. Oxygen isotope ratios of shell aragonite were used to calculate water temperatures. With increasing ontogenetic age stable carbon isotope values became shifted towards more positive values. After removal of age related trends, δ¹³C values exhibited a high degree of running similarity, permitting the construction of a δ¹³C master chronology.

Wavelet analyses of standardized shell growth and δ¹³C master chronologies revealed periodicities of 2-4 years, 6-7 years and 16 years. These oscillations closely resemble those well known from the North Atlantic Oscillation (NAO) and the tripole pattern in sea surface temperature anomalies.

Carbon in the peralkaline association: Footprints in the ashes
KEN BAILEY AND STUART KEARNS
Department of Earth Sciences, University of Bristol, Queens Road, Bristol, BS8 1RJ, U.K. (ken.bailey@bris.ac.uk)

Peralkaline felsic volcanism in the central Kenya rift, around Lake Naivasha, is well documented (age 0.4-0 Ma). Less known is the interspersed, contemporaneous mafic activity, comprising basaltic flows following initial effusion of tuffs and tuff cones. The latter include peperites with fresh basanitic glass lapilli enclosing abundant immiscible calcite globules (up to 45%): the enclosing matrix is largely comminuted lapilli, with a few accidental clasts. Some quench textures, and rare streaks of platy calcite, in the matrix indicate that this may have been still hot when erupted. Older volcanics (1.7 Ma) form the underlying rift floor. Carbonate sediments are absent from the area, and formation of calcite globules in glass by assimilation of any cold sedimentary limestone would impose impossible thermal requirements. No external source for the carbonate is known, and the carbonate globules enclosed in glass are an integral part of the eruption. Immiscible textures show all the forms expected from experimental studies for carbonate and silicate melts in equilibrium: these two melts must either have mingled or unmixed at high T. Primary carbonate is known in the phonolites and peralkaline trachytes of adjacent volcanoes; contemporaneous nephelinite-melilitite-carbonatite, as well as commercial CO₂ wells, are found along the rift, where this range of activity has prevailed for at least 23 Ma. Hence, these peperites are but a new form of carbonate volcanism, in intimate association with intensely peralkaline activity, spectacularly re-affirming the key role of CO₂ flux in rift magma genesis. Known natural samples of glass + carbonate are rare (five?), and basanite-calcite melt immiscibility has not been reported previously (the expected silicate phase from experiments is alkaline ultramafic/phonolitic, but 9 basanite + 1 calcite is equivalent to melilitite + CO₂). The P-T-X conditions for coexisting basanite-calcite melts remain to be defined, but the Kenyan peperites are not an isolated case (five others, from outside Africa, are currently under investigation). Although also from well-known provinces these too have gone unreported due to insufficient study being devoted to pyroclasts.

An attempt to use mean crystallite size of calcite for indicating metamorphic grade as exemplified by metamorphic carbonate rocks from NE-Hungary

B. BAJNÓCZI, M. TÓTH AND P. ÁRKAI
Institute for Geochemical Research, Hungarian Academy of Sciences, Budapest, Hungary (bajnoczi@geochem.hu)

A great variety of low-T metasedimentary rocks are devoid of metamorphic facies indicating mineral assemblages. Instead, they contain common mineral assemblages that are stable over wide P-T fields. The structural and related chemical changes in certain phyllosilicates proved to be reliable empirical indicators for expressing differences in metamorphic grades (zones). Illite and chlorite “crystallinity” (called Küberl, etc.) indices have been widely used to determine diagenetic and metamorphic (anchi- and epi-) zones mostly in pelitic and marly lithologies.

The present study intends to reveal whether there is any relationship between the structural and chemical changes of carbonate minerals (mostly calcite) in metamorphic rocks and the increasing metamorphic grade (increasing temperature). For this purpose such metamorphosed (recrystallized) limestones and marbles were selected from NE-Hungary, the metamorphic zones of which and their intercalated metapelitic environments have been fairly well known by earlier phyllosilicate “crystallinity” studies (Szendrő Mts.: epizonal, Uppony Mts.: epi-anchizonal, Árkai, 1983, 1991).

Petrographic and cathodoluminescence microscopy and stable isotope measurements were used to characterize the textural and chemical features of carbonate metamorphic rocks. In addition, X-ray powder diffractometric single line (Voigt) profile analysis was also applied in order to determine changes in mean crystallite size of calcite (i.e., in average size of domains that scatter coherently the X-rays).

The mean crystallite size values of calcite range between 300 and 400 Å in the bulk rock samples. The crystallite size seems to be similar in the rocks originated from different (lagoon, reef and deep marine basin) sedimentary environments. Certain carbonate generations (lenses and after deformation), however, have lower (120 to 220 Å) crystallite size values (laguna, reef and deep marine basin) sedimentary environments. Certain carbonate generations (lenses and after deformation), however, have lower (120 to 220 Å)

High-precision $^{26}$Al-$^{26}$Mg dating of early Solar System processes

JOEL BAKER¹, MARTIN BIZZARRO², MARTIN SCHILLER¹ AND ANNE TRINQUIER²

¹School of Geography, Environment & Earth Sciences, Victoria University of Wellington, Wellington, NZ
²Axiom Laboratory, Geological Institute, University of Copenhagen, 1350 Copenhagen, DK

The short-lived $^{26}$Al to $^{26}$Mg chronometer ($t_{1/2} = 0.73$ Myr) has been used to date Al-rich minerals in refractory inclusions and chondrules from chondritic meteorites, as well as feldspars from basaltic meteorites. Here, we explore the prospects of precisely and accurately resolving (and using) very small ($\leq 40$ ppm) excesses and deficits in the abundance of $^{26}$Mg in meteorites to date Al/Mg fractionation events associated with planetary differentiation in the first few Myr of the Solar System. Increases in Al/Mg ratios relative to chondritic (i.e., bulk planetesimal) values resulted from formation of basaltic magmas (Al/Mg = 1-3). Conversely, formation of essentially Al-free material resulted from olivine crystallization (pallasite olivine), formation of pyroxene cumulates (aubrites, diogenites) and partial melting (ureilites). The excesses and deficits that can be expected from these early Al/Mg fractionation events means it will be necessary to resolve $\delta^{26}$Mg* anomalies with precision and accuracy $< \pm 10$ ppm (2$\sigma$) to potentially utilize the $^{26}$Al-$^{26}$Mg chronometer to identify and date these processes.

Using a Nu Plasma MC-ICPMS, we have developed procedures that allow measurement of $\delta^{26}$Mg* anomalies (the offset of a sample's mass-bias-corrected $^{26}$Mg/$^{24}$Mg ratio compared to the mean of bracketing standards) in single analyses with precisions as low as $\pm 12$ ppm (2$\sigma$), which incorporates the uncertainties from the bracketing standards. Accuracy of data is verified by analysis of matrix-matched standards and, in some cases, by analysis of standards doped with $^{26}$Mg spike to create anomalies of known size. After anion and/or cation exchange chemistry, samples are analysed multiple times by MC-ICPMS in pseudo-high-resolution mode enabling resolution of molecular interferences (e.g., $^{12}$C$^{14}$N+) from Mg.

We have reanalyzed meteorites where small $\delta^{26}$Mg* excesses (angrites, eucrites) and deficits (pallasite olivines, ureilites, aubrites) have previously been reported, and used to constrain rapid timescales of planetesimal melting, differentiation and accretion in the young Solar System. These previous measurements were not made using high-resolution techniques and were characterized by somewhat larger analytical uncertainties than the present study. Further, we have also measured Mg isotopes in step-leaching fractions of C1 chondrites where large ($\epsilon$ to %) anomalies in neutron-rich isotopes of elements like Cr have been reported. Our new results place important constraints on the prospects of using high-precision Mg isotope measurements to date a wide range of meteoritic material and early Solar System processes.
Thallium isotope constraints on Earth’s accretion

R.G.A. BAKER 1,2, S.G. NIELSEN 3, M. REHKÄMPER 1,2, M. SCHÖNBÄCHLER 1, B.J. WOOD 4 AND A.N. HALLIDAY 3

3Dept. of Earth Science, Parks Road, Oxford OX1 3PR, UK
4GEMOC, Dept. of Earth and Planetary Sciences, Macquarie University, 2109 NSW, Australia

The extinct radionuclide $^{205}$Pb decays to $^{205}$Tl with a half-life of 15 Myr. The former presence of $^{205}$Pb in the solar system was recently inferred from a $^{205}$Pb/$^{204}$Pb isochron that was obtained for seven metal samples from the IAB iron meteorites Canyon Diablo and Toluna [1]. New Tl isotope data obtained for eight carbonaceous chondrites are in full accord with this isochron [2].

Several lines of evidence (based on I-Xe and Pd-Ag chronology; e.g., [3, 4]) indicate that the IAB parent body crystallised about 10 to 20 Myr after CAI’s. Based on this age, the IAB isochron yields an initial solar system $^{205}$Pb/$^{204}$Pb ratio of about $1.5 \times 10^{-4}$ and an initial Tl isotope composition of $\varepsilon^{205}$Tl$0 = -2.8 \pm 1.7$ [1]. The latter is unlikely to be greater than -2.5, given that the Earth’s mantle has a well-constrained age of >7 ppb for the bulk silicate Earth (BSE). This discrepancy can only be avoided if the Earth either experienced large-scale volatile loss at the time of the Giant Impact or accreted from volatile-depleted material characterised by a $^{204}$Pb/$^{204}$Pb ratio of $>2$. (2) If $\varepsilon^{205}$Tl$0$ is less than about -4.0, the present day $\varepsilon^{205}$Tl value of $-2.0 \pm 0.5$ [5, 6]. The available data thus indicates that the solar system was characterised by an initial $\varepsilon^{205}$Tl$0$ of between -2.5 and -4.5.

Two scenarios emerge if these values and recently determined metal-silicate and sulphide-silicate partition coefficients for Pb and Tl [7] are utilised to model the Earth’s accretion and core formation. (1) If $\varepsilon^{205}$Tl$0$ is greater than -3.5, then standard accretion models yield unrealistic Tl abundances of >7 ppb for the bulk silicate Earth (BSE). This discrepancy can only be avoided if the Earth either experienced large-scale volatile loss at the time of the Giant Impact or accreted from volatile-depleted material characterised by a $^{204}$Pb/$^{204}$Pb ratio of $>2$. (2) If $\varepsilon^{205}$Tl$0$ is less than about -4.0, the present day composition of the BSE can be readily reconciled with standard terrestrial accretion models, providing they feature late-stage segregation of sulphides from the mantle, as was recently proposed by Wood and Halliday [8].

The presently available Tl isotope data for meteorites do not permit a sufficiently precise definition of $\varepsilon^{205}$Tl$0$ to distinguish between these two scenarios. This indicates the importance of conducting further Pb-Tl isochron studies, which are able to provide a more precise estimate of $\varepsilon^{205}$Tl$0$.

Diffusion of fluids through quartz

RONALD J. BAKKER

Mineralogy & Petrology, Institute of Applied Geosciences and Geophysics, University of Leoben, Austria
(bakker@unileoben.ac.at)

Bulk diffusion of fluids through quartz is a process that may change the properties of fluid inclusions. The estimation of diffusion coefficients is only based on a limited number of studies, which include large uncertainties (up to 80%). Diffusion depends on the solubility of a certain diffusing species in quartz, which defines, however, a second large uncertainty: what is the nature of the diffusing species? and what is its solubility? Moreover, most experimental work has only been done at higher temperatures, within the β-quartz stability field.

This study identifies, firstly, the types of dissolved and diffusing water-related species, of which interstitial impurities, i.e. mainly H$_2$O molecules positioned between regular lattice sides form the major group that is responsible for changes in fluid inclusions and diffusion in general. This defect cannot be detected after experimentation with IR spectroscopy or secondary ion MS that mainly detect substitutional impurities and small fluid inclusions themselves. Solubility of water in quartz in previous studies has been mainly defined as charge compensating Fe and Al impurities or replacing Si atoms.

A new mathematical diffusion model (according to Fick’s laws) is developed using SI conform units, i.e concentration (mol/L), fugacity (MPa), excluding terms like ppm or wt%, which can be applied to randomly located fluid inclusions in a quartz crystal. This model is directly applied to experimental studies with synthetic fluid inclusion to characterize leakage and re-filling. Hypothetical calculations of re-equilibration rates indicate nearly instantaneous alterations of fluid inclusions properties according to the solubility of water in quartz, using the parameter values obtained from previous studies. Diffusion from or to fluid inclusions can only take place if a concentration gradient is present in the quartz. Locally, these gradients may represent thermodynamic equilibrium conditions due to pressure gradients, and, consequently, diffusion will not occur.

The properties of fluid inclusions are excellent tools for new determination of diffusion coefficients and the nature of diffusing species through quartz. Gradients in chemical potential (or fugacity) between fluid inclusions and pore fluids is a driving force for re-equilibration. In addition, pressure gradients may provoke alterations (see also Bakker and Diamond, 2003). Combination of both driving forces are interpreted as crack-assistent diffusion. New experiments will be performed to estimate the mobility of H$_2$O, CO$_2$, H$_2$, O$_2$ and Ar through quartz crystals by characterizing the changing properties of known synthetic fluid inclusions.

Status and potential of exploration for PGE in India

V. BALARAM

National Geophysical Research Institute, Hyderabad – 500 007, India (balaramv1951@yahoo.co.in)

PGE Potential in India

Discovery of new platinum group of elements (PGE) deposits/mineralized zone is of great economic importance for any country. In India, till date only the i) Baula-Nuasahi layered Complex in Orissa, ii) mafic-ultramafic Hanmalapura Complex in Karnataka, and iii) the layered Sittampundi Anorthosite Complex in Tamil Nadu, are the three known promising PGE occurrences. Recent studies show that there is a tremendous potential for PGE-mineralisation in mafic-ultramafic complexes, ophiolite complexes and the fine grained sediments such as sulfide bearing black shales, occurring in different parts of our country.

Exploration Strategies

Determination of PGE at extremely low concentrations with the accuracy and precision and at high throughputs required for exploration studies needs optimization of critical steps such as selection of a representative sample and application of sensitive analytical techniques, etc. For identifying economically viable deposits and their mining, detailed geological, petrological and geochemical studies are essential on massive potential areas.

Geochemistry and mineralogy of Serov Ni lateritic deposit, N Urals

YU. BALASHOVA¹, L. MORDBERG¹ AND R. HERRINGTON²

¹Centre of Isotopic Research, VSEGEI, St Petersburg, Russia (Yulia_Balashova@vsegei.ru)
²Department of Mineralogy, Natural History Museum, London, UK (R.Herrington@nhm.ac.uk)

Serov lateritic Ni deposit occurs within Kolsky massif in the northern part of the Serov-Magnitogorsk zone of the ultrabasites. The following zones are distinguished within the weathering profile (from the bottom to the top): serpentinites (1), leached serpentinites (2), saprolites (3) and laterites (4). The profile is covered by Early Jurassic to Late Tertiary sediments.

Ni mineralization is being studied by XRD, SEM and Microprobe in the laboratories of VSEGEI and NHM. In parent rock, Ni is distributed among the serpentine group minerals, olivine and pyroxene. For the leached serpentine zone, an increase of Ni content is typical in serpentines and appearance of “garnierite” veins, sometimes forming stockwork together with magnesite. The saprolite zone is characterized by broad variations of Ni content in serpentines – from low-common for lizardite and antigorite, to high, allowing them to be referred to as nepouite and pecoraite. Laterite is composed of goethite and haematite (< 1 % Ni), often with smectite admixture. Besides minerals listed, Ni was found in chamosite, talc, millerite and asbolane. XRD also recorded teophrastite Ni(OH)₂, honessit Ni₆Fe₂(SO₄)(OH)₁₆·4H₂O, willemseite (NiMg)₃Si₄O₁₀(OH)₂, nickeline – NiAs and maucherite Ni₁₁As₈.

Such mineral assemblage proves a long history of profile development: primary oxidized profile was partly reduced due to downward block movements evidently after covering the profile with lignites. The reduced parts of the cross section go down along the most permeable zones that connect with tectonic faults.

Later on the profile was oxidized again after recent uplifting. Such consequence of events has led to the redistribution of Ni and to the crystallization of sulphides, arsenides and chlorite.
Synthetic fluid inclusions in rutile: A new technique to study mantle fluids

E. BALI AND A. AUDÉTAT
Bayerisches Geoinstitute, Universität Bayreuth, Germany,
(Eniko.Bali@uni-bayreuth.de; Andreas.Audetat@uni-bayreuth.de)

Experimental studies concerning the major and trace element composition of hydrous fluids migrating in the mantle or released from a subducted oceanic crust are technically challenging. Currently used methods include the weight-loss technique (e.g., Newton and Manning, 2002) and the diamond trap technique (e.g., Stalder et al. 2001; Kessel et al. 2005), which both have a number of advantages and disadvantages.

Here we follow a new approach by trapping fluids at mantle conditions in rutile, and analyze their major and trace element content by LA-ICP-MS. Rutile is a perfect mineral for this purpose because its solubility in aqueous fluid is relatively low (e.g.: Audétat & Keppler, 2005), but still high enough to allow crack-healing, and because it does not contain most of the elements of interest (except for HFSE). Major advantages of this method include: (i) it is applicable to a large range of P/T-conditions, (ii) there are no limitations regarding the complexity of starting materials that can be used, and (iii) identical batches of the same fluid can be sampled numerous times. Cubes of sintered rutile were loaded into Pt/Rh capsules, together with fine grained minerals (e.g., enstatite, olivine) and 15-25 µl aqueous solution containing 1000 ppm of Cs and Rb, the latter serving as internal standards for the LA-ICP-MS analyses. Experiments are carried out in 200 t piston cylinder apparatus, using pure salt assemblies and stepped graphite heaters. Run conditions are approached along a fluid isochoric path, and then held for two days. Resulting fluid inclusions are 20-40 µm in size, which is appropriate for LA-ICP-MS analyses.

The method is currently being tested on the system quartz-H2O and olivine-enstatite-H2O, for which reliable data are available from weight-loss experiments (Manning, 1994; Newton and Manning, 2002).

Seawater recycling into the deep mantle – And the source of 3He?

C.J. BALLENTINE1, J.P. BRANDENBURG2, PETER E. VAN KEEKEN2 AND GREG HOLLAND1
1SEAES, The University of Manchester, UK
2Dept. Geological Sciences, University of Michigan, USA

Mantle-derived heavy noble gases (Ar, Kr, Xe) with isotopic components and elemental ratios similar to marine pore fluids have been unambiguously resolved in magmatic well gases and Mid Ocean Ridge ‘popping’ rock (MORB). This observation has been used to argue that recycling of marine pore fluids into the mantle dominates the non-radiogenic heavy noble gas inventory of the convecting mantle [1]. He and Ne isotopes in the mantle are unaffected because of their low concentration in marine pore fluids. This conclusion is further reinforced by the observation that slab-derived fluids trapped in the overlying mantle wedge have both halogen (Cl, Br, I) and heavy noble gas elemental compositions little different from marine pore fluids [2].

Numerical models of mantle convection provide further insight. In simulations that reproduce surface heatflow and plate motion, a seawater/Ar recycling flux into an initially degassed mantle, combined with internal radiogenic 40Ar ingrowth, can be determined that reproduces the best estimate of the mantle 40Ar/36Ar ratio of ~40,000 [1]. An independent outcome of the model, determined by the fluid dynamic control, is that the noble gas composition in the plume forming region at the core mantle boundary has a substantially lower 40Ar/36Ar, and is consistent with low plume 40Ar/36Ar observed maximum values.

A 3He flux (3He/4He=120Ra) into the same model from either D″ or the core determined to produce a convecting mantle with 3He/4He=8Ra, unsurprising, results in a plume forming region at the core mantle boundary with substantially higher 3He/4He ratios. A ‘deep’ 3He reservoir remains one explanation for plumes with high 3He/4He having low 40Ar/36Ar. The dual 40Ar/36Ar and 3He/4He result is not matched by models in which the high 3He/4He source is produced as a result of low 3He/U in the residue of shallow convecting mantle melting.

Intraplate volcanism due to small-scale convection – A 3D-numerical study

M.D. BALLMER1, J. VAN HUNEN2 AND P.J. TACKLEY3
1Institute of Geophysics, ETH Zurich, Zurich, Switzerland (ballmer@tomo.ig.erdw.ethz.ch)
2Department of Earth Sciences, Durham University, UK (jeroen.van-hunen@durham.ac.uk)
3Institute of Geophysics, ETH Zurich, Zurich, Switzerland (ptackley@ethz.ch)

Although most of the intraplate volcanism in ocean basins is expressed in linear chains, not all of those can be attributed to a stationary hotspot. Many ridges show erratic age-progressions (e.g. Musicians, Magellan seamounts) or span more than thousand kilometers in a couple of million years (e.g. Line Islands, Pukapuka ridges). Cracking of the lithosphere and small-scale convection have been invoked to account for this type of volcanism. The former presumes a partially molten asthenosphere, whereas the latter has not yet been tested and validated in a numerical model.

In the Earth’s uppermost mantle SSC is likely to develop due to instabilities of the thickened thermal boundary layer below mature oceanic lithosphere. It is characterized by convective rolls aligned by plate motion. Their onset is earlier (i.e. beneath younger and thinner lithosphere) for lower mantle viscosity (e.g. for hot or wet mantle) or adjacent to lateral inhomogeneities. In these cases, partial melt potentially emerges in the upwellings of SSC. This changes the compositional buoyancy owing to melt retention and additional depletion of the residue. Therefore, it promotes upwelling and allows for further melting. This self-energizing mechanism is able to sustain melt production in a once partially molten layer for a couple of million years.

In order to dynamically test the SSC hypothesis for intraplate volcanism, we take the step towards fully thermochemical 3D-numerical models of SSC. This is, we analyze a set of models at low mantle viscosities and varying temperatures, which provide insight into the interaction of SSC and melting. Therein, we explore the 3D-patterns of melt associated with SSC, the amounts and shapes of volcanism. We also incorporate small thermal anomalies that locally reduce the onset age of SSC.

Volcanism is predicted to evolve synchronously in a region of hundreds of kilometers after onset of SSC. Therefore, age progressions of ridges are not required to be monotonous anymore. The amount of volcanism is highly dependent on mantle viscosity. For ambient temperatures (1350 °C) viscosities have to be low (1.3·1019 Pa·s) and volcanism forms on 30 Ma old lithosphere. For elevated temperatures (1400 °C) viscosities can be higher (2·1019 Pa·s) and volcanism still forms on 50 Ma old lithosphere. Lateral thermal anomalies further increase viscosities required and are able to focus volcanism.

Stochastic modeling of surface roughness evolution during mineral dissolution

J.Z. BANDSTRA1 AND S.L. BRANTLEY2
1Center for Environmental Kinetics Analysis, Pennsylvania State University, University Park, PA, USA (jxb88@psu.edu)
2Department of Geosciences, Pennsylvania State University, University Park, PA, USA (brantley@essc.psu.edu)

Mineral dissolution rates are typically normalized by the surface area of the dissolving mineral. Any dissolution reaction, however, must cause the surface of the dissolving solid to change. It is, therefore, possible that surface area is a dynamic variable during mineral dissolution. In particular, surface roughness may evolve over time and, in order to interpret mineral dissolution rates, it is important to know whether a steady-state surface roughness exists and how this steady-state roughness might respond to variables that control dissolution rate such as dissolution reaction mechanism, solid defect density, and free energy of reaction (∆G_react).

Mineral dissolution and, by extension, surface evolution may be treated, theoretically, as a chemical kinetics phenomenon by parsing the surface into reactive sites. Unfortunately, the basic assumption of random collisions needed to formulate classical rate equations is inapplicable for surface evolution where site-site interactions are subject to geometric constraints. To address this problem, we have developed a 2-dimensional Ising model of dissolution and precipitation. In this model, the solid is represented by all spin-up lattice sites and reactions are represented by flipping the spin at a site with probability (per unit time) determined by the number of spin-up (or, occupied) nearest neighbors. By varying the functional relationship between reaction probability and the number occupied nearest neighbors, we simulated a variety of reaction mechanisms as well as the effects of ∆G_react. By introducing spatial heterogeneity into the reaction probabilities we simulated the effects of defects in the solid. Simulations were preformed with a variable time dynamic Monte-Carlo algorithm with reaction sites found with bisection of the surface.

Our simulations indicate that a unique steady-state surface roughness exists over a broad range of dissolution mechanisms. Carefully chosen defect structures were found to generate periodic surface roughness behavior which was, however, accompanied by periodicity in the net reaction rate indicating that the intrinsic reactivity of the surface was unaffected by defects. Surface roughness as a function of ∆G_react was found to be highly sensitive to the precipitation mechanism even when the net dissolution rate as a function of ∆G_react was relatively constant. Our results also shed insight into the existence of an inflection point in dissolution rate vs. ∆G_react. Results will be discussed in terms of relative step nucleation and retreat rates.
**EXAFS and XPS study of arsenate adsorption on manganite (γ-MnOOH) surfaces**

**DIPANJAN BANERJEE, HANNA NELSON AND PER PERSSON**

Department of Chemistry, Umeå University, S-90187 Umeå, Sweden (dipanjan.banerjee@chem.umu.se; hanna.nelson@chem.umu.se; per.persson@chem.umu.se)

**Introduction**

The introduction of toxic metalloid arsenic in the environment is of worldwide concern. Arsenic occurs in several oxidation states but in oxic environments the speciation is dominated by arsenate (As[V]), which is extremely reactive towards transition metal oxyhydroxide particles. The aim of this study is to characterize the structure and composition of arsenate species adsorbed on Mn oxyhydroxide surfaces as a function of pH and surface coverage.

**Experiment**

Batch experiments were conducted where arsenate was adsorbed onto manganite (γ-MnOOH) surfaces as a function of pH and surface coverage. A minimum of 72 hours equilibration time was allowed before the samples were centrifuged and the wet pastes were analyzed using EXAFS spectroscopy and cryogenic XPS techniques.

**Results and Discussion**

Arsenic K-edge EXAFS spectra were collected for manganite-arsenate samples over a wide range of pH and arsenate concentrations. The data reveal that there are no major differences in the spectra as a function of pH whereas minor differences are observed in the weak second shell features of the Fourier transforms. Data fitting indicates a first coordination shell of 4 oxygen atoms at the expected arsenate distances (ca. 1.7 Å) and a second shell caused by Mn backscattering together with multiple scattering within the first shell of As-O bonds. A complete quantitative evaluation of the EXAFS data is in progress.

Cryogenic XPS study on the same samples revealed that close proximity of the As 3d and Mn 3p lines makes it difficult to interpret the commonly used As 3d spectra, especially at low arsenic concentrations. In such cases, we found that the As 2p line is significantly more useful in order to understand the oxidation state, surface abundance and speciation of arsenic, as well as improving the detection limit for arsenic by a factor of 4 due to its high ionization cross-section. Consequently, we systematically analyzed the As 2p<sub>3/2</sub> binding energies and corresponding auger parameters of several arsenic oxide reference compounds (As<sub>2</sub>O<sub>3</sub>, As<sub>2</sub>O<sub>5</sub>, NaAsO<sub>2</sub> and Na<sub>2</sub>HAsO<sub>4</sub>) and calculated the atomic sensitivity factor. These data were subsequently used in the analysis of As 2p<sub>3/2</sub> spectra of the manganite-arsenate samples.

**Direct dating of archean microbial ichnofossils**

**N.R. BANERJEE<sup>1</sup>, A. SIMONETTI<sup>2</sup>, H. FURNES<sup>3</sup>, K. MUEHLENBACHS<sup>2</sup>, H. STAUDIGEL<sup>4</sup>, N. MCLoughlin<sup>5</sup>, M. de Wit<sup>5</sup> AND M. VAN KRANENDONK<sup>6</sup>**

<sup>1</sup>Earth Sciences, Uni. of Western Ontario, Canada  
<sup>2</sup>Earth and Atmos. Sciences, Uni. of Alberta, Canada  
<sup>3</sup>Centre for Geobiology, Uni. of Bergen, Norway  
<sup>4</sup>Scripps Institute of Oceanography Uni. of California, San Diego, USA  
<sup>5</sup>AEON Uni. of Cape Town, S. Africa  
<sup>6</sup>Geological Survey of W. Australia, Perth, Australia

A novel in situ laser ablation multi-collector-ICP-MS technique has enabled the first direct radiometric age determination of an Archean microbial ichnofossil. Direct in-situ U-Pb dating of titanite (CaTiSiO<sub>4</sub>) that infills tubular bioalteration textures in pillow basalt rims and hyaloclastites from the ~3.35 billion-year-old Euro basalt of the Pilbara craton, W. Australia (PWA) confirms their Archean Age [1]. A laser ablation spot size of ~40 µm was used to analyze titanite in the “root zones” at the centre of microtubule clusters. Thirteen analyzes in three thin sections gave a weighted average <sup>206</sup>Pb/<sup>238</sup>U age of 2921±110 Ma [1]. This late Archean age for titanite formation represents a minimum age estimate for the bioerosion. A pre-metamorphic age for the ichnofossils is consistent with chlorite overgrowths that cause their segmentation.

Multiple lines of evidence suggest that these tubular structures formed by microbial bioerosion of formerly glassy Archean lavas that were subsequently mineralized by titanite [2]. There are striking morphological similarities between Archean tubular structures from both the Pilbara and Barberton (BGB) cratons and microbial ichnofossils found in modern glasses. X-ray mapping shows carbon enriched along the margins of the tubular structures from both the BGB and PWA. Also, disseminated carbonates in the BGB pillow rims have C-isotopes depleted by as much as –16‰, which is consistent with microbial oxidation of organic matter.

Negative sulfate $^{17}$O anomalies as positive evidence for “Snowball Earth” hypothesis

HUIMING BAO
Department of Geology & Geophysics, Louisiana State University, Baton Rouge, LA 70803, USA (bao@lsu.edu)

Since the discovery of a common occurrence of sulfate $^{17}$O anomaly in Earth’s continental deposits, a considerable amount of triple oxygen isotope data has been gathered for sulfate of diverse origins over the years. Without exception, until now all $\Delta^{17}$O values are positive, reaching as high as $+5.84$‰. It is known that the positive $^{17}$O anomalies are ultimately transferred from that of atmospheric ozone. This new parameter has proven to be powerful in sulfate source identification and quantification in geological, environmental, and atmospheric problems.

Here I present a large set of sulfate $\Delta^{17}$O data for marine evaporites and barites, which have had no direct link to atmospheric ozone chemistry. The data reveal variable negative $\Delta^{17}$O values among sulfates of different occurrences or ages. Specifically, sulfate $\Delta^{17}$O values lower than $-0.20$‰ are common in the lower Cambrian around the world (e.g., Siberia, Australia, and India) while none in the late Paleozoic or modern settings. Most remarkably, barites from the Marinoan cap carbonate sequences deposited ~635 million years ago possess a spike of extremely negative $\Delta^{17}$O values. Values lower than $-0.40$‰ are found in both northwestern Namibia and South China.

I propose that the triple oxygen isotope composition of shallow marine sulfate carries a portion of the tropospheric $\text{O}_2$ signal, which has had variable negative $\Delta^{17}$O values that were determined largely by stratospheric $\text{O}_3\text{-CO}_2\text{-O}_2$ chemistry. A quantitative relationship between atmospheric conditions and the $\Delta^{17}$O of atmospheric $\text{O}_2$ requires a comprehensive atmospheric model. If we assume that the $\Delta^{17}$O of air $\text{O}_2$ scales roughly linearly with $\text{pCO}_2$, as is supported by published glacial and interglacial data, the marine sulfate $\Delta^{17}$O data suggest that $\text{pCO}_2$ was much higher in Early Cambrian than in younger era, agreeing with previous modelling results. Most significantly, the negative sulfate $\Delta^{17}$O spike in the Marinoan cap carbonate sequences points to an extremely high $\text{pCO}_2$ at the immediate aftermath of a global deglaciation, supporting the Neoproterozoic ‘snowball’ Earth hypothesis. An on-going survey in South China is expected to yield a better picture of this negative “spike”.

Geochemical investigation of Kuhe - Dom Volcanic Rocks, central Iran

The Urumieh-Dokhtar magmatic zone is a calc-alkaline magmatic arc of Eocene to Plio-Quaternary age. These magmatic arcs are linked to the subduction of the Neo-Tethys to the North below the Central Iranian Block. The Eocene volcano - sedimentary Rocks of Kuhe - Dom are located in Urmieh - Dokhtar magmatic belt in the northeast of Ardestan district, central Iran. The stratigraphic sequence is composed of lower Eocene Gorgab and Middle Eocene sahlab formations. The volcanic Rocks are olivine basalt, basalt, basaltic andesite, trachy basalt, trachy andesite, dacite, rhyodacite and rhyolite. The pyroclastics rocks are less common in this area and consist mainly of various types of crystal lithic tuffs and breccias, which crystals are essentially plagioclases and lithic fragments are mainly basaltic-andesites and trachy-basalt-andesites. On the basis of major, trace and REE element diagrams, the Kuhe – Dom rocks show characteristics of calcalkaline series typical of Urumieh-Dokhtar magmatic belt. Petrological and geochemical investigations demonstrate that the Kuhe – Dom Volcanic Rocks are high – K, Meta – aluminous and are consistent to continental arc environment.

Lu-Hf dating of sedimentary successions: Lessons learned

G.H. BARFOD
Dept. of Geology, UC Davis, Davis, CA 95616
(barfod@geology.ucdavis.edu)

It is notoriously difficult to obtain geochronological constraints for sedimentary formations with few or no biostratigraphic tracers and ash layers. The reasons for this are the necessity that the mineral phases chosen for dating 1) are truly authigenic, 2) remained closed systems since deposition and 3) do not include minor inherited phases such as clays at the time of analysis. Furthermore, the mineral must be rich in the radioactive parent isotope relative to the daughter product for the radiometric dating scheme. Phosphates, such as apatite and francolite, occur widely in sedimentary rocks as fossils and nodules, and are suitable candidates for sedimentary dating. In these phases, rare earth elements and uranium are favorably incorporated into the crystal lattice making them potentially suitable for dating by the lutetium-hafnium (Lu-Hf) and uranium-lead (U-Pb) systems. This talk presents a review of the results from sedimentary phosphates obtained to date, as well as the pro’s and con’s of the technique. Despite its limitations, dating of sedimentary phosphate by the Lu-Hf and U-Pb systems provides new age constraints for the sedimentary record that may lead the way for a better understanding of Earth history.

Sr isotope constraints on extent and character of fluid flow in EPR crust

A.K. BARKER1, L.A. COOGAN1, K.M.GILLIS1 AND D. WEIS2
1SEOS, University of Victoria, PO Box 3055 STN CSC, Victoria, B.C., V8W 3P6, Canada. akbarker@uvic.ca
2Pacific Centre for Isotopic and Geochemical Research, UBC, 6339 Stores Road, Vancouver, B.C., V6T 1Z4, Canada.

Crust formed at the super-fast-spreading southern East Pacific Rise ~3 my ago has been sampled at the north of the Easter microplate (22ºS) from two NW-SE striking escarpments at Pito Deep. The escarpments expose lavas, sheeted dikes and plutonics and provide a unique opportunity to investigate the lateral variations in hydrothermal alteration in the ocean crust. We use Sr isotope and trace element analyses integrated with petrographic indications of alteration to examine heterogeneity of fluid flow though the ocean crust.

The mobile metals Cu and Zn are variably depleted relative to magmatic concentrations but this depletion is decoupled from enrichments in 87Sr/86Sr. Strontium isotopic enrichment is also decoupled from Sr concentration suggesting that uptake of seawater Sr, for example into epidote, is not the principal control on the changing 87Sr/86Sr.

Two escarpments at Pito Deep allowed sampling of sheeted dykes over vertical extents of 700 m and 1000 m respectively. Sheeted dykes from two escarpments show 87Sr/86Sr of 0.70252-0.70364 and 0.70267-0.70466 respectively. Fresh MORB in this area has a 87Sr/86Sr of 0.70239. Localised (few to 10’s m) anomalously high 87Sr/86Sr (> 0.703) are associated with proximal faults. We interpret these data as indicating that these acted as conduits to channel fluid flow at high-temperatures. This provides compelling evidence for significant modification of rock and consequently fluid compositions during channelised flow.

In order to compare the extent of Sr-isotopic exchange between hydrothermal fluids and the crust at Pito Deep with the other two areas that have been studied in detail (Hess Deep and ODP Hole 504B) we have modelled the fluid flux through the system. We use the modelling approach developed by Bickle (1992) that assumes pervasive, kinetically hindered, isotopic exchange during one dimensional fluid flow. Although this does not appear to describe the hydrology of the system it allows quantitative estimates of the differences in fluid flux between these areas to be considered.

Modelling of Sr isotopic differences between the two escarpments at Pito Deep reveals spatial variability in fluid flux through the ocean crust formed in one location. Comparison with Hess Deep and ODP site 504B indicates that Pito Deep has experienced greater Sr isotopic exchange and consequently higher fluid flux. Interpretations will be discussed in the context of structural and thermal variations on regional and local scales.

The effect of sample matrix on the precision and accuracy of radiogenic isotope ratio measurements by MC-ICP-MS

J. BARLING, I. NOBRE SILVA AND D. WEIS

Pacific Centre for Isotopic and Geochemical Research, Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, B.C. V6T 1Z4, Canada (jbarling@eos.ubc.ca, inobre@eos.ubc.ca, dweis@eos.ubc.ca)

Introduction

Residual sample matrix is known to cause non-spectral matrix effects that adversely influence the accuracy of non-traditional stable isotope ratio determinations by MC-ICP-MS (e.g. Carlson et al., 2001). It is commonly assumed however, that matrix effects do not significantly influence the accuracy and precision of radiogenic isotope determinations by MC-ICP-MS (e.g. Nd, Hf, Pb). The external normalisation method (Tl) used to correct Pb data for instrumental mass bias means that Pb data are potentially susceptible to matrix effects if matrix causes different instrumental mass bias responses for Pb and Tl. We have therefore investigated the significance of matrix effects on the precision and accuracy of MC-ICP-MS radiogenic isotope data.

Observations and experiments

In the case of Hf, subtle differences have been observed between measured stable isotope ratio correlations (i.e. 178/177, 179/177, 180/177) for mafic and felsic sample material (Weis et al., 2007), raising the spectre that instrumental mass bias for samples may not follow the same empirical fractionation law as for standards. Preliminary experiments with Nd however, suggest that internal normalisation is effective in compensating for matrix effects.

In purified Pb samples, residual sample matrix decreases with increasing SiO2. Ca is the dominant matrix element, followed by Al, Fe and Mg; organics derived from ion exchange resin may also be present. This matrix causes changes in instrumental mass bias and signal enhancements of up to 80%. Experiments carried out on standards doped with Ca, Al, Fe and Mg, demonstrate that these four elements can account for Pb and Tl signal enhancements of up to ~50% and that enhancement of Tl > Pb. Pb and Tl instrumental mass biases also respond differently to matrix elements; both effects are greatest in the presence of Ca. Samples passed twice through chemistry show significant reduction in matrix effects and better reproducibility. Sample matrix must therefore be reduced to negligible levels for high precision and accuracy radiogenic isotope data.

Chlorine stable isotopes as a geochemical tracer along the Central American and the Izu-Bonin-Mariana arcs

J.D. BARNES, Z.D. SHARP AND T.P. FISCHER

Department of Earth & Planetary Sciences, University of New Mexico, Albuquerque, New Mexico 87131 (jdbarnes@unm.edu; zsharp@unm.edu; fischer@unm.edu)

Chlorine stable isotope ratios of different potential sources of Cl to subduction zones (sediments (~ -2‰?), pore fluids (~8 to ~0.1‰), mantle (0‰), subducted oceanic crust, e.g., serpentinites (~1.8 to +0.5‰)) are distinct, thereby providing a geochemical tracer of the fluid source responsible for melts and arc volcanism. We have analyzed volcanic gases (collected in Giggenbach flasks), volcanic gas condensates, aqueous fluids from crater lakes, streams, geothermal wells, tephras, lavas, sediments from the subducting plate, backarc basalts, and clasts and muds from serpentinite seamounts to help identify the sources of Cl in the Central American (CA) and Izu-Bonin-Mariana (IBM) subduction zones.

δ37Cl values of volcanic gases from along the CA arc range from ~4 to +12‰. Gas samples from Poás (Costa Rica) have the most positive δ37Cl values (+5.2 to +12.1‰) of all volcanoes analyzed. However, the lake and streams in the Poás crater have near zero δ37Cl values with little to no variation over time. Gases from nearby, Turrialba and Irazú (Costa Rica) have negative δ37Cl values (averaging ~ ~2‰). Santa Ana (El Salvador) and Momotombo (S. Nicaragua) have δ37Cl values of +6.3 and +4.0‰, respectively. San Jacinto, San Cristobal, and Cerro Negro (N. Nicaragua) have negative δ37Cl values (averaging ~ ~2‰). Fuego (Guatemala) also is isotopically negative, ~0.6‰. Tephra and lava samples from six Nicaraguan volcanoes range from ~3.0 to +1.6‰.

δ37Cl values of volcanic gases from along the IBM arc are generally negative (averaging ~2.2 ± 1.2‰). Serpentinite clasts from the Conical and South Chamorro seamounts have bulk δ37Cl values of 0.33 and 0.31‰, respectively. Serpentine muds from both seamounts have bulk δ37Cl values of 0.12‰. Backarc basalts from the Guguan cross-chain also average 0.12‰. Sediments from ODP Leg 129 have negative bulk δ37Cl values, ranging from ~0.3 to ~1.2‰ (n = 3).

The consistently negative δ37Cl values of volcanic gas samples from along the IBM arc indicate that chlorine is likely sourced from subducting sediments, isotopically negative serpentinites, and/or pore fluids. Similar conclusions may be drawn from isotopically negative volcanic rocks from N. Nicaragua, Guatemala, and some volcanoes in Costa Rica. Additional ODP sediment samples from the Pacific plate will be analyzed to better define the δ37Cl value of the sediment source, which is not well known at present. The high δ37Cl values from Poás, Santa Ana, and Momotombo may be due to volatilization of acidic fluids at high temperatures, where extreme fractionations have been observed experimentally.
Highly siderophile elements in platinum-group element ore deposits
S-J Barnes¹, H.M. Prichard², R.A. Cox¹, P.C. Fisher²
and B. Godel¹

¹Sciences de la Terre, Université du Québec, Chicoutimi,
Canada G7H 2B1 (sjbarnes@uqac.ca)
²Earth, Ocean and Planetary Sciences, Cardiff University,
United Kingdom (sglhmp@cardiff.ac.uk)

We have studied the distribution of siderophile elements among base metal sulphides (BMS) and platinum-group minerals (PGM) found in platinum-group element (PGE) ore deposits. In order to address the question of which processes affect the formation of these deposits we have selected deposits that have undergone different cooling rates and degrees of metamorphism.

In sulfide droplets from the unmetamorphosed Noril’sk sills, which have undergone rapid cooling, almost all of the siderophile elements (except Pt and Au), occur in BMS. This suggests the model whereby a base metal sulfide liquid collects the PGE to form these deposits is correct. Platinum occurs as PGM exsolutions within the BMS. Possibly the Pt partitioned into the sulfide liquid, but it exsolved from the BMS during cooling.

In the PGE-reefs of unmetamorphosed layered intrusions (Busveld Complex and Great Dyke) ~30 to 60% of the siderophile elements (except Pt and Au) are present in BMS. The balance is found in PGM, which occur as exsolutions in the BMS or as grains at the contact with the BMS. The reason that a larger percentage of PGE are in the form of PGM is the slower cooling of the BMS in the layered intrusion, which would allow more time for exsolution of the PGE than in the case of the BMS from subvolcanic sills.

In the PGE-reefs from the metamorphosed layered intrusion (Penikat) the percentage of siderophile elements present in BMS covers a larger range, ~8 to 70 percent. There are many more PGM present and there has been extensive recrystallization of the BMS. Possibly the recrystallization of BMS during metamorphism facilitated the formation of a large number of PGM. The Pd-PGM are not always found associated with BMS. Three processes could have led to this: a) the BMS, which originally contained Pd, dissolved during metamorphism, leaving an insoluble Pd-PGM; b) the Pd could have been introduced to the PGE reef by metamorphic fluids; c) the Pd could have been locally remobilized into the silicates adjacent to the BMS.

The use of Campanian pumices in the Roman mortars of Messina area (Sicily) as indicator of technological tradition
G. Barone¹, M.F. La Russo¹, P. Mazzoleni¹, A. Pezzino¹ and G. Tigano²

¹Dipartimento di Scienze Geologiche Università di Catania,
Corso Italia 55 (m.larussa@unict.it)
²Soprintendenza BB.CC.AA. di Messina Viale Boccetta

In this work we present the petrographic and geochemical characterization of pumices employed in the roman mortars sampled in the archeological sites of Messina area (Capo Peloro and Messina). The petrographic analysis shows the presence of two principal groups of mortars: i) cocciopesto bearing mortars; ii) pumices bearing mortars.

These data confirm the Romans’ knowledge of the property of pyroclasts and pottery fragments as raw material in the preparation of hydraulic binders with optimal physical and mechanical characteristics.

The archeologists, on the basis of the proximity, considered the pumice coming from the Aeolian Islands but no archeometric data exist till now supporting this hypothesis.

With the aim to establish the provenience of the pumice inclusions chemical analysis, carried out with SEM/EDS, were made on numerous mortars samples. The multivariate principal components diagram of the geochemical data (Fig.1) indicates the use of campanian pozzolana that was preferred to the Aeolian pumices because it guaranteed better hydraulic properties.

Fig.1
Geochemistry and tectonic setting of mafic rocks from the Othris Ophiolite, Greece

M.G. BARTH AND T.M. GLUHAK
Institut für Geowissenschaften, Universität Mainz, Germany (barthm@uni-mainz.de)

The Othris Ophiolite in central Greece is a remnant of the Jurassic Neotethys Ocean, which existed between Eurasia and Gondwanaland. The mantle section of the Othris Ophiolite shows evidence for both mid-ocean ridge and supra-subduction zone tectonic settings (Barth et al., 2007). In this study geochemical analyses of minerals and whole rocks are presented for a suite of mafic rocks from the crustal section of the Othris Ophiolite. The mafic rocks form three chemically distinct groups.

Group 1 is characterized by N-MORB-type basalt and basaltic andesite with Na- and Ti-rich clinopyroxenes. These rocks show mild LREE depletion and no HFSE anomalies, consistent with moderate degrees (~15%) of anhydrous partial melting of depleted mantle followed by 30-50% crystal fractionation.

Group 2 is represented by E-MORB-type basalt with clinopyroxenes with higher Ti contents than Group 1 basalts. Group 2 basalts also have higher concentrations of incompatible trace elements with slightly lower HREE contents than Group 1 basalts. These chemical features can be explained by ~10% partial melting of an enriched mantle source.

Group 3 includes high MgO cumulates with Na- and Ti-poor clinopyroxene, forsteritic olivine, and Cr-rich spinel. The cumulates show strong depletion of HFSE, low HREE contents, and LREE enrichments. These rocks may have formed by olivine accumulation from boninitic magmas.

The petrogenesis of the Group 1 basalts is in excellent agreement with the melting conditions inferred from the MOR-type peridotites in Othris. Furthermore, the inferred parental magmas of the Group 3 cumulates are broadly complementary to the SSZ-type peridotites found in Othris. These results suggest that the crustal section may be genetically related to the mantle section.

In the Othris Ophiolite mafic rocks recording magmatic processes characteristic both of mid-ocean ridges and subduction zones occur within close spatial association. These observations are consistent with the formation of the Othris Ophiolite by intra-oceanic thrusting and forced subduction initiation at (or near) a mid-ocean ridge.

Nd model ages ($T_{DM}$) as an indicator of West Gondwanan suture in southeastern South America

M.A.S. BASEI AND O. SIGA JR.
Geoscience Institute, University of Sao Paulo, Brazil

Available Nd ($T_{DM}$) ages for a roughly W–E transect across the units observed on both sides of the South Atlantic Ocean shows a conspicuous decrease in model ages eastwards; with the Damara Belt displaying the youngest values. There is a concentration of model ages around 2.0 Ga for the Supracrustal Schist Belt of the Dom Feliciano Belt, whereas for the Eastern Granite Belt the average falls to 1.3–1.6 Ga. For the Damara Belt (mainly its granitoids), the average also falls in the 1.3–1.6 Ga interval (McDermott and Hawkesworth 1990; Jung et al. 1998). This similarity, which may represent an affinity of the source areas for the Eastern Granite Belt and the African portion, can be explained by the participation of similar sources in the generation of these materials. Therefore, the isotopic differences between the Eastern Granite Belt and those further west, strengthen suggestions that the Major Gercino–Sierra Ballena lineament should be viewed as a Neoproterozoic Lithospheric suture (Basei et al. 2005). These results highlight the differences in the detrital zircon signatures across a proposed West Gondwanan suture, with those in the west being derived from distinctive South American basement sources and those in the east from distinctive African sources. An important gravimetric anomaly along the MGSB lineament also supports this interpretation (Hallinan and Mantovani 1993).

Any supernova $^{60}$Fe excess on Earth? Evidence from $^3$He in ferromanganese crust

S. Basu$^1$, F.M. Stuart$^1$, C. Schnabel$^1$ and V. Klemm$^2$

$^1$Isotope Geosciences Unit, SUERC, East Kilbride G75 0QF
(S.Basu@suerc.gla.ac.uk)
$^2$Department of Earth Sciences, ETH-Zurich, Clausiusstrasse 25, CH 8092, Switzerland (klemm@erdw.ethz.ch)

 Supernova (SN) explosions within 30 parsecs of Earth have the potential to affect the biosphere. Identifying SN debris on Earth allows models of SN frequency to be tested and assess their role in global environmental change. Identification of rare SN-produced isotopes in slow accumulating terrestrial archives is one method. The detection of $^{60}$Fe in 2.4-3 Ma layers in a ferromanganese crust from the deep Pacific Ocean (237KD) has been attributed a SN source [1]. However $^{60}$Fe is also produced by galactic cosmic-ray (GCR) interaction with Ni in extraterrrestrial material. Helium isotopes offer a way of testing the source of the $^{60}$Fe in 237KD. $^3$He is produced by GCR reactions and delivered to Earth in extraterrestrial dust, but SN-helium is not predicted to make it to the Earth. We have quantified the GCR-He contribution in 237KD, and, by comparing production rates in possible extraterrestrial material, we estimate the GCR-$^{60}$Fe from micrometeorites to test the SN hypothesis [2].

$^3$He/$^4$He (5.5 to 4440 R A) is a mixture of extraterrestrial He (implanted solar ions + GCR-He) and radiogenic He in terrestrial dust. Prior to 4-5 Ma $^3$He concentrations vary little and no $^3$He/$^4$He was higher than the solar wind value (290 R A). In the last 4 Myr average $^3$He increases significantly, six samples have $^3$He/$^4$He higher than solar wind and the average $^3$He/$^4$He (330 R A; n = 32) is higher than the average of the older samples (54 R A; n = 36). The statistical variability of $^3$He between replicates of < 4 Myr samples indicates that a small number of extremely GCR-He-rich micrometeorites have been incorporated. The $^3$He/$^4$Fe of 237KD (80-850) is comparable to the measured GCR $^3$He/$^4$Fe production rate ratio (400-500) in Ni-rich minerals in iron meteorites. The $^{60}$Fe in 237KD can be explained by a small number of FeNi-rich micrometeorites and rules out the need for SN debris.

To test whether the $^3$He in crusts reflect normal micrometeorite flux or ablation debris from entry melting of large meteorites we are analysing sections at the KT boundary from crusts with low $^{187}$Os/$^{188}$Os excursions that are temporally associated with enhanced meteoritic flux.

Fractionation of HSE during melt transport processes in supra-subduction mantle

Valentina Batanova$^1$, Gerhard Brügmann$^2$, Galina Savelieva$^3$ and Alexander Sobolev$^{1,2}$

$^1$Vernadsky Institute of Geochemistry and Analytical Chemistry RAN, Moscow, Russia (batanova@geokhi.ru)
$^2$Max-Planck-Institut für Chemie, Mainz, Germany (bruegmag@uni-mainz.de)
$^3$Geological Institute RAN, Moscow, Russia

Highly siderophile elements (HSE) represent powerful tools for monitoring and dating mantle processes. Here we report a detail study of HSE and Re-Os isotopes of lithologies from the Voykar Ophiolite (Polar Urals) which formed in a subduction tectonic environment. The Voykar mantle rocks are extraordinary fresh and often free of serpentine. Even primary sulfides are preserved. This suggests that the original PGE distribution and the Re-Os isotope systematics have not disturbed by low temperature secondary alteration processes.

Our data suggest that old, more than 2 Ga old refractory harzburgite was percolated by suprasubduction melts about 0.6 Ga. These melts have formed dunite reaction channels and pyroxenite veins and locally redistributed the HSE in the surrounding harzburgite. In dunite channels and pyroxenite veins numerous sulfide globules transported by silicate melts have been observed. These sulfide globules make up the HSE budget of the pyroxenites and they are characterized by low concentration of Os, Ir and Ru compared to Pt, Pd and Re. High Re abundance in the pyroxenite (up to 2 ppb) suggest contribution from subduction slab.

HSE composition of dunites results from reaction between percolating melt and host peridotite. Close to the contact, residual peridotites become enriched in Pt, Pd and Re. But primary HSE features of the harzburgite, such as Pd, Pt, Re depletion relative to Ir, Os and Ru appear to be preserved in a distance of about 1 m away from the contact with dunite channel.

![Figure 1: HSE distribution through the dunite channel.](image-url)
Humic substances (HS) are natural organic polymers present in most environmental systems. They are redox-active and participate in microbiologically catalyzed redox reactions. Iron-reducing and many fermenting bacteria can use HS as an alternative electron acceptor in their metabolism. The reduced HS transfer electrons in a chemical reaction to electron acceptors like metal ions or organic pollutants, thus functioning as an electron shuttle between microorganisms and these terminal electron acceptors. So far the kinetics and thermodynamics of redox reactions of HS with iron(II) and iron(III) minerals as well as with microorganisms are poorly understood.

In order to tackle these knowledge gaps, the kinetics of microbial reduction of various HS by Fe(III)-reducing bacteria (Geobacter and Shewanella sp.) was quantified and compared to i) the direct microbial reduction of iron(III) minerals and ii) the reduction of iron(III) minerals by reduced HS. We determined the minimum concentration of HS necessary for observable electron shuttling.

The thermodynamics of redox reactions between HS and dissolved and solid iron(II) and iron(III) compounds was evaluated. Since O2 is the most important electron acceptor in nature, redox reactions of HS with iron compounds possessing different redox potentials were compared to HS oxidation by O2. We applied electron spin resonance (ESR) spectroscopy in order to quantify radical formation during HS redox reactions. As the contribution of HS-complexed iron to HS redox reactions is unclear, we extracted different iron fractions from HS by sequential extraction and quantified the redox properties of HS after each extraction step.

Our results showed that HS can react with several iron(II) and iron(III) minerals and efficiently catalyze biogeochemical processes in the environment. The fact that these processes a variety of reactive HS species such as semiquinone radicals are formed suggests that HS have the potential to be an important player in the redox cascade in natural environments.
Thermally altered early Silurian cyanobacterial mats: Biomarkers and $^{15}$N isotopic signatures

THORSTEN BAUERSACHS$^1$, STEFAN SCHOUTEN$^1$, JAAP S. SINNINGHE DAMSTÉ$^1$ AND BARBARA KREMER$^2$

$^1$Royal Netherlands Institute for Sea Research, Dept. Marine Biogeochemistry and Toxicology, P.O. Box 59, 1790 AB Den Burg, The Netherlands
$^2$Institute of Paleobiology, Polish Academy of Sciences, Twarda 51/55, 00-818 Warszawa, Poland (kremer@twarda.pan.pl)

Morphologically preserved cyanobacterial mats are rare in the fossil record due to destructive biological and diagenetic processes. Early Silurian black radiolarian cherts from the Holy Cross Mts. and Sudetes (Poland) contain abundant variously degraded remnants of benthic coccoid cyanobacterial mats. These cherts underwent thermal alteration with various intensity, which influenced the organic matter preservation.

Here we examined the organic matter of these cherts to investigate its origin and maturity. Aliphatic fractions of the extracted organic matter was dominated by n-alkanes in a range of 15 to 36 carbon atoms exhibiting unimodal distribution with a maximum between C$_{17}$ and C$_{19}$. The most immature cherts still contained hopanoids dominated by 22S-isomers attesting to the relative high maturity of the organic matter. The dominance of hopanoids over steranes and the isomers attesting to the relative high maturity of the organic matter. The dominance of hopanoids over steranes and the isomers attesting to the relative high maturity of the organic matter. The dominance of hopanoids over steranes and the isomers attesting to the relative high maturity of the organic matter. In contrast, the more mature sediments did not contain recognizable cyanobacterial biomarkers which are presumably lost during diagenesis. Thus, in spite of good morphological preservation, the biomarker signatures of the Silurian cyanobacteria, due to their thermal maturation, are no longer recognizable.

Nitrogen isotopic signatures of bulk organic matter in the studied cherts vary from -2.2 to +0.1‰ what is consistent with values observed for biological nitrogen fixation. Although it is known that diagenesis and bacterial degradation may alter the nitrogen isotopic composition, the rather low $\delta^{15}$N values from the studied cherts seem to reflect isotopic N signals not considerably changed by maturity and degradation.

Fingerprinting of a thin secondary mineral film on DU

N. BAUMANN$^1$, T. ARNOLD$^1$, H. FOERSTENDORF$^1$, D. READ$^2$, S. BLACK$^3$ AND A. MASSANEK$^4$

$^1$FZ Dresden-Rossendorf, Institute of Radiochemistry, P.O. Box 510119, D-01214 Dresden, Germany
$^2$Enterprise, Universities of Reading & Aberdeen, UK
$^3$University of Reading, Whiteknights, UK
$^4$Geoscientific Collections, TU Bergakademie Freiberg, D-09596 Freiberg, Germany

Depleted uranium (DU), a by-product in the production of nuclear fuel, is used for military purposes in projectiles for attacking armoured vehicles. Concerns about the ecological consequences following the use of DU as ammunition in wars in Iraq and in the former Yugoslavia have received much public attention. The long-term effect on groundwater and drinking water as a result of dispersed DU projectiles in soil is far from understood. In this study, the weathering of DU in conditions representing agricultural soil, rich in calcium and phosphate, was studied in laboratory experiments. Surface alteration products were identified by infrared spectroscopy (IR) and time-resolved laser-induced spectroscopy (TRLFS).

Discs of DU, 0.5 mm in thickness and 25 mm in diameter, obtained from a British pristine military tank shell were used in our experiments. One sample was placed in a solution containing $2.5 \cdot 10^{-3}$ M Ca(NO$_3$)$_2$ and $1.05 \cdot 10^{-3}$ M (NH$_4$)$_3$PO$_4$. After a contact time of 360 days the sample was taken out of the solution. IR- and TRLFS measurements were made on the surface of the sample, immediately after rinsing with deionised water and drying. The spectra obtained were compared with those of natural uranium minerals, formed under oxidising weathering conditions, provided by the Mineral Collection of the TU Bergakademie Freiberg. Comparison of the IR-spectra from the DU surface with those of the reference minerals revealed that the newly formed secondary mineral on DU is a uranium (VI) phosphate. Further identification of the respective uranium phosphate mineral was not possible with IR. However, a comparison between the TRLFS spectra of the newly formed unknown uranium phase on the DU disc with well-known TRLFS spectra of uranium reference compounds clearly showed the presence of meta-autunite. The hypothesis established in [1] was confirmed based on much better spectra with regard to signal-to-noise ratio and reproducibility. Agreement between TRLFS spectra from altered DU and the fingerprints was obtained not only in the position of the peak-maxima, but also in the life time of the fluorescence signals. TRLFS clearly shows the presence of a very thin layer of the newly formed uranium phosphate mineral on the DU disc, which is formed from the metallic uranium and the calcium phosphate solution, an alteration process that may well occur in agricultural soil.

Influences of the quartz host mineral on the Raman spectra of H₂O and aqueous salt bearing fluid inclusions

M. BAUMGARTNER, Y. COQUINOT AND R.J. BAKKER
University Leoben, Department of Applied Geosciences and Geophysics, Leoben, Austria
(miriam.baumgartner@mu-leoben.at)

Raman Spectroscopy offers a powerful tool for the investigations of aqueous phases in fluid inclusions and can provide insights of vibrational modes of different species. The water stretching vibrations between 2800 up to 3800 cm⁻¹ are the most informative signals for the investigation of fluids. This region shows one broad signal, which is a complex profile of overlapping bands. Dissolved electrolytes, which are present as simple ions are not Raman active but they can influence the characteristic Raman bands of the aqueous solution. The shape of the Raman contour shows a systematical change in dependence of the amount of dissolved anions and cations in the solution. The intensity in the front area of the water peak is decreasing to smaller values and a peakshift to higher wavenumbers could be observed. For this reason the Raman spectra of the stretching region of liquid water is often used to determine the salinity of fluid inclusions.

The Raman spectra of liquids were studied in synthetic H₂O and aqueous salt bearing fluid inclusions in quartz. The inclusions were synthesized at 600°C and various pressures in our laboratory. The Raman spectrum of H₂O is substantially different between a drop of water and a fluid inclusion. The spectrum of fluid phases in inclusions is not only defined by the fluid phase itself. The host mineral can influence the signal dramatically and modify the shape of the Raman bands due to polarization of the laser beam. In birefringent minerals such as quartz the spectra is strongly influenced by the crystallographic orientation of the host. Other modifications on the spectra are caused at the quartz- fluid inclusions interface depending on the angel of the surface of the inclusion wall. These phenomena may cause erroneous estimations of the salinity of fluid inclusions. We have qualified and quantified the variability of the Raman spectra due to these polarization effects in quartz.

Slow reaction rates, disequilibrium, and excess Argon: Teaching some bad dogs new tricks

ETHAN F. BAXTER
Boston University, Earth Sciences, 685 Commonwealth Ave., Boston, MA, 02215 USA (efb@bu.edu)

Geochemical, petrological, and geochronological interpretations about the evolving earth require assumptions about the poorly constrained rates of fundamental geologic processes. Among these processes are chemical reactions - whose rates determine whether systems reach equilibrium, and chemical transport mechanisms - whose rates control the lengthscale of equilibrium as well as important boundary conditions in models of isotopic closure. Here, I describe ways in which we can make use of otherwise problematic field situations where, 1) the equilibrium assumption, and 2) the standard model for isotopic closure, break down.

Models of reactive-transport within layered rock systems can be used to exploit fluid-rock disequilibrium to quantify reaction kinetics attending metamorphism. This method, involving Sr-isotopic diffusion and exchange is reviewed, as well as the fundamental result of its first application which suggests natural metamorphic reactions rates are many orders of magnitude slower than required for equilibrium to be maintained in most systems [1]. Such slow time-integrated reaction rates, corroborated by several other field based observations, mean that the petrologic evolution of the crust cannot a priori be assumed to follow equilibrium based predictions [2]. Quantification of reaction rates, coupled with equilibrium models, permits more accurate modeling of dynamic natural systems.

Excess argon, the result of a violation of the standard closure model, is a frequent annoyance in Ar/Ar thermochronology. Most important in the development of excess argon is the breakdown of the “zero-concentration boundary condition” assumption. Two system parameters ultimately control this: 1) the transmissive timescale, which is the time required for Ar-40 to escape from the local rock system, and 2) the total local sink capacity, which is the degree to which other local phases (minerals, fluids, and even grain boundaries [3]) may take in (i.e. partition) the Ar-40 relative to the mineral of thermochronologic interest. Numerical modeling of diffusive transport and exchange has yielded an empirical analytical equation which predicts the amount of excess argon in any phase in a system as a function of these two parameters [4]. With this quantitative model, it is possible to use this measureable quantity (excess Ar) as a tracer of transport, timescales, and cooling in its own right.

Focused pulses of regional metamorphism

ETHAN F. BAXTER1, JAY J. AGUE2 AND PENELOPE J. LANCASTER3

3University of Wisconsin, Dept. of Geology and Geophysics, 1215 W. Dayton St., Madison, WI, 53706 (planast@geology.wisc.edu)

Growing evidence is emerging to support the idea that metamorphism, even in a regional context, may be punctuated – or dominated – by relatively short pulses of heating, fluid flow, and/or mineral growth. Here, we describe data from two Barrovian metamorphic terranes which test this idea.

In the Barrovian zones of Scotland, garnet Sm/Nd geochronology from the garnet and sillimanite zones yield the same peak metamorphic ages [1] (~465 Ma). The age is similar to the age of crystallization of large igneous bodies in the area. The contemporaneity of peak ages is explained by an efficient, advective component of heating, perhaps mediated by synchronous fluid flow [2]. The duration of this region-wide pulse of peak metamorphism is constrained by new Sr-in-apatite diffusion modeling. Apatite grains have detrital cores and metamorphic overgrowths and are included within porphyroblasts (e.g. garnet, staurolite). Modeling of intragrain diffusion of Sr constrains the duration of peak metamorphism to <250 kyr for garnet through staurolite zone samples. Garnet multi-component diffusion modeling from the sillimanite zone corroborates this brief pulse duration.

The Wepawaug Schist of Connecticut USA, also yields contemporaneous peak-T garnet Sm/Nd ages from different grades across the terrane (~380 Ma). This age matches a population of texturally young zircons associated with igneous intrusions in these rocks. Garnet cores from the kyanite zone, which have growth textures indicative of extremely rapid growth [3], have been dated by Sm/Nd at 388.6 Ma. This age is matched by another population of zircons also associated with igneous intrusions. This earlier prograde growth event may be related to another pulse of metamorphic growth, brought on by magmatic fluid and heat.

Brief pulses of metamorphic heating and mineral reactions, perhaps catalyzed by the introduction of fluids, may be superimposed on regional scale conductive heating at tectonic rates. Such short pulses could help explain the discrepancy between rapid lab-based reaction kinetics and much slower time-integrated field-based reaction kinetics [4].

Uranium and thorium concentrations and isotope compositions were measured on a set of 16 samples drilled across an authigenic carbonate pavement, providing the first stratigraphy for a cold seep carbonate crust. The 5.5-cm thick crust (NL7-CC2) was collected by submersible on the Nile deep-sea fan in an area of active fluid venting. U-Th analyses were corrected for initial Th using isochron methods.

Our calculated 230Th/U age-depth profile for NL7-CC2 provides evidence for continuous carbonate precipitation at the studied location over the last ~ 5000 years. Three distinct phases can be distinguished from top to bottom with average growth rates of ~ 0.4, 5.5 and 0.7 cm/kyr, respectively, corresponding to carbonate precipitation rates ranging from ~ 8 to 125 µmol/m²/h, consistent with previous estimates. High-resolution profiles for δ13C and major elements across NL7-CC2 show that those variations in carbonate precipitation rates were also accompanied by changes in carbonate mineralogy and composition of contemporaneous fluids.

We suggest that all those changes reflect primarily modification of the diagenetic environment, i.e. a progressive depletion of dissolved sulphate through anaerobic oxidation of methane, caused by carbonate crust formation. Overall, U-Th dating of cold seep carbonates offers a promising tool to bring new insights into biogeochemical processes at cold seeps and to assess the timing and duration of fluid venting on continental margins.
Spinel-lherzolite xenoliths from the Hoggar swell: Evidence for intracratonic asthenosphere upwelling and lithosphere rejuvenation

L. BECCALUVA1, A. AZZOUNI-SEKKAL2, A. BENHALLOU3, G. BIANCHINI1, R.M. ELLAM4, M. MARZOLA1, F. SIENA1 AND F.M. STUART2

The mantle xenoliths included in Quaternary alkaline volcanic rocks from the Manzaz-district (Central Hoggar) are proto-granular, anhydrous spinel lherzolites. Major and trace element analyses on bulk rocks and constituent mineral phases show that the primary compositions are widely overprinted by metasomatic processes, which however are not reflected by pyrometamorphic textures. Trace element modelling of the metasomatized clinopyroxenes allows the inference that the metasomatic agents that enriched the lithospheric mantle were highly alkaline carbonate-rich melts such as nephelinites/mellilitites (or as extreme silico-carbonatites). These metasomatic agents were characterized by a clear HIMU Sr-Nd-Pb isotopic signature, whereas there is no evidence of EM1 components recorded by the Hoggar Oligocene tholeiitic basalts. This can be interpreted as being due to replacement of the older cratonic lithospheric mantle, from which tholeiites generated, by asthenospheric upwelling dominated by the presence of a HIMU signature. Accordingly, this rejuvenated lithosphere (accreted asthenosphere without any EM influence), may represent an appropriate mantle section from which deep alkaline basic melts could have been generated and shallower mantle xenoliths sampled, respectively. The available data on lherzolite xenoliths and alkaline lavas (including He isotopes, Ra < 9) indicate that there is no requirement for a deep plume anchored in the lower mantle, and that sources in the upper mantle may satisfactorily account for all the geochemical/petrological/geophysical evidence that characterizes the Hoggar swell. Therefore the Hoggar volcanism, as well as other volcanic occurrences in the Saharan belt, are likely to be related to passive asthenospheric mantle upwelling and decompression melting linked to tensional stresses in the lithosphere during Cenozoic reactivation and rifting of the Pan-African basement. This can be considered a far-field foreland reaction of the Africa-Europe collisional system since the Eocene.

Lithosphere/asthenosphere interaction in a plume region: Evidence from Ethiopian mantle xenoliths

L. BECCALUVA1, G. BIANCHINI1, R.M. ELLAM2, C. NATALI1, F. SIENA1 AND F.M. STUART2

1Dipartimento di Scienze della Terra, Università di Ferrara, Italy (bec@unife.it)
2Isotope Geoscience Unit, Scottish Universities Environmental Research Centre, East Kilbride, UK

Mantle xenoliths entrained in alkaline lavas from Injibara (Gojam) and Nekemte (Wollega) at the western border of the Ethiopia-Yemen basaltic plateau provide information on the lithospheric mantle evolution in an area where the existence of a deep mantle plume is widely accepted (Afar plume; Courtillot et al., 2003).

The studied xenoliths include prevalent spinel lherzolites and subordinate harzburgites (sometimes containing metasomatic amphibole) and olivin-websterites characterized by generally flat chondrite-normalized bulk-rock REE patterns, with only few enriched samples (La/Yb up to 5). Clinopyroxene (cpx) REE patterns are generally flat or LREE depleted (La/Yb down to 0.6). In a few samples a pristine Eu depletion is observed in garnet peridotite clinopyroxenes.

Sr-Nd isotopes on separated cpx mainly show compositions (87Sr/86Sr < 0.7030; 143Nd/144Nd > 0.5132) approaching the Depleted Mantle end-member, or displaced (87Sr/86Sr 0.7033-7034; 143Nd/144Nd 0.5129-0.5128) toward the Enriched Mantle components which also characterize the Ethiopian Oligocene plateau basalts.

These characteristics indicate that most xenoliths were variably affected by metasomatic processes, whose agents may be envisaged as mafic subalkaline melts that infiltrated and reacted at high melt/peridotite matrix ratio.

Sr-Nd isotopes on separated cpx mainly show compositions (87Sr/86Sr < 0.7030; 143Nd/144Nd > 0.5132) approaching the Depleted Mantle end-member, or displaced (87Sr/86Sr 0.7033-7034; 143Nd/144Nd 0.5129-0.5128) toward the Enriched Mantle components which also characterize the Ethiopian Oligocene plateau basalts.

The compositional evolution of the studied samples seems to reflect complex asthenosphere/lithosphere interactions occurring in a plume region where lithospheric bulging and thinning by the uprising asthenosphere is accompanied by pervasive refertilization due to reactive percolation of sublithospheric subalkaline melts. Therefore the studied mantle xenoliths may represent asthenosphere-derived mantle material entrained by the buoyancy flux of the Afar plume which equilibrated to shallower levels and accreted to the lithosphere.

Petrogenesis of the Ethiopian plateau basalts and their bearing on mantle plume components

L. BECCALUVA, G. BIANCHINI, C. NATALI AND F. SIENA
Dipartimento di Scienze della Terra – Università di Ferrara

The Ethiopian-Yemen continental flood basalts represent an Oligocene Large Igneous Province where some typical features of deep mantle plume, including high ⁴He/³He ratios, have been documented (Afar plume; Courtillot et al., 2003). In the Ethiopian plateau large volumes (ca. 300000 Km³) of tholeiitic magmas, erupted in a short time span (31-28 Ma), appear to be zonally arranged with low-Ti basalts in the NW part of the province, and high-Ti basalts (and picrites) in the eastern sector neighbouring the Afar-Red Sea region (Pik et al. 1998).

An integrated petrogenetic model based on major element mass balance calculations, phase equilibria, and thermo-barometric evaluations indicates that primary basaltic magmas were generated by ca. 15-20% melting of mantle lherzolite at 1250-1300 °C / 13-16 Kb and ~1300-1350 °C / 14-19 Kb for low-Ti and high-Ti tholeites, respectively; high-Ti picrites by ~30% melting at ~1400-1450 °C / 20-30 Kb.

The calculated mantle sources invariably require hydrated lherzolite composition with up to 5% and 10% of amphibole for low-Ti and high-Ti magmas respectively, and a parallel increase of 2 – 17 times incompatible element abundances with respect to those observed in the Ethiopian mantle xenoliths. Further Ti-rich metasomatic phases (e.g. rutile, ilmenite, armalcolite) are required in the mantle sources, particularly for the generation of extremely high-Ti magmas (TiO₂ up to 5-6%). Therefore, low-Ti basalts may have been generated in the outer zone of the Afar-plume by partial melting of moderately metasomatized lithospheric mantle sources, in connection with the activation of the hotspot and related crustal bulging. High-Ti basalts/picrites could in turn be generated in the inner part of the Afar buoyancy flux from mantle sources significantly more enriched by plume components. These metasomatizing components may correspond to Na-alkali silicate mafic melts enriched in Ba, Th, Nb, Ti, Zr as well as light REE and show compositional analogies with the Ti-rich alkali silicate metasomatism documented in some mantle xenoliths from Kerguelen Islands (Grégoire et al., 2000).

Biogeochemistry of advective intertidal sediments

M. BECK¹, O. DELLWIG¹,², M. GRUNWALD¹ AND H.-J. BRUMSACK¹

¹ICBM, Carl-von-Ossietzky University, Oldenburg, Germany (last.name@icbm.de)
²IOW, Rostock, Germany (olaf.dellwig@io-warnemuende.de)

Introduction
At tidal flat margins where the sediment surface slopes towards tidal creeks, deep advective pore water flow may be generated driven by the hydraulic gradient between sea water and pore water level at low tide (Billerbeck et al. 2006; Howes and Goehringer 1994; Wilson and Gardner 2006). Tidal and seasonal variation of trace metal and nutrient concentrations in deep pore waters of advective intertidal sediments have however remained largely unknown.

Results and Discussion
In-situ pore water sampling down to 5 m sediment depth in an intertidal sand flat in NW Germany revealed trace metal profiles similar to those observed in the upper centimetres of deep sea sediments. The pore water composition is strongly influenced by the location of the sampling site and its specific characteristics, like oxygen penetration depth and H₂S concentration.

At a location close to the main tidal creek tidal variations of trace metals, dissolved organic carbon (DOC), and nutrients were determined. Manganese concentrations e.g. increase by a factor of two from low to high tide in these depths, whereas uranium concentrations are decreasing to values half as high in the same time period. Pore water advection is shown to be most significant at 1 to 3 m depth. In these depth levels DOC and nutrients are enriched, whereas trace metals are enriched or depleted depending on their specific behavior under reducing conditions. Elemental species enriched in deep pore waters presumably represent an important source for the open water column when seeping out of the sediment. Release of manganese-enriched pore water supposedly explains tidal variations observed in the open water column of the study area. Seasonal pore water composition and temperature variations in depth profiles support the hypothesis that advection is significantly influencing the tidal flat system. The study of seasonal concentration patterns further evidences the interaction of trace metals like vanadium with DOC.

Geochemical tracing of core-mantle interaction: High-precision W isotopic data on komatiites using TIMS

H. BECKER1,2, A. D. BRANDON3 AND R. J. WALKER4

1Lunar and Planetary Institute Houston
2Freie Universität Berlin, Institut für Geologische Wissenschaften (hbecker@zedat.fu-berlin.de)
3ARES Division, Johnson Space Center Houston (alan.d.brandon@nasa.gov)
4Department of Geology, University of Maryland (rjwalker@geol.umd.edu)

It has been suggested that coupled suprachondritic 187Os and 186Os in some plume-derived picrites and komatiites may be best explained by a small contribution (≤0.5-1%) of a component from the outer core in the mantle sources of these lavas. Tungsten is another siderophile element that might help tracing core-mantle interaction. The excess of 182W (from the decay of short-lived 182Hf during the first 60 Ma of solar system history) in the mantle relative to chondrites suggests that the core may have a deficit of 182W relative to the mantle (ε182W ≈ -2). A previous study of 182W systematics of Hawaiian picrites that show suprachondritic 187Os and 186Os did not reveal resolvable deficits in 182W at the 10-20 ppm level (Schersten et al. 2004). Because the effects of a 0.5-1% core contribution on 182W likely may be less than 30-40 ppm, external precisions better than 10 ppm (2σ) on 182W/184W or 183W/184W of lavas are required in order to resolve a core contribution. The goal of this project was to establish analytical protocols that allow the measurement of differences in the abundance of 182W in komatiites at the 5-10 ppm level by negative thermal ionization mass spectrometry using the Johnson Space Center TRITON TIMS. Komatiites show W abundance excesses (relative to similar incompatible elements such as Ce or Th) that remain unexplained and the association of some komatiites with plume/LIP provinces may hint at an origin of the source rocks in the deep mantle. Results over a 3 month period yielded in-run precisions (2σ) of individual W standard runs between 4 and 6 ppm for 182W/184W and 183W/184W, respectively, and external precision (2σ) of 7 and 9 ppm on 182W/184W and 183W/184W, respectively (n=10). After 3 months, it was observed that standard runs were systematically shifted to higher values by 10-15 ppm for both 182W/184W and 183W/184W. Two aliquots of a 2.7 Ga Belingwe komatiite yielded the best in-run precision (~6 ppm), and show values for 182W/184W that are within uncertainties of W standards run during the same time period. A single run for komatiite GOR 94-7 (Gorgona) shows an uncertainty of ±17 ppm (2σm) and a 182W/184W value overlapping with standard measurements. The main limitations on high-precision 182W measurements by N-TIMS are the influence of variable O isotopic compositions and minor Re oxide interferences on W oxide corrections. Normal W isotopic compositions and W abundance excess in these komatiites may reflect addition of crustal W during komatiite alteration.

Searching for selenium: In situ measurement in base metal sulfides

L.P. BÉDARD1, J. BERNARD2 AND S.-J. BARNES3

1Science de la Terre, Université du Québec à Chicoutimi, Canada (pbedard@uqac.ca)
2Science de la Terre, Université d’Orléans, France (jean.bernard56@laposte.net)
3Science de la Terre, Université du Québec à Chicoutimi, Canada (sjbarnes@uqac.ca)

To test the idea that most of the Se in rocks is located in base metal sulfide minerals (BMS), in situ Se concentrations in BMS would be useful. This is important for two reasons. Firstly, whole rock S/Se ratios have been used to model the formation of magmatic sulfide ore deposits. This approach is based on the idea that the whole rock analyze reflects the S/Se ratio of the BMS. Secondly, S and Se determination can be difficult and for Se, labor intensive. If Se could be determined in situ in BMS, then the whole rock Se would not be necessary.

Both whole rock Se and in-situ measurements of Se in BMS have been carried out on the BMS of the JM-reef of the Stillwater Complex and Merensky Reef of the Bushveld Complex.

In-situ Se is determined with a collision cell laser ablation (LA) ICP-MS (Thermo X7). Kinetic energy discrimination and a 50:50 mixture of H2:H2+He added to the collision cell minimize argide interferences. Sulfur is used as the ablation monitor. Detection limits range in the 1-5 • g/g Se (depending on laser beam), although quite high in terms of ICP-MS, it fits the purpose for Se determination in sulfide where Se ranges from 50 to 1000 • g/g Se. In order to better match the matrix, reference materials (RM) are Se-doped NiS beads (80-1000 • g/g Se) made from a technique similar to fire-assay preconcentration. Se is determined independently by preconcentration on thiol-cotton and INAA. RM homogeneity is tested with SEM imaging, microprobe determinations and LA-ICP-MS repeated determinations within a single bead. Reproducibility is in the range of 10 % RSD (at 2 •) for more than 30 Se determinations on different NiS beads.

Mass balance calculations show that within analytical uncertainties all, Se is hosted in BMS. Furthermore, our results compare favorably with previous PIXE determinations of Se in BMS of the Merensky Reef. These results suggest that assuming that all Se is hosted in BMS to interpret S/Se is valid.

Single-grain bulk Hf and in situ O isotopes as indicators of crustal recycling in magmas of the northern Arabian-Nubian Shield

Y. Be'eri-Shlevin¹, Y. Katzir¹, J. Blickert-Toft²
and M.J. Whitehouse³

¹Department of Geological and Environmental Sciences, Ben-Gurion University, Be'ery Sheva, Israel (beeri@bgu.ac.il)
²Laboratoire des Sciences de la Terre, Ecole Normale Supérieure, Lyon, France
³Swedish Museum of Natural History, Stockholm, Sweden

We present new in-situ (SIMS) oxygen isotopic ratios (δ₁⁸O(Zrc)) and bulk (MC-ICP-MS) ¹⁷⁶Hf/¹⁷⁷Hf (Hf(Zrc)) for single zircons from a series of basic to felsic plutons (n=12) of the Arabian-Nubian Shield (Sinai Peninsula, Egypt, and Southern Arabia) characterized by low δ¹⁸O(Zrc) and Hf(Zrc) measurements systematically were carried out on the same zircon grains, thus providing a robust set of combined δ¹⁸O(Zrc)-Hf(Zrc) data for these rocks.

In-situ δ¹⁸O(Zrc) values span the range from 3.8 to 14.2‰ (±0.1 to 0.25; 2σ) and generally compare well with previously determined bulk δ¹⁸O(Zrc) but in some cases identify the presence of different components within the zircon population analyzed here. Coupled with previously determined U-Pb ages, these are inferred to be xenocrysts (~770 Ma and ~900 Ma) characterized by low δ¹⁸O(Zrc) of 3.8-4.4‰ within two plutons of ~630 Ma and δ¹⁸O(Zrc)=5.5-6.6‰.

Hf(Zrc) shows a large spread of εHf(t) varying between +5.4 and +17.7. TDM model ages span the interval of 650-1200 Ma. Some of these model ages thus correspond to older reservoir ages than the so far accepted ~1000 Ma for this part of the ANS [1]. In general Hf(Zrc) correlates well with δ¹⁸O(Zrc) with lower but positive zircon εHf(t) matching higher δ¹⁸O(Zrc).

Three zircon O-Hf groups are identified: (a) moderately high to high δ¹⁸O(Zrc) with low (but positive) εHf(t); (b) mantle-like δ¹⁸O(Zrc) (5.3±0.6‰; 2σ [2]) with intermediate εHf(t); (c) very low δ¹⁸O(Zrc) (3.8-4.6‰) with high εHf(t).

These groups define three different components involved in the generation of the ANS post-collision calc-alkaline to within-plate alkaline-peralkaline magmatism. Group b reflects partial melting of lower crust material, while juvenile upper felsic crust assimilation is inferred for group a. The peculiar group c includes xenocrysts from two plutons and magmatic zircon from another two plutons and may reflect hydrothermally altered basaltic crust that was subducted and assimilated by some of the ANS magmas. It is interesting to note that the highest εHf(t) in this group correlate with TDM model ages close to the U-Pb ages, thus implying very rapid generation, subduction, and assimilation of the basaltic crust.

Sulfur saturation of Etna Basalt at 200 Mpa: Experimental setup and first results

O. Beermann, M. Nowak, R.E. Botcharnikov and F. Holtz

Institut für Mineralogie, Leibnitz Universität Hannover, Callinstr. 3, D-30167 Hannover

The amount and composition of volatile components in magmatic systems affect significantly magma degassing and control the partitioning of volatile components between melt and fluid phase on pressure release.

This study is focused on the solubility of S in natural Etna basalt at high temperatures (up to 1200 °C) and 200 MPa. Here we report the experimental setup for high temperature experiments and first results.

Sulfur is known to be a very aggressive component limiting the application of experimental approaches that use noble metal capsules, especially Pt and AuPd. Therefore, we applied two methods: experiments in gold capsules at 1050°C and in olivine capsules at T>1050°C. The olivine capsules are made of single crystal olivines (natural St. Carlos olivine) inserted into an outer Au₈₀Pd₂₀ capsule. Native S, palladium sulphide (PdS) and pyrrhotine (FeS) were used as sulfur sources in the experiments.

The experiments were conducted in internally heated pressure vessels at 200 MPa in a range of redox conditions from relatively reducing at quartz-fayalite-magnetite (QFM) oxygen buffer to oxidizing conditions (~QFM+4).

The experiments at 1050°C show that S concentration in hydrous (5 wt.% H₂O) basaltic melt at saturation with S-bearing mineral phase (anhedrite at oxidizing conditions and pyrrhotite at reducing conditions) decreases from ~6000 ppm to ~2000 ppm with decreasing fO₂. This dramatic 3-fold decrease in S content of the basalt is related to the change in S speciation from sulfate (SO₄) to sulfide (S²⁻) with reduction of the system. The transition of S⁰ to S²⁻ occurs in a very narrow range of fO₂ from QFM+2 to QFM+0.5.

Glasses obtained from experiments at 1200°C are in equilibrium with FeS and/or PdFeS phases and content 600 to 2000 ppm sulfur. Furthermore, these glasses are enriched in MgO due to reequilibration with MgO-rich olivine. Water concentrations of H₂O-presaturated basaltic glasses decreased from 5 wt.% to 2.8 wt.% indicating additional redox reactions inside the capsules, presumably interaction with host olivine. Further improvement of this experimental approach is required to better control the experimental conditions in the capsules.
Trace, REE and Sr isotopic investigation in the core top sediments from Bay of Bengal

ZAHIDA BEGUM, V. BALARAM AND S.M. AHMAD
National Geophysical Research Institute, Hyd -07, India

Trace and rare earth element (REE) data obtained using ICP-MS and Sr isotopic composition determined by TIMS was used for the detailed study of geochemistry and transport pathways of the sediments from Bay of Bengal. These terrigenous sediments are derived from: a) the Irrawaddy-Salween rivers b) Peninsular Indian rivers, c) Ganges-Brahmaputra (G-B) rivers, and d) erosional products from the Indo-Burman ranges. The objective of the present study is to understand the geochemistry of sediments and identify their provenance in Bay of Bengal using $^{87}\text{Sr}/^{86}\text{Sr}$ and trace elemental proxies. The results from core SK-157-27 (Lat:15°48.55′ N, Long:82°8′E, water-depth:1723m) show a high concentration of REE (~153 ppm) with high $^{87}\text{Sr}/^{86}\text{Sr}$ (~153 ppm) with high $^{87}\text{Sr}/^{86}\text{Sr}$ (0.72372±0.20), which may be due the source rock characteristics in the drainage basins of the Krishna and Godavari rivers. The core was retrieved from a region that represents mainly the terrigenous sediments of Godavari and Krishna rivers. The remaining three cores were collected from the northern part of the Ninetyeast Ridge. All these cores consist of fine grained sediments. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio (0.713689 ±12) from core SK-157-14 (Lat:5°11.56′N, Long:90°5.97′E, water depth: 3306 m) suggest that the main source at this location is Irrawaddy-derived sediments with minor contributions from the Ganges-Brahmaputra rivers. High Ba and high Th/Ta ratio characterize the sediments from this core. The other two cores SK-157-15 (Lat: 7°48.55′N, Long: 90°15.92′E, water depth: 2870 m) and SK-157-16 (Lat: 8°46.86′N, Long: 90°18.42′E, water depth: 2920m) from the northern part of the Ninetyeast Ridge have relatively higher $^{87}\text{Sr}/^{86}\text{Sr}$ values (0.716995±12 and 0.716670±24) suggesting a greater contribution from the Ganges-Brahmaputra sediments. Sediments from these two cores have high Sr, high Ba and relatively low concentration of redox sensitive elements. The decrease in the redox sensitive elements is attributed to the oxic deep-water environment. Our results clearly suggest that the $^{87}\text{Sr}/^{86}\text{Sr}$, REE and trace elemental characteristics in the Bay of Bengal sediments are highly variable and depend on the source and pathways of sediments.

Interrelations between Fe(II)/Fe(III) and U(IV)/U(VI) redox couples

T. BEHRENS AND P. VAN CAPELLEN
Faculty of Geosciences, Department of Earth Sciences – Geochemistry, Utrecht University, Utrecht, The Netherlands (behrens@geo.uu.nl)

The mobility of uranium in natural environments is strongly affected by changes in its redox state. Reduction of U(VI) to U(IV) typically leads to an immobilization of uranium due to the low solubility of U(IV) minerals such as uraninite. Hence, initiating uranium reduction by stimulating microbial iron reduction has been proposed as a remediation strategy for aquifers contaminated with U(VI). Indications for U(VI) reduction concomitant to dissipative iron reduction have been obtained in several studies. Uranium might become directly reduced by iron reducing bacteria or indirectly by microbially produced Fe(II). It has been demonstrated that Fe(II) containing iron minerals such as magnetite and green-rust or Fe(II) adsorbed onto iron oxide surface can act as reductants for U(VI). However, also the oxidation of U(IV) by iron oxides has been reported. Consequently, it seems that both, uranium reduction and oxidation, can be coupled to Fe(II)/Fe(III) redox transformations. Here we want to discuss possible reasons for these apparently contradictory observations. Thermodynamic considerations show that the energetically favourable direction of a coupled U-Fe redox reaction depends on U and Fe concentrations and their speciation in the system. In addition to the speciation in solution, the thermodynamic stabilities of the solid phases, which are involved in the reactions, are of great importance. In particular, reduction of U(VI) becomes less favourable if the U$^{4+}$ activity is not controlled by the solubility of crystalline uraninite but by an U(IV) phase with higher solubility.

In a series of biotic and abiotic incubation experiments involving the metal reducing organism *Shewanella putrefaciens* and nanoparticulate hematite occurrence and extent of uranium reduction was investigated. Results from X-ray absorption spectroscopy reveal that, in the presence of hematite, U(VI) was not or only partially reduced. We propose that formation of crystalline uraninite is hindered in the experiments and by this complete reduction of U(VI) is inhibited. This hypothesis is supported by extended X-ray absorption fine structure (EXAFS) analyses which indicate that uraninite is not the primary product of microbial U(VI) reduction. Microbially produced U(IV) is either bound in an amorphous precipitate or remains adsorbed at the bacterial cell wall. It was further found that reoxidation of “labile” U(IV) by addition of hematite is possible. Occurrence or inhibition of uraninite formation might therefore explain the contradictory observations regarding the coupling of U and Fe redox reactions. That is, oxidation of U(IV) by iron oxides is feasible and only partial reduction of U(VI) can be achieved when uraninite formation is inhibited.
Argon and water diffusion in water-poor silicate glasses

HARALD BEHRENS

Institut für Mineralogie, Leibniz University of Hannover,
Callinstr. 3, D-30167 Hannover, Germany
(h.behrens@mineralogie.uni-hannover.de)

Knowledge on volatile diffusion is crucial for understanding the degassing behaviour of silicate melts as well as for understanding corrosion of glasses. H₂O is commonly the most abundant volatile in magmatic systems but it plays an important role in glass manufacturing as well. Argon diffusion is of particular interest because the diffusivity of argon is similar to that of molecular CO₂. Comparison of argon and water diffusion gives insights into the diffusion mechanisms of volatiles in general. At low concentrations H₂O dissolves as OH groups in silicate melts/glasses while argon acts as an inert species.

Here we report new experimental studies on Ar and H₂O diffusion in silicate and aluminosilicate glasses. The major objective of the work was to evaluate compositional effects on diffusion. Experiments were performed in cold seal gas pressure vessel using argon as the pressure medium. Polished glass wafers of water-poor, air-melted glasses (typical size 4 x 3 x 2 mm) were wrapped into Au foil so that the samples were directly exposed to the pressure medium. Water is usually present as impurity in the gas at per mill concentration. Thus during the experiment both H₂O and Ar diffuse into the samples. After the experiment, a section was cut perpendicular to the polished surface. Ar profiles were measured on the polished section by electron microprobe, H₂O profiles were analyzed using IR microspectroscopy. Surface concentrations in aluminosilicate glass are typically 0.13 -0.20 wt% Ar and 0.1 – 0.2 wt% H₂O at 200 MPa. Ar profiles are always described well with an error function while some of the H₂O profiles show a slightly convex shape. Deviation from ideal diffusion profiles in case of H₂O may be due to temporary changes in water content in the pressure medium and/or to increasing water diffusivity with increasing water content.

In silica glasses Ar diffusivity (D_Ar in m²/s) decreases by a factor of 1.5 from water-rich Suprasil (450 ppmwt H₂O) to water-poor Infrasil (<10 ppmwt% H₂O) emphasizing the role of dissolved water on noble gas diffusion. In alkali aluminosilicate glasses Arg diffusion is typically faster than in silica glass, but the diffusivity depends strongly on Al/(Na + K) ratio (ASI). For example at 705°C, 200 MPa log D_Ar increases from -14.1 for ASI=0.5 over -13.5 for ASI=1.0 to -13.1 for ASI=1.5. Incorporation of alkaline earth elements in aluminosilicate glasses reduces strongly the mobility of argon. At 620°C, 200 MPa D_Ar is two orders of magnitude smaller in an Ca:Mg bearing aluminosilicate (andesite) than in a pure alkali aluminosilicate (rhyolite). Water diffusion in alkali aluminosilicate glasses is one order of magnitude slower than argon diffusion at 500°C but due to lower activation energy only 0.2 log units slower at 800°C.
Li isotope studies of mantle-derived olivine by SIMS

DAVID R. BELL1, RICHARD L. HERVIG2 AND PETER R. BUSECK3

1Department of Chemistry & Biochemistry and School of Earth and Space Exploration, Arizona State University, Tempe AZ 85287-1604, USA (David.R.Bell@asu.edu)
2School of Earth and Space Exploration, Arizona State University, Tempe AZ 85287-1604, USA (Hervig@asu.edu)
3Department of Chemistry & Biochemistry and School of Earth and Space Exploration, Arizona State University, Tempe AZ 85287-1604, USA (pbuseck@asu.edu)

We report Li isotope variations analyzed by SIMS in olivine from terrestrial mantle xenoliths and mantle-derived magmas. The dependence of the δLi measured by SIMS on olivine composition was calibrated for compositions between Fo94 and Fo74 and amounts to 1.3 ‰ per Fo unit. Separated olivine grains were analyzed in epoxy mounts on the Cameca IMS-3f and IMS-6f SIMS at ASU. Precision of individual analyses including sample and standard uncertainties is typically ~1.5 - 3‰ (2σ).

Samples include spinel- and garnet-peridotites from Archean and Proterozoic mantle, pyroxenites, olivine megacrusts from kimberlites, and olivine phenocrysts in Hawaiian basalts. Samples display varying degrees of isotopic heterogeneity, from homogeneous δLi compositions with or without minor variations at grain margins, to large internal variations up to 16‰ within individual xenoliths. Significant variability may also occur among petrologically related samples that appear internally homogeneous.

Southern African low-temperature garnet peridotites display a range in δLi = -0.8 to +8.9 ‰. An orthopyroxenite has δLi at the high end of this range. The majority of Archean peridotites from Siberia display a relatively restricted range (mean δLi = 2.9 ± 3‰, 2σ, n=9) with minor internal heterogeneity, but exceptional xenoliths are isotopically heterogeneous with grains, or portions of grains extending to ~14‰. Fertile spinel lherzolites from SW USA including hydrous xenoliths from the Colorado Plateau appear relatively homogenous in δLi, with minor intra-grain isotopic zonation. In contrast, refractory peridotites from San Carlos, AZ display excursions up to +27‰, with strong intra-mineral zonation. Megacrusts from South African kimberlites, interpreted as melt-rock reaction products, have internal variations up to 10‰. Hawaiian phenocryst olivines and dunite xenoliths display internal heterogeneity up to ~6‰.

3Li/4Li fractionation during magmatic and metasomatic processes limits the use of Li isotopes as a tracer of crustal components in mantle-derived samples. However, with appropriate calibration of 3Li and 4Li diffusivities, the spatial and inter-mineral distribution of Li isotope variations can provide quantitative constraints on the kinetics of mantle and magmatic processes.

Experimental shock decomposition of siderite and the origin of magnetite in Martian Meteorite ALH84001

M.S. BELL1,2

1Geosciences Department, The University of Houston, Houston, Texas 77204
2Jacobs @NASA/Johnson Space Center, Bldg. 31, Room 222, Mail Code KT, Houston, TX 77058 (mary.sue.bell1@jsc.nasa.gov)

Methods

Shock recovery experiments to determine whether magnetite could be produced by the decomposition of iron-carbonate were initiated. Naturally occurring siderite was first characterized by electron microprobe, transmission electron microscopy (TEM), Mossbauer spectroscopy, and magnetic susceptibility measurements to be sure that the starting material did not contain detectable magnetite. Samples were shocked in tungsten-alloy holders (W=90%, Ni=6%, Cu=4%) to further insure that any iron phases in the shock products were contributed by the siderite rather than the sample holder. Each sample was shocked to a specific pressure between 30 to 49 GPa.

Discussion of results

Transformation of siderite to magnetite as characterized by TEM was found in the 49 GPa shock experiment. Compositions of most magnetites are > 50% Fe2+ in the octahedral site of the inverse spinel structure. Magnetites produced in shock experiments display the same range of single-domain, superparamagnetic sizes (~50 to 100nm), compositions (100% magnetite to 80% magnetite - 20% magnesioferrite), and morphologies (equant, elongated, euhedral to subhedral) as magnetites synthesized by Golden et al. (2001) or magnetites grown naturally by MV1 magnetotactic bacteria, and as the magnetites in Martian meteorite ALH84001. Fritz et al. (2005) previously concluded that ALH84001 experienced ~32 GPa pressure and a resultant thermal pulse of ~100-110°C. However, ALH84001 contains evidence of local temperature excursions high enough to melt feldspar, pyroxene, and a silica-rich phase.

Conclusions

This 49 GPa experiment demonstrates that magnetite can be produced by the shock decomposition of siderite as a result of local heating to > 470°C. Therefore, magnetite in the rims of carbonates in Martian meteorite ALH84001 could be a product of shock devolatilization of siderite as well.

A new metallophore for the nitrogen fixing bacteria *Azotobacter vinelandii*

JEAN-PHILIPPE BELLENGER, THOMAS WICHARD AND ANNE M.L. KRAEPIEL

Department of Geosciences (P.E.I), Guyot Hall, Princeton University, NJ 08544 USA

Nitrogen fixation, which is responsible for the natural input of new nitrogen into ecosystems, is performed by *N₂*-fixing bacteria using the enzyme nitrogenase. The Mo-nitrogenase is the most common and efficient form of the enzyme, but a V and a Fe-only nitrogenases, that are expressed when Mo is unavailable, have also been reported. The acquisition of Fe, Mo and V is thus essential for diazotrophic growth. The nitrogen fixing soil bacteria *A. vinelandii* excretes small organic ligands (siderophores) that bind Fe and increase its bioavailability [2-3]. Recently we reported that azotochelin, a bis(catechol) siderophore produced by *A. vinelandii* binds V(V) with a high affinity [1].

Here, we show that diazotrophic cultures of *A. vinelandii* use azotochelin as a vanadium carrier ("vanadophore") when Mo is limiting. Larger amounts of azatochelin (compared to other catechol compounds) are excreted in the growth medium when V is used for *N₂* fixation. The V-azotochelin complex is taken up by the bacteria via a specific transport system that doesn’t recognize other V-complexes (see Figure). Further, azatochelin can remove V from an unavailable DFB complex, resulting in an increase of uptake (see Figure). The transporter for V-azotochelin is regulated and shuts down at high (toxic) V concentrations.

Vanadium is the one of the first oxoanions, and the only transition metal with iron and copper, shown to have a high affinity uptake system involving a metallophore.

![Graph showing short term uptake of V](image)

Short term uptake of V (4 \(10^{-8}\) M V₅, 3.10⁻⁴M DFB (desferrioxamine B)) by *A. vinelandii* (CA 11.70). 10⁻⁴M azotochelin were added after 31 minutes.

Mantle rocks of Voykar ophiolites could be subdivided into residual harzburgites (age over 2 Ga), dunites representing channels for migrating melts (Kelemen et al, 1995) and pyroxenite veins (age 0.6 Ga). Clinopyroxene (CPX) presents in all these rocks and it’s trace element composition could give an information about migrating melt composition (represented by interstitial CPX in dunites), degree of melting and subsequent modification by percolating melts of residual harzburgite (CPX in harzburgites). Also CPX composition may shed light on the mechanism of pyroxenite veins formation.

We have analyzed CPX from 9 harzburgites, 13 dunites and 13 pyroxenites using LA ICP MS at Max Plank Institute for Chemistry. The most uniform compositions are displayed by CPX from pyroxenites yielding subparallel patterns of incompatible elements at primitive mantle normalized spider diagram. They show clear supra subduction zone signatures - HFSE (e.g. Nb and Zr) depletion and relative LILE (e.g. Sr) enrichment, representing therefore late stage supra-subductional melts and/or fluids. Such conclusion is confirmed by presence of magmatic amphibole in several samples of pyroxenites testifying presence of magmatic water. The better estimates of melt compositions thus require measuring of water contents in those amphiboles due to severe influence of water on crystal-melt partitioning coefficients (Sobolev et al, 1996, Wood et al, 2002).

CPX from harzburgites also display subparallel trends in MREE-HREE part of spectrum, but their LREE concentrations display different degrees of modification by percolating melts (e.g. Batanova et al, 1998). CPX from dunites have the widest ranges of LREE/HREE ratios representing melts ranging from N-MORB-like melts to highly depleted in LREE melts which experienced reaction with large volume of residual rocks.

Data on olivine compositions still has to be evaluated.

Nickel sorption on chalk and calcite
D.A. BELOVA1,3, L.Z. LAKSHTANOV1,2 AND S.L.S. STIPP1
1NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen Ø, Denmark. (apolinaria@list.ru; stipp@geol.ku.dk)
2Institute of Experimental Mineralogy RAS, 142432 Chernogolovka, Russia. (leonid@iem.ac.ru)
3Institute of Geology Karelian Research Center of RAS, Pushkinskaja 11, 185610 Petrozavodsk, Russia.

Heavy metal retention in aquifers is controlled by sorption on aquifer material. Processes such as precipitation, incorporation and solution complexation also influence retardation, but in all cases, sorption plays a role. At natural or slightly polluted levels, it may be the predominant immobilization process. In several countries, such as those bordering the North Sea, drinking water comes from chalk (>90% calcite, CaCO₃). Nickel contamination can arise from industrial spills, waste disposal leaching, and in some cases [1], from the weathering of pyrite, where Ni is present in solid solution. However, little is known about sorption of Ni or other heavy metals onto chalk as an aquifer material.

We examined sorption on two types of natural chalk and compared it to the behaviour of synthetic calcite. Our purpose was to produce data for safety assessment and more effective remediation strategies. Batch experiments were performed at 25°C with atmospheric CO₂ partial pressure, in calcite equilibrated solutions, in the pH range 7.6 to 8.8.

Nickel sorption on calcite as well as chalk followed the same pattern observed for other divalent cations, namely:
1. At constant pH, Ni sorption was well-described by a Freundlich-type isotherm.
2. Adsorption increases with higher pH in the equilibrium suspension, higher surface area and decreasing adsorbate concentration. This is more consistent with Ni²⁺ exchange on surface sites than with coprecipitation.

Experimentally determined chalk Kd values (L/kg) correlate linearly with pH (as log Kd). Variability over about one order of magnitude disappears when surface area (L/m²) is taken into account: log Kd = (1.55 ± 0.17) pH – (14.2 ± 1.3). Such behaviour confirms the similarity of sorption properties for chalks and calcite, which is its main constituent.

Kd values can be related to migration velocity (i.e. relative to pore water flow) by the retardation factor R. With this new Kd, a Ni retardation factor for chalk was determined to be R = 130 and 9 at pH 8 and 7, respectively. This means that sorption onto chalk can significantly decrease Ni mobility, even in aquifers with low clay and organic matter content. Only at pH below 6, where calcite is dissolving, does Ni move substantially in chalk aquifers.

New evidences for existence of early Archaean terrains within Enderby Land, Antarctica
B.V. BEL'YATSKY1, N. RODIONOV2, G.L. LEITCHENKOV1 AND S.A. SERGEEN2
1VNIOkeangeologia, St.Petersburg, Russia
2VSEGEI, St.Petersburg, Russia (bbelyatsky@mail.ru)

Enderby Land is known as the oldest terrain of the Earth with age estimations ≥4 Ga (Sobotovich et al., 1974). Further study of different geological objects at the Enderby Land proved, from one hand, the unique age of this crust segment (DePaolo et al., 1982; Black et al., 1986) and, from the other hand, the unique thermodynamic conditions of accompanying evolution of these rocks (>1000°C) (Sheraton et al., 1987; Harley, Motoyoshi, 2000). As it had been demonstrated in the first studies of zircons from orthogneiss of Sones Mountain (Williams et al., 1984), in such cases we may face very local heterogeneity of zircon grains. It could be caused by their age and complicated reaction of zircon crystalline structure to the condition of ultra-high temperature metamorphism, which is marked twice during the existence of Napier Complex and disturbed all other isotope systems (McCulluch, Black, 1984; Black, 1988). This results in obtaining discordant ages in a rather wide range along U-Pb concordia which may not reflect the real geological events (Harley, Black, 1997).

Zircons from charnockite-enderbite rocks (Aker Peaks, Napier Mountains), which we have dated by SHRIMP-II, were analyzed earlier by conventional multigrain U-Pb ID-TIMS method (Belyatsky et al., 1990), but did not reveal age concordancy and colinearity. Our study demonstrates that the most optimal way to evaluate geologic events is the preliminary complex examination of zircons (CL, BSE, REE composition) and outline of cogenetic groups which allow to use traditional approach to age estimation through discordia construction. This approach has resulted in obtaining, at the first time, the reliable age of magmatic crystallization for enderbites – 3620±30 Ma and the age of primary enderbite’s protolith origin – 3950–3970 Ma. While some previously estimated younger ages of 2850–3050 Ma, which are considered as main metamorphic events of granulite facies for the whole Enderby Land (Harley, Black, 1997; Kelly, Harley, 2005), are absent in the studied zircons. At the same time in all dated zircons the metamorphic event of 2450–2480 Ma ago is clearly recorded and it is in agreement with the granulite facies metamorphism described by many authors. It is necessary to note, that zircons also are free of 1000–1200 Ma record in spite the extensive Proterozoic metamorphism dated by Harley, Black, 1988). These conclusions coinside with Sm-Nd isotope systematics of the enderbites: whole-rock (n=12) isochron corresponds to the age 3660±170 Ma and ε≥+0.7, with mineral isochrons show age of metamorphic event – 2440–2490 Ma. In general, it evidences to cratonization of the Napier Complex at about 2450–2480 Ma ago.

This study was supported by RFBR grant 07-05-00736a.
Jetting and frictional melting in impactites

C. Bender Koch
Department of Natural Sciences, Faculty of Life Sciences, University of Copenhagen (cbk@life.ku.dk)

The almost instantaneously pressure drop that occurs in the atmosphere following an impact leaves a vesicular rock of variable strength and considerably overpressure (> $10^5$ bar).
This pressure may potentially rupture the rock completely, but in a situation where part of the rock possess sufficiently strength the gas will flow from vesicle to vesicle, rupturing the vesicle walls and creating orifices. The gas flow may reach a jet-like condition with e.g. unstable flow and friction may partially remelt the vesicle walls.

Frictional melting may also occur by movement of the impactite body in the impact cloud causing the formation of melts on the exterior surfaces of the impactite.

In this study we demonstrate similarities and differences between the two types of glasses from SEM studies.

Modelling metal speciation in aquatic systems

Marc F. Benedetti
Laboratoire de Géochimie des Eaux, Université Paris Diderot – IPGP, 2 place Jussieu, 75251 Paris Cedex, France

Nowadays, environmental problems related to aquatic pollution with heavy metals are numerous, therefore, it is important to understand metals behaviour in aquatic environments and to appreciate their transfer to the biota. The fate of the metals in the environment and especially their bioavailability is closely related to their interactions with the major reactive compartments (organic matter, iron and manganese oxides, clays). The objective of this work is to develop an approach based on the combination of several model to study metal ion speciation in different environmental systems. Models used to describe the interactions of metals with the main reactive phases in aquatic systems are CD-MUSIC (amorphous and crystallized iron oxides), NICA-Donnan (organic matter and manganese oxides), cationic ion exchange model (clays). First, this work implies the definition of generic parameters to describe the interactions of the studied metals with specific fractions of natural organic matter (i.e. exopolymers, alginic acids), iron and manganese oxides, a part of this information is missing in the literature. Then, after the validation of the approach by comparison with analytical results, this multi-surface model is applied to test sites corresponding to riverine environments.

These new models give good predictions of the behaviour of major and trace metal ions (Ca, Fe, U...) even in heterogeneous systems characteristic of the natural environment. The measured free metal concentrations in the solution are in agreement with those obtained from model calculations. In the case of bioavailability test experiments, the results are predicted with the natural organic matter constituents characteristics and and in fairly reasonable agreement with the experimental data.
Surface complexation and proton promoted dissolution in aqueous apatite systems

ÅSA BENGTSSON, PER PERSSON, ANDREI SHCHUKAREV AND STAFFAN SJÖBERG

Department of Chemistry, Umeå University, S-90187 Umeå, Sweden (Asa.Bengtsson@chem.umu.se; Per.Persson@chem.umu.se; Andrei.Shchukarev@chem.umu.se; Staffan.Sjoberg@chem.umu.se)

Apatites (Ca$_5$(PO$_4$)$_3$F,Cl,OH) are the most abundant phosphorus-bearing minerals in nature and they are very important in agriculture as phosphorus containing fertilisers, as well as in medicine as main constituents of mammalian bones and teeth enamel.

The surface chemistry, in terms of surface complexation models, of these minerals is very much unexplored, and the dissolution mechanism is still debated. The objectives with our apatite studies are to characterize possible surface phase transformations and to clarify surface acid/base properties, ion exchange and readsorption reactions involving phosphate and calcium. Furthermore, ligand complexation reactions of these apatites with different organic polycarboxylic acids are also being studied. Studies are being made in pH ranges with/without extensive dissolution.

The strategy in modelling surface complexation and dissolution of apatite is to yield information provided by different macroscopic techniques: i) potentiometric pH and pF measurements; ii) dissolution characterization with respect to soluble fractions of calcium, phosphate and fluoride; iii) readsorption studies of phosphate, fluoride and calcium, as well as iv) surface charge measurements. Furthermore, this information is combined with surface spectroscopic characterizations using FTIR and XPS methods.

Crust-mantle dynamics in the early Earth: The 142-143Nd and 176Hf isotopic perspective

V. BENNETT$^1$, A. BRANDON$^2$, J. HEISS$^1$ AND A. NUTMAN$^3$

$^1$Research School of Earth Sciences, The Australian National University (vickie.bennett@anu.edu.au)
$^2$NASA Johnson Space Center, Houston, TX, USA
$^3$Chinese Academy of Geological Sciences, Beijing, China

New high precision isotopic data for 3.6 Ga to 3.87 Ga rocks from southwest Greenland and Western Australia show $^{142}$Nd excesses (formed by the decay of now extinct $^{146}$Sm [$t_{1/2}=103$ myr]) of 4 to 20 ppm compared to modern terrestrial compositions and 22-38 ppm with respect to primitive meteorites [e.g. 1]. Combined data from the same samples for the short-lived [146Sm-142Nd] and long-lived [147Sm-143Nd] decay schemes directly date the formation of chemically distinct silicate reservoirs during the first 30-50 myr of Earth history, near the time of core segregation. Differences in 142Nd signatures from coeval rocks from the two most extensive early Archean cratons reveal large-scale chemical dichotomies in the Earth’s mantle that persisted for at least the first billion years of Earth history. Temporal variations in $^{142}$Nd signatures track the subsequent incomplete remixing of these very early-formed mantle chemical domains.

Initial Hf isotopic compositions from zircons from the same samples yielding positive $^{142}$Nd anomalies are all within error of chondritic values (using $\lambda$ = 1.867 x 10$^{-11}$yr$^{-1}$). The $^{142-143}$Nd and initial $^{176}$Hf isotopic compositions of Archean rocks define the time-averaged Lu/Hf and Sm/Nd of their mantle source regions. Generation of positive $^{142}$Nd anomalies as well as $\varepsilon^{143}$Nd $\approx +3$ in 3.85 Ga samples, requires an early formed high Sm/Nd reservoir. In contrast, the near chondritic initial $^{176}$Hf/$^{177}$Hf compositions from the same early Archean samples indicate a source with a long-term chondritic Lu/Hf ratio. Thus the trace element pattern of the pre-3.85 Ga depleted mantle differs from the MORB source mantle, which is characterized by both supra-chondritic Lu/Hf and Sm/Nd. Significantly this suggests that typical continental crust with low Lu/Hf and Sm/Nd ratios is not the primary complimentary enriched reservoir to the early depleted mantle. Rather these observations support models for very early (30-60 myr after T$_0$) silicate differentiation of the Earth [e.g. 2] unrelated to early continental crust formation. Although >4.0 Ga zircons, including those from the Jack Hills, Western Australia, provide evidence that some Hadean continental crust was present, it may have been of only limited extent.

Thermochronological evidence for long-term elevated geothermal gradients in Ribeira Belt, SE Brazil

T. BENTO DOS SANTOS1; J. MUNHÁ1; C. TASSINARI2, P. FONSECA3 AND C. DIAS NETO2

1Centro/Departamento de Geologia, Universidade de Lisboa, Portugal (tmsantos@fc.fc.ul.pt; jmunha@fc.fc.ul.pt)
2Instituto de Geociências, Universidade de São Paulo, Brazil (ccgtassi@usp.br; coridias@usp.br)
3LATTEX, Universidade de Lisboa, Portugal (gpetfons@fc.fc.ul.pt)

This study addresses petrological/thermochronological relations in the São Fidelis-Santo António de Pádua (SFSAP - N Rio de Janeiro State, Brazil) sector of the central segment of the Neoproterozoic collisional Ribeira Belt. SFSAP mainly comprises granitoid (orthogneissic) rocks, migmatites and granulites/charnockites. Following the earlier collisional stage at 630-600 Ma, main (thrusting) regional deformation was coeval with peak metamorphism (850 ± 50º C, 8.0 ± 1.0 kbar), lower crustal melting and widespread charnockite development at 565 ± 8.0 Ma (U/Pb-zircon); further high-grade metamorphism evolved (at P ≥ 4 kbar) to ~ 600º C, being followed by decompression and retrogradation (~ 350º C) during long-term transpressional shearing at the late stages of the Braziliano Orogeny (Biotite-WR Rb/Sr age = 455 ± 4.0 Ma). The overall average cooling rate was low (< 5º C / Ma from 850 to 350º C), but distinct cooling paths indicate differential uplift and complex mechanical/kinematics interactions among the distinct lithotypes. Although migmatites show a globally stable 3º C / Ma cooling rate, most charnockites remained at T > 650º C until 510 - 470 Ma (Garnet-WR Sm/Nd), being then rapidly exhumed/cooled (~ 30º C / Ma) during post-orogenic granite emplacement in the area at 491 ± 7.1 Ma (U/Pb-zircon). Both charnockite thermal evolution and extensive production of granitoid melts imply that high geothermal gradients must have been sustained for a long period of time (50 – 100 Ma) in the studied area. Crustal geotherms are sensitive to both mantle heat-flux input and the amount/distribution of heat producing elements (HPE). Collisional active mountain building should have been followed by gravitational collapse of the orogen, induced by thermal erosion and progressive thinning of the lithosphere. The timing for the onset of the resulting thermal anomaly seems to have started at ca. 570 - 550 Ma and reflect initial upwelling of asthenospheric mantle and magma underplating along the main axis of the Ribeira orogenic belt. This, coupled with long-term generation of (high-HPE) granitoids, should have sustained elevated crustal geotherms (relative to the pre-granite conductive geothermal regime) for almost 100 Ma, promoting widespread charnockitization at middle to lower crustal levels.

From planetesimals to planetary embryos

WILLY BENZ

Physikalisches Institut, University of Bern, Switzerland

We investigate the collisional growth of planetesimals by means of numerical simulations using an orbit-averaged Monte Carlo approach (Nyffenegger 2005) originally proposed by Hénon for the study of stellar clusters. Such an approach is situated between explicit N-body and statistical methods. Similar to statistical treatments, we assume an overall potential to determine the general motion of the bodies. Perturbations to this motion are then caused by local interactions between the bodies (collisions, close encounters, etc.) which account for the stochastic nature of the system. In this respect, the Monte Carlo technique resembles the N-body method but it allows the use of a much large number of bodies. In addition and again similarly to N-body simulations, the tracking of individual bodies over time is easily done. Therefore, the entire collisional history of planetary embryos can be reconstructed.

After presenting some tests of the method, we shall focus on the collisional evolution of a swarm of planetesimals in the terrestrial planet region. We derive some important characteristics of this evolution such as the typical formation time, collision frequency, impactor mass, etc. We then discuss the implications of these quantities focusing in particular on planetary differentiation and the constraints placed by the extra-solar planets.

4Surface & Aqueous Geochemistry Group, Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305-2115, USA.

Bulk chemical and mineralogical data (bulk XANES, EXAFS and XRD) showed that indigenous bacteria living in the As-rich Carnoules Acid Mine Drainage ([As] = up to 350 mg.l-1) play an important role in the nature and composition of the solid phases that sequester arsenic at the site: some bacteria oxidize Fe(II) but not As(III) and promote the precipitation of a rare ferric arsenite sulfate oxy-hydroxide mineral, called tooeleite (Morin et al. 2006), while other bacterial species catalyze As(III) to As(V) oxidation leading to the formation of amorphous As(V) rich ferric oxy-hydroxides (Morin and Calas 2006).

In order to better document the interactions between microbes and Fe and As redox processes in the Carnoules AMD, we combined Scanning Transmission X-ray Microscopy (STXM) and Transmission Electron Microscopy (TEM) to collect near-edge x-ray absorption fine structure spectra (NEXAFS) at high spatial and energy resolution and to perform high resolution imaging at the submicrometer scale, following procedures described previously (Benzerara et al., 2006). Spectromicroscopy was performed at the C K-edge, Fe L2,3-edge, and As L2,3-edge offering the possibility to locate living and/or mineralized bacterial cells and to characterize Fe and As oxidation states in the vicinity of those cells. Many precipitates were found associated with extracellular organic polymers. Moreover, some As-Fe precipitate show a vesicular appearance that we interpret as microbial cell’s products. TEM was used to image the same areas, providing higher resolution images and complementary crystallographic and chemical information through electron diffraction and EDX analysis. This approach offers a unique opportunity to assess at the submicrometer scale the various and heterogeneous geochemical activities of complex microbial communities in acidic environments.

Sedimentary phosphorus speciation and its relation to the CNS and bottom water in an estuary influenced by anthropic activities

G.B.B. BERBEL1, M. RODRIGUES2, M.M. MAHIQUES2 AND E.S. BRAGA1

1Laboratório de Nutrientes (LABNUT) (glaucoberbel@uol.com.br; edsbraga@usp.br)
2Laboratório de Análise de Matéria Orgânica (LMO)
Instituto Oceanográfico –Universidade de São Paulo- Brazil

Phosphorus element plays a key role on the biogeochemical cycles in estuaries. Phosphorus is one of principal nutrients to the organic matter production in the aquatic system and its excess contribute to eutrophization process. This study focus on the sedimentary phosphorus speciation in the Santos Estuary, a strongly impacted coastal area located at São Paulo State – Brazil, where accommodates the largest harbour of Latin America with an important industrial pole which include 5 fertilizer industries, urbain poles with represenative domestic wastes and some mangrove vegetation along the system. During the summer period, the tourism activities contribute to the nutrient inputs to the aquatic environment. In this study, the sedimentary concentrations of bioavailable-P (P-bio) varied from 1.78 to 9.36 µmol g⁻¹, iron oxyhydroxides-P (P-Fe), from 1.09 to 37.68 µmol g⁻¹, authigenic-P (P-auth), from 0.37 to 10.64 µmol g⁻¹, fluorapatite-P (P-FAP) varied from 0.94 to 7.21 µmol g⁻¹ and organic-P (P org) varied from 0.37 to 10.50 µmol g⁻¹. The organic carbon (Corg) varied from 0.14 to 6.26 %, total nitrogen (TN) varied from 0.01 to 0.55 %, total sulfur (TS) varied from 0.01 to 2.11 % with high concentrations in the internal part of the port channel decreasing in direction to the Santos’ Bay. The TN and TS were highly correlated with C org and P org (r > 0.87, p<0.01), indicating that S org is the second pool of reduced S in the sediments, after S content associated to pyrite. Organic speciation of C, N, S and P were higher during the winter, while the inorganic ones were higher during the summer, due to the different intensities of mineralization process in these two marked seasonal periods at this region. In general, the sedimentary parameters show high positive correlations with the bottom hydrochemical characteristics as observed for dissolved inorganic phosphorus (DIP) (r > 0.77, p<0.01). There was negative correlations with dissolved oxygen (r = -0.69, p <0.01) in relation to sedimentary parameters. The sedimentary sulphur concentration increased when the water reduced conditions were present in the environment as occurred during the summer, facilitating the phosphorus liberation. On the other hand, there were significative percentages of P-Fe (around 40-53 %) in relation to total P and this is correlated to the C/N and C/S. The C/N (>6) and C/S (> 10) molar ratios showed that the continental organic matter input probably had high content of humic substances that could be sequestrate iron oxyhydroxides bound phosphorus.
Archaean evolution of the Okhotsk terrane by U/Pb zircon chronology

Centre of Isotopic Research, VSEGEI, St.-Petersburg, Russia (cir@vsegei.ru)

Okhotsk terrane (NE Russia) is a most aged segment of the Pacific mobile belt. The Kukhtuy domain, the largest (45x120 km) part of this terrane, mainly consists of polymetamorphic basalt-dacite series and metasediments, covered by Riphean and Paleozoic sediments.

For revealing the succession of geological processes we studied accessory zircons from four typical rock units: hypersthene-plagioclase granulite schist (HPS), garnet-hypersthene-plagioclase granulite schist (GHPS) – from Maymecha area and garnet-biotite gneiss (GBG), wall-rock for biotite granite-gneiss (BGG) – from Khorundzha area. Before U/Pb SIMS SHRIMP dating, zircons were subdivided into morphotype groups. The U/Pb ages are in Table.

The following evolutionary succession is proposed for the Kukhtuy domain, Okhotsk terrane, based on U/Pb age data, zircon REE pattern, geochemistry, fluid (FI) and melt (MI) inclusion study.

I. Initial mafic volcanism 3.7-3.65 Ga ago. Hf data for the same zircons: (\(^{187}\text{Hf}/^{187}\text{Hf}) = 0.280575 ± 0.00005, ε\(^{187}\text{Hf}(t) = +3.4\) show non-depleted magma source and 3.7-Ga protolith-mantle separation. II. First granite facies metamorphic (ultrametamorphic) event, 3.58-3.52 Ga ago. III. Second granite metamorphic event (3.48-3.46 Ga). IV. Third granite ultra-

Combining in situ isotope dating, petrology, and tectonic observations to infer rates of regional metamorphism

ALFONS BERGER¹, EMILIE JANOTS¹, MARTIN ENGI¹ AND DANIELA RUBATTO²

¹Institut für Geologie, Universität Bern, Switzerland, (berger@geo.unibe.ch; ejanots@geo.unibe.ch; engi@geo.unibe.ch)
²ANU; Research Schol of Earthscience; Canberra, Australia, daniela.rubatto@anu.edu.au

The determination of metamorphic rates demands high precision dating of samples for which the physical conditions of formation are well constrained. For such rates to be meaningful, the tectonic evolution of the sampled units needs to be established. We derive rates of metamorphism from in-situ dating of structurally controlled REE minerals combined with field observations in the Central Alps to gain insight into geodynamic rates.

In metamorphites, the sequence of REE minerals reveals a series of irreversible reactions among silicates and phosphates. At diagenetic and low metamorphic conditions, detrital and newly formed monazite grains occur. Around 450°C, monazite disappears to form allanite, which is oriented in the main foliation. At temperatures >570°C, allanite is replaced by monazite, which grows after the development of the main foliation Sₘₜ. Garnet also overgrows Sₘₜ but predates monazite. These observations hold information on different processes: (1) collision and tectonic thickening, (2) regional heating, and (3) post-collisional folding. Th-Pb and U-Pb dating of allanite and monazite yields ages of 31.5±1.3 Ma and 18.0±0.1 Ma, respectively. Considering that the difference of 13.5 Ma between the two ages represents the T-interval from 450°C to 570°C, the average heating rate is 8-10°/Ma.

This rate may relate to a combination of processes, involving at first substantial tectonic transport (advecive heating dominant). This stage is followed by a period of minor tectonic transport, post nappe folding and thermal relaxation, when conductive heat transport dominates.

Tectono-thermal modeling (2D FEM) yields similar heating rates for units in front of the nappe stack, which is being exhumed owing to erosion and tectonic unroofing. Late orogenic heating during decompression lead to the thermal maximum in this external portion of the orogen 18-15 Ma ago, at a later stage than in the internal segment of the Central Alps (~30-22 Ma ago just north of the Insubric Line). In the latter part of the orogen, the metamorphic rates are largely dominated by advection due to tectonic extrusion of thrust sheets, i.e. units previously subducted. In the external parts of the Leptontine dome, the thermal field and metamorphic patterns evolved later, and rates reflect the heating followed by rapid cooling during orogenic exhumation.
Mass-dependent and mass-independent fractionation of Hg isotopes in aquatic systems

B.A. BERGQUIST AND J.D. BLUM
Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109 (bbergqui@umich.edu)

Mercury is a globally distributed and highly toxic pollutant, the mobility and bioaccumulation of which is dependent on its redox cycling. Hg isotope analysis by MC-ICPMS is an important new tool for identifying Hg sources and tracking Hg transformations in the environment (Smith et al., 2005; Jackson et al., 2006; Bergquist et al., 2006; Kritee et al., 2007), with most measured natural samples displaying mass-dependent isotope fractionation (MDF). A small body of data suggests that natural samples also display mass-independent isotope fractionation (MIF) of the odd Hg isotopes (Jackson et al., 2006; Bergquist et al., 2006).

Reduction of Hg species to Hg(0) vapor is an important pathway for removal of Hg from aqueous systems into the atmosphere and occurs by abiotic and biotic mechanisms. In laboratory experiments, we find that photochemical reduction of both Hg$^{2+}$ and CH$_3$Hg$^+$ by natural sunlight leads to large MIF of the odd isotopes (\(^{201}\text{Hg}, \ ^{199}\text{Hg}\)) and preferential retention of the odd isotopes in the reactant (soluble) phase. Also, the relationship between MIF for the two odd isotopes of Hg is significantly different for the two photo-reduction pathways (Hg$^{2+}$ to Hg$^0$ versus CH$_3$Hg$^+$ to Hg$^0$). In contrast, both biological reduction (Kritee et al., 2006) and dark abiotic organically-mediated reduction follow MDF.

Natural samples from aquatic ecosystems preserve both MDF and MIF. In fish, MDF increases with the size and Hg concentration of the fish suggesting MDF may be useful in understanding Hg bioaccumulation (similar to $\delta^{15}$N). Fish also display a large range in MIF (4‰) with MIF always having positive values. Additionally, the relationship between MIF of the two odd isotopes in fish has a similar slope to the slope found for photo-reduction of CH$_3$Hg$^+$. Since fish bioaccumulate CH$_3$Hg$^+$, fish may be recording the extent to which CH$_3$Hg$^+$ is lost via photochemical reduction in an aquatic ecosystem. Fish populations from different locations have different MIF values, but mostly display similar MIF within a location. This suggests that MIF is preserved in the food web and could be used to quantify photo-reduction of CH$_3$Hg$^+$ of an ecosystem. Both MDF and MIF of Hg isotopes hold promise for quantifying and understanding Hg pathways and bioaccumulation in the environment.

CO$_2$-bearing fluid inclusions in upper mantle xenoliths from Tihany (western Hungary): Minimum trapping pressures and trace element compositions

MÁRTA BERKESI$^1$, CSABA SZABÓ$^1$, ROBERT J. BODNAR$^2$ AND LUCA FEDELE$^2$

$^1$Lithosphere Fluid Research Lab, Eötvös University Budapest, 1117 Pázmány P. stny. 1/C, Budapest, Hungary (marta.berkesi@gmail.com)
$^2$Department of Geosciences, Virginia Polytechnic Institute and State University, 4044 Derring Hall, Blacksburg, United States of America

Analytical Techniques
In this study, microthermometry, Raman microspectroscopy and LA-ICP-MS analysis of dense CO$_2$-rich fluid inclusions hosted in orthopyroxenes from spinel peridotite xenoliths of the subcontinental lithospheric mantle from Tihany (western Hungary) were carried out.

Discussion
Petrographically two types of fluid inclusions are distinguished. Based on microthermometry, two different density ranges were observed. The CO$_2$-densities, together with the geothermometry of the peridotites based on orthopyroxene/clinopyroxene equilibrium, suggest that the studied xenoliths represent two, physically distinct domains in the lithospheric mantle, one shallow and one deeper. Raman microspectroscopy confirms that the fluid inclusions consist mostly of pure CO$_2$, but rarely H$_2$S is also observed. For multi-element analysis in situ LA-ICP-MS was used to identify elements associated with the CO$_2$ fluid inclusions in orthopyroxene. LIL elements such as K, Ba and Rb which are incompatible to the host orthopyroxene, were found to be concentrated at the CO$_2$ inclusions.

Conclusion
Since a precise geobarometer for the spinel peridotite stability field is not available yet, the minimum trapping pressure estimation from CO$_2$ fluid inclusions provides the best method available for pressure estimation in these mantle rocks. The CO$_2$ fluid inclusions in the studied peridotites suggest ~12°C/km temperature gradient for the upper mantle 8 million years ago when the xenoliths were brought to the surface by the host basalt.

The results of LA-ICP-MS analysis suggest that the orthopyroxenes and the enclosed fluids have very different trace element compositions. These results also suggest that the CO$_2$-rich fluids are important agents for transporting incompatible trace elements in the lithospheric mantle.
Reduction of FeO-rich chondrules in Kakangari and enstatite chondrites

J. BERLIN, R.H. JONES AND A.J. BREARLEY

Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM 87131, U.S.A.
(iberlin@unm.edu, rjones@unm.edu, brearley@unm.edu)

Kakangari (K) is a unique chondrite [1] whose bulk chemical composition is similar to enstatite (EC) and ordinary chondrites (OC). However, its high matrix abundance is more comparable to carbonaceous chondrites (CC). K chondrules have oxygen isotopic compositions indistinguishable from EC chondrules [1], suggesting that there might be a genetic relationship between the chondrules in these two chondrite groups.

We studied a suite of Kakangari chondrules [2] and noticed that they are similar to EC3 chondrules [3,4] in the following aspects: (a) no typical FeO-rich type II chondrules are present, (b) most chondrules are pyroxene-rich and (c) many chondrules contain SiO2. These characteristics make K and EC chondrules more similar to each other than to OC and CC chondrules. However, there are also major differences [e.g. 5] which imply that EC chondrules formed in a more reducing environment. For example, most chondrule silicates are more Mg-rich in EC (0.1<Fa<2.8, 0.4<Fs<2.2 [3]) than in Kakangari (2.5<Fa<5.5, 3<Fs<16 [2]) and their sulfide mineralogy is different (Mg-, Mn-,Ca-bearing sulfides in EC chondrules vs. troilite only in K chondrules).

Even though no typical FeO-rich type II chondrules are present, ubiquitous FeO-rich silicates have been observed in EC chondrules [e.g. 6-8]. Their characteristics and chemical compositions are very similar to FeO-rich pyroxenes and olivines in K chondrules [2]. In both K and EC chondrules, FeO-rich silicates show clear evidence that they have undergone solid-state reduction (e.g. reverse zoning, Ni-poor metal and troilite blebs, presence of SiO2 [2,6-8]). This reduction must post-date the first chondrule forming event.

[7] proposed a multi-stage model for EC chondrules that contain FeO-rich pyroxenes. These chondrules were originally formed in an oxidizing environment and then underwent solid-state reduction in a more reducing nebular environment. Furthermore, [8] showed that oxygen isotopic compositions of FeO-rich and FeO-poor silicates in an EH3 chondrite have the same oxygen isotopic groups.

We suggest that FeO-rich K chondrules originated from similar FeO-rich precursor material and underwent a similar, but less extensive reduction event. Subsequently, the evolutionary paths of FeO-rich K and EC chondrules diverged.

In situ characterizing the structural and chemical evolution of biopolymers during advanced fossilization: From Nature to experiments

S. BERNARD1, K. BENZERARA2 AND O. BEYSSAC3

1Laboratoire de Geologie, ENS CNRS, Paris, France
(Sylvain.Bernard@ens.fr) (Beyssac@geologie.ens.fr)
2IPMC, IPG CNRS, Paris France
(benzerar@ipmc.jussieu.fr)

The Biogenic origin of fossil organic matter (OM) contained in metamorphic rocks is usually not easy to assess. Diagenetic and metamorphic processes are indeed responsible for the transformation of primary biogenic OM, leading to the loss of original chemical and structural information. However, it has been observed that morphological, textural and chemical bi-signatures might be preserved in some contexts [1]. To understand the conditions leading to such preservation, we have investigated the evolution of reference carbonaceous biocompounds (e.g. sporopollenin, lignin and cellulose) during pyrolysis using Raman and near edge x-ray absorption fine structure (NEXAFS) spectroscopy at the µm down to the nm scale. We hence describe and constitute a reference dataset for the differential evolutions of these precursors during carbonification and graphitization. Using the same techniques, we have in situ characterized, at multiple length scales, fern-related spores and vascular tissues within diageneric rocks from Alsace (France) and within high grade metamorphic rocks of the same Triassic age (230 Ma) from the western Alps (France)1. Biogenic OM as well as associated various carbonates minerals were mapped at the micrometer scale using Raman imaging. Ultrathin sections were prepared by Focused Ion Beam milling for further structural and chemical imaging of OM/minerals down to the nanometer scale with Transmission Electron Microscopy and Scanning Transmission X-ray Microscopy. In particular, the chemical nature of the carbon functional groups composing these OM and their spatial distribution were documented at a submicrometer scale using high spatial (~25 nm) and energy (~0.1 eV) resolution NEXAFS spectroscopy. Altogether, by combining microscopic and spectroscopic imaging techniques, we evidence in these samples systematic textural, chemical and mineralogical heterogeneities which are interpreted as remnants from primary biological structures. Such a multiscale characterization approach sheds new light on the fossilization processes of biogenic OM during advanced diagenesis and metamorphism, and allows for reconstructing their biological heritage which is of particular interest for the study of soft bodied fossils.

Aragonite: Crystallographically oriented fibres in eclogite-facies garnet from Corsica

S. BERNARD, O. BEYSSAC AND C. CHOPIN
ENS, CNRS, Laboratoire de Géologie, 24 rue Lhomond, 75005 Paris, France (chopin@geologie.ens.fr)

Aragonite, the high-pressure polymorph of calcite, occurs as a metamorphic index mineral in the lowest-grade low-temperature, high-pressure metamorphic terranes. The rapid kinetics of its back-reaction to calcite upon decompression makes its preservation an indicator of decompression under quite low temperatures, implying either anti-clockwise P-T paths or at least continuous cooling during decompression. There are indeed extremely few records of aragonite relics in relatively high-grade rocks, then as tiny inclusions in a rigid host mineral, which prevents expansion and transformation of the high-pressure carbonate polymorph, in the same way as it does for coesite or microdiamond.

We record here the occurrence and preservation of aragonite in eclogitic blueschists of eastern Corsica, showing a most uncommon microtexture. Aragonite exclusively (?) occurs as oriented rods in garnet crystals of a black calcite marble that immediately overlies serpentinite bodies of the meta-ophiolitic unit. The crystallographic control imparts to the garnet the appearance of a sector zoning, and the whole texture is very reminiscent of the crystallographically oriented intergrowths of either quartz or organic material ('graphite') already described in garnet of a few amphibolite-facies metamorphic terranes (Norway [1], Ireland). These observations and their significance will be discussed in the light of a detailed petrological description of these rocks, Raman imaging of the calcite/aragonite polymorphs in the sections and of Raman investigation of the abundant carbonaceous material of the samples. The bearing on the significance of other crystallographically oriented inclusions in (high-pressure?) garnet will be discussed as well.

The effect of paleozoic land plant evolution on atmospheric CO2 and O2

ROBERT A. BERNER
Dept. of Geology and Geophysics, Yale University, New Haven, CT 06520-8109, USA (robert.berner@yale.edu)

Modeling, field and experimental studies, and proxy measurements support the idea that the rise and evolution of large vascular land plants, especially trees, during the mid-to-late Paleozoic had a profound effect on the biogeochemical carbon cycle. The development of extensive root systems brought about increased Ca and Mg silicate weathering and increased transfer of atmospheric CO2 to dissolved bicarbonate and ultimately to marine carbonates. Atmospheric CO2 was also removed as a result of increased burial of plant-derived organic remains, especially in the form of microbially resistant lignin. Increased weathering and organic burial led to a large drop in CO2, helping, via the atmospheric greenhouse effect, to set the stage for the vast Permo-Carboniferous glaciation.

Increased organic burial also resulted in the increased production of O2. This led to a Permo-Carboniferous maximum in atmospheric O2 at levels possibly as high as 30%. This elevated O2 likely contributed to an increase in the size of organisms, such as insects and amphibians, which breathe via various diffusive-like processes. During an approximately 20 million year period across the Permian-Triassic boundary, due to a decline in large land plant production that resulted in decreased terrestrially-derived organic burial, O2 production declined and brought about a large drop in O2. This drop must have been a contributing factor to the Permo-Triassic extinction.
New Ir data from K-T sections in the Paraiba Basin, NE Brazil

Z. BERNER1, U. KRAMAR1, G. KELLER2 and D. STÜBEN1

1Institut für Mineralogie und Geochemie, Universität Karlsruhe, 76131 Karlsruhe, Germany
2Geosciences, Princeton University, Guyot Hall, Princeton, NJ 08544, USA (gkeller@princeton.edu)

New drill cores and outcrops across the K-T transition in the Paraiba Basin (Poty Quarry near Recife) of NE Brazil were collected in order to evaluate the environmental changes and evidence of the Chicxulub impact. Here we report on the sedimentology, stratigraphy and Ir concentrations, with an emphasis on the stratigraphic position of the Ir anomaly, which is of crucial importance in the ongoing Chicxulub impact debate.

The K-T transition is marked by a 40-50 cm thick conglomerate, which is present in the Poty well and outcrops, as well as in another two wells drilled over a distance of 75 km. The origin of this conglomerate is still under debate. It has been variously interpreted as impact-generated tsunami deposit, storm deposit, tectonic breccia or mass flow associated with a sea level lowstand. Our study shows that the conglomerate consists mainly of phosphate and glauconite pebbles, occasionally graded, and floating in a micrite matrix. No impact spherules were detected.

The age of deposition of this conglomerate is still in question. Although previous studies have placed it at or below the K-T boundary, the presence of Danian planktic foraminifera Parvularugoglobigerina eugubina indicates an early Danian zone P1a age, as also observed by Koutsoukos (2006).

At the base of the conglomerate and 15 cm above it we detected two Ir anomalies with concentrations of 0.5 and 0.6 µg/kg, respectively. At 5 cm and 15 cm above the conglomerate are two thin dark clay layers interbedded in marls of early Danian zone P1a age. In the upper clay layer, Albertao et al. (1994) reported Ir concentrations of 0.6 µg/kg. At 15 cm above the conglomerate and 15 cm above the conglomerate are two thin dark clay layers interbedded in marls of early Danian zone P1a age. In the upper clay layer, Albertao et al. (1994) reported Ir concentrations of 0.6 µg/kg. Thus, our results indicate multiple Ir anomalies, though all appear to be within the early Danian. This can be explained in two ways: 1) The Ir anomalies are derived from reworked ejecta material that was deposited at or prior to the K-T boundary, or 2) The Ir anomalies reflect an early Danian impact with subsequent reworking.

The speciation of metals in natural fluid inclusions at temperatures up to 700°C

A.J. BERRY1, A.C. HARRIS2, V.S. KAMENETSKY2, M. NEWVILLE3 AND S.R. SUTTON1,4

1Department of Earth Science and Engineering, Imperial College London, South Kensington SW7 2AZ, UK (a.berry@imperial.ac.uk)
2CODES, University of Tasmania, Hobart, Tasmania 7001, Australia
3Consortium for Advanced Radiation Sources (CARS), University of Chicago, Chicago, IL 60637, USA
4Department of Geophysical Sciences, University of Chicago, Chicago, IL 60637, USA

The speciation (oxidation state and coordination environment) of metals in fluids is key to understanding their transport in hydrothermal systems. For example, in the formation of porphyry and related epithermal ore deposits the type and stability of metal complexes will control partitioning between melt, brine, and vapour, and the mechanism of ore deposition.

Fluids trapped as inclusions in quartz can be heated, allowing in situ XANES and EXAFS studies of metal speciation. The ideal inclusions are 10s of µm in size, have metal concentrations in excess of 100s of ppm, contain no insoluble phases, and can survive heating to magmatic temperatures.

XAS spectra were recorded at beamline 13-ID-C (GSECARS) of the Advanced Photon Source from individual fluid inclusions in miarolitic quartz from the Omsukchan granite, Russia (Kamenetsky et al. 2004). The quartz sections were mounted in a windowless Linkam 1500 heating stage and the temperature of an inclusion determined by a thermocouple on the top surface of the sample. The inclusions are primitive, polyphase, have salinities in excess of 35 wt%, homogenise completely on heating to temperatures up to 700 °C, and contain 100s of ppm of Cu and wt% amounts of Fe, Mn, and Zn.

Two generations of magmatic polyphase inclusions with markedly different metal ratios were studied. In both cases Cu was found to occur exclusively as the linear species [CuCl2]− from 200 °C to at least 700 °C. Despite the high salinities there is no evidence for higher order coordination. Preliminary speciation results for Fe, Mn, and Zn at 700 °C will also be reported.

Evaluation of the CO₂-sequestration capacity of sandstone aquifers in the Campine Basin (NE-Belgium) based on autoclave experiments and numerical modelling

P. BERTIER 1,2, R. SWENNEN 1 AND B. LAENEN 2

1KULeuven, Geodynamics & Geofluids Research Group,
Celestijnenlaan 200E B-3001 Heverlee, Belgium
2VITO, Materials Technology - Raw Materials Projectteam,
Boeretang 200, B-2400 Mol, Belgium

The Campine Basin in NE-Belgium houses important CO₂-emitting industries. Injection of CO₂ in sandstone aquifers in this sedimentary basin could significantly reduce emissions towards the atmosphere.

An integrated study was set up to evaluate the effects of CO₂-water-rock interactions on the reservoir properties of 3 sandstone aquifers in the basin, i.e. the fluvial sandstones of the Westphalian C, Westphalian D and the Lower Triassic (Buntsandstein). A number of representative samples, from boreholes, of each reservoir were characterised by means of a broad spectrum of petrographical, geochemical and petrophysical methods. Five samples of each reservoir were exposed for a period of 6 months to the conditions prevailing in the reservoirs during and after CO₂ injection, in high temperature - high pressure autoclaves. CO₂-water-rock interactions were inferred from the evolution of the chemical composition of the brine in the autoclaves and comparison of the treated and untreated samples after the experiments.

Data from the detailed characterisation of the experimentally treated samples was used to construct a reaction model in PHREEQC. Reaction kinetics of 17 rockforming minerals are based on user-defined rate laws and parameters. CO₂-water-rock interactions inferred from the experiments were used to adjust reaction progress.

Numerical modelling confirms that the sequestration capacity of the studied reservoirs will be greatly enhanced by CO₂-water-rock interactions. During injection carbonate dissolution can enhance permeability of the reservoirs. In the first 15 years after injection alteration of Al-silicates (feldspars and clays) to kaolinite and illite buffers the pH-drop caused by CO₂-injection. Higher pH and release of K and Na promote ionic trapping, i.e. sequestration as dissolved bicarbonate species. Slow release of Fe and Mg from altering Al-silicates offers some potential for mineral trapping, i.e. sequestration of CO₂ as carbonate minerals. Dissolution of hematite and pyrite causes reduction of Fe³⁺ and precipitation of siderite. Substantial siderite precipitation occurs after more than 25 years and is initiated when a certain pH is reached due to Al-silicate reactions.

These numerical simulations illustrate that the sequestration capacity offered by CO₂-water-rock interactions is highly variable, depending on the reservoir mineralogy. The sequestration capacity of the studied reservoirs ranges from approximately 100-500 gCO₂/kgw.

40Ar/39Ar ages of the sill complex of the Karoo large igneous province: Implications for the Pliensbachian-Toarcian climate change.

H. BERTRAND 1, F. JOURDAN 2,3, G. FERAUD 4, M.K. WATKEYS 5 AND P.R. RENNE 1,3

5University of Natal, Republic of South Africa

Reliable geochronological results gathered (n=76) so far have considerably constrained the timing of the emplacement of the Karoo large igneous province. Yet strikingly missing from this dating effort is the huge sill complex cropping out in the >0.6x10⁶ km² main Karoo sedimentary basin. We present sixteen new ⁴⁰Ar/³⁹Ar analyses carried out on fresh plagioclase and biotite separates from fifteen sill samples collected along a N-S trend in the eastern part of the basin. The results show a large range of plateau and mini-plateau ages (176.2 ± 1.3 to 183.8 ± 2.4 Ma) with most dates suggesting a ~3 Ma (181-184 Ma) duration for the main sill events and confirming the relatively long emplacement duration of the main volume of the province. The youngest plateau age at 176.2 ± 1.3 Ma obtained on a sill and two plateau ages at ~176 Ma obtained by [1] on the neighbouring Uderberg dyke swarm, unambiguously define a young “hot line” extending from the eastern Lesotho to the coast. This possibly illustrates important and late stress constraints related to the continental breakup near the future rifted margin.

The available age database of the Karoo province allows to correlate the Karoo CFB emplacement with the Pliensbachian-Toarcian second order biotic extinction and associated global warming and with the Toarcian anoxic event (providing that adequate calibration between the ⁴⁰K and ²³⁸U decay constant is made). The mass extinction and the isotopic excursions recorded at the base of the Toarcian appear to be synchronous with both the increase of magmatic production rate of the Karoo province and the emplacement of the sills. Field evidences and ⁴⁰Ar/³⁹Ar ages suggest that the sills intruding carbon-rich sedimentary layers filling the souther Africa Karoo basins might be one of the main culprits of the global warming and oceanic anoxic conditions recorded at this time. However, the long duration of the igneous activity is not easily reconcilable with the shorter time scales required by recent climate models derived from sill-sediment interaction [2,3]. We propose that the relatively low eruption rate of the Karoo province is one of the main reasons explaining why its impact on the biosphere is relatively low contrary to e.g. the CAMP (Triassic-Jurassic) and Siberia (Permo-Triassic) provinces.

Hydrogeochemistry of the Mutnovsky volcano (South Kamchatka)
E.P. BESSONOVA, S.B. BORTNIKOVA AND V.N. SHARAPOV
Institute Geology and Mineralogy SB RAS, Novosibirsk State University, Novosibirsk, Russia, (liza@uiggm.nsc.ru)

The Mutnovsky volcano (52°21'N, 158°16'E, 2323 m) is located 75 km southward from the town of Petropavlovsk Kamchatsky. In terms of explosive activity and heat discharge, this volcano is presently among the most active volcanoes of the Kamchatka volcanic belt. In 2003 and 2005, we sampled springs, pools, and mud pots of the Donnoe fumarolic field. Sampling of aqueous solutions was accompanied by in situ measurement of pH, Eh, and Cl- and F- contents. The springs studied in the Mutnovsky volcano crater have diverse composition, but most of them belong to acid waters (pH ~ 2.5-3.5). The solutions have high contents of Al, Ca, Mg, Na, Mn, Fe, As, Cu, Ti, Co, Cr, and P. The highest contents of these elements previously known from the Kuril-Kamchatka volcanic arc at Kunashir Island are one to three orders of magnitude lower. The solution is also characterized by high concentrations of Au, Mo, and Zr, which are not usual for hydrothermal springs in areas of basaltic andesite volcanoes, and extremely high contents of B and Sr. Modeling was conducted with the method of using a Selector Win program in continuous reactor modification [1]. Large-scale extraction of components from basalts requires the presence of oxidized high-temperature gases, which could be formed in the upper part of the volcanic-hydrothermal system via mixing of magmatic fluids with overheated vapors of oxygen-enriched surface water. High-temperature mixed gases (surface water vapor and magmatogenic acid gases) are formed along the external boundary of condensation. The newly formed aggressive gas can leach most elements from host basalts. The gas is partially condensed to mix with magmatic fluid, while solutions are diluted and cooled in the course of their ascent. The next geochemical barrier (the second boiling zone) is characterized by the exsolution of some components (primarily, water vapor and small amount of acid gases) into the gas phase, while the remaining portion is enriched in some elements (Cr, Ni, V, Ti, and others) up to the required level. Thus, we assume that the hydrothermal spring in the Donnoe field is related to the zone of enriched brines arising at the secondary boiling boundary. This assumption is confirmed by thermodynamic calculations.

Archaean enriched mantle reservoir beneath east Indian Shield
S. BHATTACHARYA, P. DAS AND A. SAW
Indian Statistical Institute, Calcutta 700108, (samar@isical.ac.in)

Prograde hornblende-bearing mafic granulite xenoliths, associated with massif-type charnockite, is a significant feature of the collisional Eastern Ghats orogen (Kar, 2003). These mafic xenoliths have geochemical signature of arc-derived basalts (Fig. 1). No correlation in Sr-Nd isotopic compositions is observed and hence mixing of different mantle components can not be envisaged. But present day low 143Nd/144Nd values and high 87Sr/86Sr values indicate an enriched mantle reservoir as the source of these mafic xenoliths (Fig. 2). The 1.8 Ga Rb-Sr isochron represents the isotopic homogenization during granulite event in a collisional setting. Nd-model dates, calculated after Milisenda et al., 1994, ca 2.7 Ga (2688 to 2784 Ma), represents the time of extraction from the mantle. Also the enriched mantle reservoir in this segment of the east Indian Shield might have resulted from a previous crust-mantle interaction or crustal recycling (Shan Gao, 2004), during ca 3.0 Ga granulite event in the Eastern Ghats belt (Bhattacharya, 2001).

Sm-Nd isochron ages from Southern Granulite Terrain, South India: Age of protolith and metamorphism

RAJNEESH BHUTANI, S. BALAKRISHNAN, C.G. NEVIN AND S. JEYABAL

Department of Earth Sciences, Pondicherry University, Pondicherry-605014, India (rbhutani@gmail.com)

Temporal correlation of metamorphism and deformation in the poly-metamorphic and poly-deformed Southern Granulite Terrain (SGT) in south India is of primary importance to understand the evolution of continental lithosphere and tectonics. However, because of intensive overprinting of successive metamorphic and deformation events the time correlation could not be unambiguously achieved for SGT. We used an approach of analysing the carefully selected whole rock samples and mineral-separates for Rb-Sr and Sm-Nd systems to retrieve and resolve different tectono-metamorphic events experienced by these samples. A sample from the eastern part of the SGT and north of Cauvery Shear Zone, near Namakkal town yielded a good seven point Sm-Nd mineral isochron, for minerals garnet-1, garnet-2, diopside, ortho-pyroxene, plagioclase, biotite and whole-rock with an age of 879 ± 9 Ma (MSWD = 1.6). We have interpreted this to be an age of granulate facies metamorphism. Whereas, a regression line for the same minerals in Rb-Sr isotope evolution diagram corresponds to an age of ~ 524 ± 80 Ma. Furthermore, pairs of whole-rock – biotite and biotite-plagioclase yielded identical Rb-Sr ages of 540 ± 21 Ma and 543±21 Ma respectively with initial 87Sr/86Sr ratio of ~ 0.7023. We, therefore interpret this sample of granulate has experienced two tectono-thermal events. The older event at ~ 880 Ma completely re-equilibrated all the minerals for Sm-Nd system and therefore, has provided time of granulitization. Another younger event did not disturb the Sm-Nd system but reset the minerals for Rb-Sr system to variable extent at ~ 540 Ma. The four point Sm-Nd isochron for the whole-rock samples of granulites from the same region yielded isochron age of 2208 ± 130 Ma with MSWD 1.6. The Nd T CHUR model ages for the granulite samples from this region range from 2369 to 2935 Ma. This indicates that the formation of protolith of these granulites completed by ~2208 Ma ago which had undergone granulate facies metamorphism at ~ 880 Ma ago when the Sm-Nd radio-chronometer remained un-affected as the equilibration took place only at mineral scale.

The above results provide important time constraints for the protolith formation and two subsequent tectono-thermal events. The older at 880 Ma corresponds to Rodinia supercontinent period which caused the granulate facies metamorphism and younger at 540 Ma could be related to intensive regional deformation during Pan-African assembly of Gondwanaland.

REE pattern and Oxygen isotopes in zircons from different rocks (the Fennoscandian and Ukrainian Shields) as indicators of their genesis

E. BIBIKOVA1, A. FEDOTOVA1 AND S. CLAESSON2

1Vernadsky Institute of Geochemistry and Analytical Chemistry RAS, Moscow, Russia (bibikova@geokh.ru)
2Swedish Museum of Natural History, Stockholm, Sweden

There are different views on the role of REE distribution in zircons as indicator of the rock genesis. Recent studies have shown deviations from the crystallochemical REE pattern typical for zircons of magmatic genesis: in high-pressure rocks (eclogites) -deficiency in HREE, and in so called “hydrothermal” zircons [1] –enrichment in LREE. The role of oxygen isotopes in zircons has been discussed in many publications.

We have studied the distribution of REE and oxygen isotope composition in zircons from Archaean sanukitoids (Karelia, the Fennoscandian Shield) and from ancient enderbites (Dniestr-Bug region, the Ukrainian Shield). The REE distribution was determined on a Cameca 4F SIMS instrument in Yaroslavl, the oxygen isotope composition on a Cameca 1270 SIMS instrument in Stockholm.

A detailed study of Karelian sanukitoids is given in [2]. Sanukitoid zircons which have been dated to 2740 Ma are enriched in LREE with (Yb/Sm)N=10-50, (Yb) N=1200-2700. Sanukitoid zircons which have been dated to 2740 Ma are enriched in LREE with (Yb/Sm)N=10-50, (Yb) N=1200-2700. This deficiency is not as pronounced as in eclogitic zircons, but still it indicates “granulitic” zircon generation has much lower concentration of REE elements with deficiency in HREE, and in so called “hydrothermal zircons” [1]. We have connected the genesis of sanukitoids with subduction processes that involve fluids or melts from a subducted slab in a mantle wedge [2].

Enderbites from the Dniestr-Bug region are the oldest rocks of Ukrainian Shield. They contain two zircon generations. The first one of magmatic genesis is as old as 3.65 Ga, the second, metamorphic generation is about 2.85 Ga old and was grown during granulitic metamorphism overprint on magmatic tonalities [3]. The distribution of REE elements in the early zircon generation is typical for magmatic zircons having chondrite-normalized REE pattern with positive slope from La to Lu and positive Ce and negative Eu anomalies. The second, “granulitic” zircon generation has much lower concentration of REE elements with deficiency in HREE (Yb/Gd)N=2-8, (Yb)N=300-400. This deficiency is not as pronounced as in eclogitic zircons, but still it indicates crystallization of zircon during metamorphism along with garnet enriched in heavy REE.

Our study has confirmed the indicator role of REE and oxygen isotopes in zircons in establishing the mineral genesis highly important for geochronological studies.

Metagenomics of deeply buried marine sediments

JENNIFER F. BIDDLE1, CHRISTOPHER HOUSE2, SOREL FITZ-GIBBON3, STEPHAN SCHUSTER4 AND JEAN BRENCHLEY4

4Dept. of Biochemistry and Molecular Biology, Pennsylvania State University (jeb7@psu.edu)

Deeply buried marine sediments make up a vast potential biosphere and contain up to one-third of all microorganisms [1]. Sediments collected on Ocean Drilling Program Leg 201, which visited the Peru Margin in 2002, have been examined by many different methods. Using different molecular and biogeochemical procedures, two vastly different views of the subsurface microbial world have emerged. Based on intact polar lipids, RNA and FISH counts, there is evidence for a dominant and active archaeal community in sediments on the Peru Margin [2, 3]. Using different techniques on similar samples, evidence also exists that the subsurface microbial population is mostly bacterial [4, 5, 6]. Our recent study tried to address the discrepancies between experiments to resolve the understanding of subsurface microbial communities.

We have obtained 61.9 Megabases of metagenomic sequence from 4 separate horizons at ODP Site 1229 on the Peru Margin. Analysis of this metagenome shows that based on small subunit ribosomal RNA in-silico biomarkers, the subsurface community is dominated by Archaea at depth, reaching 88% of the microbial community at 50 meters below seafloor. We have also analyzed the gene content of the metagenome and over 85% of the genetic sequence does not have a closely related homolog in the public databases, suggesting that the deeply buried sediments hold a vast amount of genetic diversity. In addition to this metagenomic study, we have analyzed nucleic acid retrieved from this sediment environment by quantitative polymerase chain reaction and confirm that at depth, there is an archaeal dominance of the sediment microbial populations.

The subsurface sediment of the Peru Margin is extremely unique in that it holds a vast amount of archaean microorganisms, more than any environment previously studied. This has now been determined by both measurements of active cells and total genetic material.

5Institute of Ocean Sciences, 9860 West Saanich Road, Sidney, BC V8L 4B2 Canada

Hexachlorocyclohexane (HCH) is the most abundant organochlorine pesticide in the Arctic Ocean. Most of the HCH loadings took place by atmospheric deposition until ~1980, and by ocean current transport thereafter. The α-HCH concentrations in surface water on the North American side of the Arctic Ocean are 2-4 times higher than on the Eurasian side. Measurements made on the Swedish Tundra Northwest 1999 expedition in the Canadian Archipelago showed that surface water concentrations of the HCH isomers varied by about 2-fold, with higher concentrations near the Beaufort Sea to the west and lower ones in Baffin Bay – Davis Strait at the east end. Enantiomer fractions of α-HCH, EF = (+)/[(+)+(−)], were less than the racemic value of 0.500 and ranged from 0.436 in the Beaufort Sea to 0.454 in Baffin Bay, indicating preferential microbial degradation of (+)α-HCH. HCH distributions in the eastern Archipelago were consistent with mixing of three water bodies with characteristic end member concentrations and EFs. Levels of α-HCH in air of the central Archipelago were 37 ± 9 pg m−3 and 53 ± 5 pg m−3 before and after the mid-July ice breakup, a significant (p <0.001) increase of 30%. The concentration increase was accompanied by a reduction in the EF in air after ice breakup, from 0.495 ± 0.003 to 0.482 ± 0.010, indicating sea-to-air transfer. It is suggested that enantiomers of α-HCH in air can provide a sensitive indication of ice cover loss in the Arctic.
Soil-air exchange of legacy organochlorine pesticides

1,2,4Centre for Atmospheric Research Experiments, Environment Canada, 6248 Eighth Line, Egbert, ON, L0L 1N0 Canada
3Environment Canada, 4905 Dufferin St., Downsview, ON, M3H 5T4 Canada
5Dept. of Environmental Science, Policy and Geography, University of South Florida St. Petersburg, 140 Seventh Avenue South, St. Petersburg, FL, 33701 U.S.A.
6Dept. of Environmental Science and Centre for Chemical Management, Lancaster University, Lancaster, LA1 4YQ, U.K.

Of the dozen persistent organic pollutants (POPs) to be eliminated under the Stockholm Convention, eight are organochlorine pesticides (OCPs: DDT, aldrin, dieldrin, endrin, heptachlor, chlordane, mirex and toxaphene). Residues of OCPs remain in agricultural soils and are continually emitted into the atmosphere, thereby buffering atmospheric concentrations and slowing rates of decline. OCPs also contaminate background soils, presumably as a result of atmospheric deposition. "Chemical markers" for identifying sources and tracing soil-air exchange include pesticide isomers, parent/metabolite pairs and enantiomers of chiral compounds. Elevated concentrations of OCPs in air over agricultural soils confirm their emissions and, when coupled with micrometeorological techniques, such measurements can determine fluxes. The relative volatilities of soil residue components can be used to reliably predict their proportions in air. Campaigns in southern Mexico show much higher concentrations of DDT in air compared to temperate North America, yet proportions of DDT/DDE in air of the Great Lakes region implicate emissions from regional soils rather than transport from Mexico. Profiles of toxaphene constituents in soil and air of the southern U.S.A. and Mexico show characteristic depletion of certain labile congeners. These congeners are also depleted in surface water samples from the Atlantic Ocean during the 1990s, however sample profiles from the 1980s more closely resemble technical toxaphene. Enantiomers of two chiral components of technical chlordane, trans- and cis-chlordane, are in nonracemic ratios in present-day ambient air samples, but were racemic in atmospheric deposition samples from Sweden in the early 1970s. Background soils contain residues of DDT which vary over four orders of magnitude and are poorly correlated with latitude or percent soil organic matter. Residues of chiral OCPs in these soils show much more variability in enantiomer composition than do the same compounds in ambient air. These observations indicate the dual role of soils in supplying OCPs to and receiving them from the atmosphere, the changing role of agricultural application vs. soil emission sources and postdepositional diagenesis of OCPs in background soils.

Experimental investigation of the behaviour of CO₂ droplets rising in seawater under hydrate forming conditions

N. BIGALKE1, G. REHDER2 AND G. GUST3

1(nbigalke@ifm-geomar.de)
2(gregor.rehder@io-warnemuende.de)
3(gust@tu-harburg.de)

We present comprehensive experimental results on the upward motion of CO₂-droplets in simulated deep-sea environments. A cooled high pressure tank was used to establish conditions along a natural oceanic hydrotherm. At pressures and temperatures well inside the CO₂ hydrate stability field, observed rise rates were in accordance with predictions based on empirical equations developed to match momentum of hydrate-covered, deformed droplets. In contrast, droplets rising at P,T conditions closer to the phase boundary deviated from model predictions in numerous instances. This was related to a partially incomplete or missing hydrate skin due to insufficient thermodynamic forcing. To support this relationship, additional experiments outside the field of hydrate stability were carried out and compared to the erratic data. The results confirm expectations and show that non-hydrated droplets have a markedly different rising behaviour and rise rates of up to 40% higher than equally buoyant droplets with a hydrate skin. This might have a significant impact on the vertical distribution of dissolved CO₂ in the ocean and has to be taken into account when assessing CO₂ sequestration at mid water depth.
Complementary methods for characterization of stream sediments as an aid in assessment of sediment quality

H. Bilinski1, S. Francišković-Bilinski1, M. Nečemer2, D. Hanžel2, G. Szalontai and K. Kovács3

1Institute “Ruđer Bošković”, POB 180, HR-10002 Zagreb, Croatia (bilinski@irb.hr, francis@irb.hr)
2Institute “Jožef Stefan”, Jamova 39, SI-1001 Ljubljana, Slovenia (marijan.necemer@ijs.si, darko.hanzel@ijs.si)
3University of Veszprém, Pf. 158, H-8200 Veszprém, Hungary (Gabor.Szalontai@sparc4.mars.vein.hu, kris@almos.vein.hu)

Introduction

The European water framework directive (WFD) has not come yet up with environmental quality standards for sediments. It is still open which sediment monitoring approaches will be used.

The aim of the present work is to demonstrate on selected stream sediments what type of characterization can be obtained when using interdisciplinary approach.

Methods

Complementary methods were: X-ray diffraction (XRD), inductive coupled plasma – mass spectroscopy (ICP-MS), X-ray fluorescence (XRF), solid state 27Al MAS NMR, 29Si MAS NMR, grain size analysis and Mössbauer spectroscopy.

Results, discussion and conclusion

Advantages and disadvantages of each method were discussed. Solely ICP-MS method requires chemical decomposition. It is the most useful for microelement analysis (51 element), which data can be used in geostatistical analysis and detection of anomalies. Other techniques are non destructive and require simple physical sample preparation. XRD method can give with certainty class and group of minerals. Determination of clay minerals, when present <5%, is less certain. XRF method is suitable for determination of major elements, particularly of Si and limited number of trace elements. However, Mg and Na cannot be detected. The particle size distribution was determined in fraction <63 µm. It was found that the amount of clays (fraction <4 µm) was in the range 7.4 – 12.6%. Mössbauer spectra taken at room temperature and at 70 K in a mixture of several minerals are difficult to interpret. Valuable information concerning the valence and site populations of iron in poorly crystallized minerals can be obtained. Solid state 29Si MAS NMR can give structural information, like the number of different SiO4, Si(Al)O3 units. 27Al MAS NMR gives the presence and number of tetrahedral and octahedral Al sites and their ratio. Grain size analysis and surface area of particles is a fundamental property of sediments and is important in pollution research. All of the studied methods are recommended in future sediment analysis.

Oxygen isotope heterogeneity and disequilibria of olivine phenocrysts in large volume basalts: Case of Iceland

Ilya Bindeman1*, Andrey Gurenko2, Olgeir Sigmarsson3 and Marc Chaussidon4

1Department of Geological Sciences, 1272 University of Oregon, Eugene, OR, USA (bindeman@uoregon.edu)
2Max-Planck-Institut für Chemie, Mainz, Germany
3CNRS, Clermont-Fd, France; EarthSciences,Univ.of Iceland
4CRPG-CNRS, Nancy, France

Olivine phenocrysts in the largest volume Holocene fissure basalts from Iceland’s eastern rift zone are moderately to severely out of oxygen isotope equilibrium with their host magma. We present a set of laser fluorination analysis of >70 individual and bulk crystals of olivine and plagioclase, and their host glasses with average precision of better than 0.07‰. We also report ion microprobe analyses of cores and rims of 61 olivine crystals from 13 samples with precision on single spots of 0.10-0.35‰ (1stdev). Within each sample studied, we find that basaltic glass is relatively homogeneous, plagioclase phenocrysts exhibit δ18O variability, while individual olivines are more variable and span from mantle values of 5.2‰ down three permil below, in equilibrium with their low-δ18O glass. The famous Laki basalt studied here still holds the record for Holocene volcanism.

Discussion

The famous Laki basalt studied here still holds the record for Holocene volcanism. In addition, we have found subtle disequilibrium in this and other Icelandic basalts. As discussed in the Introduction, this disequilibrium is not accurately predicted by the usual U-series model of mantle melting. lattice disequilibria are most likely produced by variations in the degree of hydration and/or assimilation of host rocks. We find that basaltic glass is relatively homogeneous, plagioclase phenocrysts exhibit δ18O variability, while individual olivines are more variable and span from mantle values of 5.2‰ down three permil below, in equilibrium with their low-δ18O glass.

Results, discussion and conclusion

Advantages and disadvantages of each method were discussed. Solely ICP-MS method requires chemical decomposition. It is the most useful for microelement analysis (51 element), which data can be used in geostatistical analysis and detection of anomalies. Other techniques are non destructive and require simple physical sample preparation. XRD method can give with certainty class and group of minerals. Determination of clay minerals, when present <5%, is less certain. XRF method is suitable for determination of major elements, particularly of Si and limited number of trace elements. However, Mg and Na cannot be detected. The particle size distribution was determined in fraction <63 µm. It was found that the amount of clays (fraction <4 µm) was in the range 7.4 – 12.6%. Mössbauer spectra taken at room temperature and at 70 K in a mixture of several minerals are difficult to interpret. Valuable information concerning the valence and site populations of iron in poorly crystallized minerals can be obtained. Solid state 29Si MAS NMR can give structural information, like the number of different SiO4, Si(Al)O3 units. 27Al MAS NMR gives the presence and number of tetrahedral and octahedral Al sites and their ratio. Grain size analysis and surface area of particles is a fundamental property of sediments and is important in pollution research. All of the studied methods are recommended in future sediment analysis.

The speciation of sulfur in magmatic-hydrothermal fluids

BERND BINDER\textsuperscript{1} AND HANS KEPPLER\textsuperscript{2}

\textsuperscript{1}Institut für Geowissenschaften, Universität Tübingen, 72074 Tübingen, Germany (Bernd.Binder@uni-tuebingen.de)
\textsuperscript{2}Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany (Hans.Keppler@uni-bayreuth.de)

Sulfur compounds are major constituents of volcanic gases and magmatic-hydrothermal fluids. They are responsible for the climatic effect of major volcanic eruptions as well as for the transport and precipitation of metals during the formation of magmatic-hydrothermal ore deposits. Up to now, it was usually assumed that SO\textsubscript{2} and H\textsubscript{2}S are the only important sulfur species occurring in high-temperature magmatic fluids.

The speciation and oxidation state of sulfur in aqueous fluids was studied using synthetic fluid inclusions in quartz cores generated in rapid-quench autoclaves under controlled oxygen fugacity and variable pressures and temperatures (500 – 950 °C; 500 – 3000 bar). Run durations lasted up to several weeks. The sulfur speciation in the fluid inclusions was determined by Raman spectroscopy. Raman spectra were calibrated against standard solutions.

At Ni-NiO buffer conditions, H\textsubscript{2}S was the dominant sulfur species in the fluid, coexisting with small amounts of SO\textsubscript{2}. At Re-ReO\textsubscript{2} buffer conditions, the quenched fluid contained a mixture of SO\textsubscript{2}, SO\textsubscript{4}\textsuperscript{2-} and HSO\textsubscript{4}\textsuperscript{-}. Our data therefore suggest that under oxidizing conditions as they may prevail in many magmatic systems in subduction zone settings, aqueous fluids contain abundant species of hexavalent sulfur (see Fig. 1).

Figure 1: Experimentally determined sulfur speciation in aqueous fluids. Shown are the conditions under which the molar fraction of SO\textsubscript{2} equals that of H\textsubscript{2}S and under which SO\textsubscript{2} is equally abundant as species of hexavalent sulfur (“SO\textsubscript{3}”).

REE enrichment in authigenic and biologically mediated minerals of phosphate rocks

A.F. BISHAY\textsuperscript{1}, Z. BERNER\textsuperscript{2} AND D. STÜBEN\textsuperscript{2}

\textsuperscript{1}Nuclear Materials Authority, Cairo, Egypt (abram_bishay2002@yahoo.com)
\textsuperscript{2}Institute of Mineralogy and Geochemistry, Karlsruhe, Germany, (zsolt.berner@img.uni-karlsruhe.de; doris.stueben@img.uni-karlsruhe.de)

The geochemical behavior of the REE under the influence of chemical and microbial activity is still insufficiently explored issue. REE significant bioaccumulation and fractionations was recently reported by many authors in plant organs (Ding et al., 2005) and with microbial activity (Bishay, 2005).

The REE are accommodated in minute authigenic minerals in the phosphate rocks which reach to about 12.65% \Sigma REEs. The NASC normalized REE pattern of these minerals are nearly flat with occasional distinct -ve Eu anomaly suggesting fluctuations in the redox environment during their formation (Fig.1). The mobilization and enrichment of the REE is evidenced by both abiotic and biotic laboratory experiments. It is indicated that under controlled boundary conditions, some organic acids as well as biological mediation of the phosphate rocks influence the redistribution and enrichment of REE.

Fig.(1): NASC REE diagram of some authigenic minerals showing Eu anomaly.

Doping-induced structural phenomena in Pb-based relaxors

U. BISMAYER\textsuperscript{1}, B. MIHAILOVA\textsuperscript{1}, C. PAULMANN\textsuperscript{1}, T. MALCHEREK\textsuperscript{1}, B. GÜTTLER\textsuperscript{2} AND M. GOSPODINOV\textsuperscript{3}

\textsuperscript{1}Mineralogisch-Petrographisches Institut, Grindelallee 48, Universität Hamburg, D-20146 Hamburg, Germany (mi4a001@uni-hamburg.de)
\textsuperscript{2}Physikalisch-Technische Bundesanstalt, Bundesallee 100, 38116 Braunschweig, Germany
\textsuperscript{3}Institute of Solid State Physics, BAS, Blvd. Tzarigradsko Chausse 72, 1784 Sofia, Bulgaria

Perovskite-type relaxor ferroelectrics are among the key materials in modern solid-state science due to their outstanding dielectric, electro-optic, and electro-elastic properties, which are the basis of a number of technological applications including information storage and processing. The unique physical properties of relaxors are related to their local structure, which strongly deviates from the global, average structure. Here we report on the relationship between the observed phonon anomalies and the local atomic arrangements in Pb-based perovskite-type relaxors studied by synchrotron X-ray diffraction and polarized Raman spectroscopy of representative lead scandium tantalate/niobate single-crystal compounds. It is shown that the development of ferroic species and ferroelectric state on cooling can be followed by analysing quantitatively the intensity ratios of the Raman scattering arising from the corresponding local structural distortions \cite{1}. The degree of B-site doping can control the size of ferroelectric domains. Different types of local structural changes occur upon A-site doping, depending on the ionic radius of doping element, its valence and affinity to form stereochemically active lone-pair electrons.

Variation in natural mercury isotopic ratios of coal formations

A. BISWAS, J.D. BLUM AND B.A. BERGQUIST

2534 CC Little Bldg, 1100 N University Ave, Ann Arbor, MI, 48109 (biswasa@umich.edu, jdblum@umich.edu, bbergqui@umich.edu)

High precision mercury (Hg) stable isotope measurements of coal offer a new tool to investigate inputs of Hg to the atmosphere from coal combustion. Mercury was quantitatively isolated from coal by combustion and trapping in a KMnO\textsubscript{4} solution. Mercury isotopic measurements were determined by cold vapor multi-collector inductively coupled plasma mass spectrometry (MC-ICPMS). Instrumental mass bias was corrected using an internal thallium standard and concentration-matched sample-standard bracketing. Mercury isotopic variations are reported here in delta notation (\[^{202}\text{Hg}/^{198}\text{Hg}\]) and referenced to the NIST SRM 3133 Hg standard. Sample and standard replicates had an external 2\% standard deviation of \(<\pm0.2\\%\) for \[^{202}\text{Hg}\] (Blum and Bergquist, 2007).

Coal samples were analyzed from across the USA that ranged in rank from lignite to bituminous and in age from Eocene (~55 Ma) to Pennsylvanian (~300 Ma). The \[^{202}\text{Hg}\] of these samples ranged from -0.98 to -2.27 \%. A positive correlation was observed between calorific value of coal (BTU lb\textsuperscript{-1}) and \[^{202}\text{Hg}\] values for coals (\(p < 0.05, R^2 = 0.89\)) (Figure 1). One interpretation of this trend is that the Hg isotopic composition of coal shifts towards isotopically heavier values with increased metamorphism due to preferential volatilization of isotopically lighter Hg.

We also observed mass independent fractionation (MIF) in these coal samples with \(^{200}\text{Hg}\) and \(^{198}\text{Hg}\) (Blum and Bergquist, 2007) ranging from -0.1 to -0.3 \%, which we suggest may be caused by photochemical reduction of Hg prior to deposition in coal. Analyses of Hg ores and refined Hg do not show MIF and thus may be isotopically distinguishable from coals (Smith \textit{et al.}, 2005). Our results suggest that Hg isotopic ratios of coal formations could aid in source apportionment of coal combustion emissions of Hg and lead to a better understanding of the global Hg cycle.

Evidence for a late $^{60}$Fe injection into the protoplanetary disk

MARTIN BIZZARRO1, DAVID ULFBECK1, ANNE TRINQUIER1, KRISTINE THRANE1, JAMES CONNELLY1,2 AND BRADLEY MEYER3

1Geological Institute, University of Copenhagen, Øster Voldgade 10, DK-1350, Denmark

Understanding the origin of short-lived isotopes in meteorites can constrain the astrophysical setting of Solar System formation and the earliest evolution of the protoplanetary disk and proto-Sun. Whereas early Solar System abundances of short-lived isotopes with relatively long half-lives like $^{53}$Mn and $^{182}$Hf broadly reflect input from stellar sources over the history of our Galaxy, the inferred levels of $^{41}$Ca, $^{26}$Al and $^{60}$Fe are too high to uniquely derive from Galactic production. Some of the $^{41}$Ca and $^{26}$Al may have formed by particle irradiation near the proto-Sun. In contrast, the exclusive stellar origin of $^{60}$Fe requires that it was synthesized in a nearby star and injected into the nascent Solar System. Here, we show that meteorites with highly-variable Fe/Ni ratios originating from differentiated planetesimals that accreted within 1 Myr of Solar System formation record identical deficits of ~25 ppm in $^{60}$Ni (the daughter product of $^{60}$Fe) compared to samples from Earth, Mars and chondrite meteorites. With clear evidence for live $^{60}$Fe when the chondrite and eucrite parent bodies formed, our study requires that $^{60}$Fe was injected into the protoplanetary disk ~1 Myr after Solar System formation, at a time when $^{26}$Al was homogeneously distributed. This decoupling of the first appearance of $^{26}$Al and $^{60}$Fe indicates that our forming Solar System interacted with massive stars ($\geq 30$M$\odot$) where $^{26}$Al was solely expelled by stellar winds of the Wolf-Rayet stage, and $^{60}$Fe subsequently injected during the supernova explosion associated with a dying star. Lastly, the terrestrial Ni isotope composition suggests that Earth accreted from material distinct from that of known primitive and/or differentiated meteorites.

Influence of landscape type on trace metals in small boreal catchments

L. BJÖRKVALD1, H. BORG2, H. LAUDON3 AND C.M. MÖRTH1

1Dept. of Geology and Geochemistry, Stockholm University, Sweden (louise.bjorkvald@geo.su.se)
2Dept. of Applied Environmental Science, Stockholm University, Sweden (hans.borg@itm.su.se)
3Dept. of Ecology and Environmental Science, Umeå University, Sweden (bjalmar.laudon@emg.umu.se)

We studied temporal and spatial variations of trace metal (TM) concentrations (As, Cd, Co, Cr, Cu, Ge, La, Ni, Pb, Rb, Sc, and Y) in stream water and their correlation with catchment properties (i.e. coverage of wetland and forest), but also with Fe and Mn. During 2004 and 2005 water samples were collected from 10 streams (0.13 km$^2$ to 67 km$^2$) in the Krycklan Catchment Study, a boreal stream network in northern Sweden. Since spring snowmelt is the most important hydrological event, the monthly sampling was intensified during spring flood (April-May) when samples were collected every second day. Total and dissolved (<0.4µm) concentrations of Fe and Mn were determined by ICP-OES. Dissolved concentrations of TM were determined by ICP-MS.

Preliminary results show a seasonal variation for all TM, in particular during spring flood. In forested catchments most TM concentrations increased at spring flood, but for Rb and Sc a decrease was observed. Conversely, in wetland influenced catchments the opposite seasonal variation was observed, i.e. concentrations of all TM decreased by a factor of 2 to 3. The seasonal variation of Fe shows a similar pattern to many TM, due to the association of TM to Fe oxyhydroxides. In particular, Fe correlates significantly with Cr and Pb in a forested headwater stream ($r^2=0.77$ and $r^2=0.71$, respectively, p<0.05). In the wetland headwater stream similar correlations between Fe and TM are found, but DOC also correlates significantly with As, Cd, Ni, and Pb ($r^2=0.92$, p<0.05).

A significant negative correlation (p<0.05) was observed between coverage of wetlands and average concentrations of Cr, Cu, Ge, Ni, Sc and Y. The results indicate that wetlands act as sinks for these elements. Alternatively, there is a source limitation in wetlands and that increased concentrations during base flow are due to mineral groundwater influence. Positive correlation with wetland coverage was only observed for Pb ($r^2=0.79$, p<0.05), indicating that wetlands acts as a source for this element. Sulfate concentrations correlated negatively ($r^2=0.97$, p<0.05) with increasing coverage of wetlands, which highlights the importance of sulfate reduction within wetland areas.

This study emphasizes the importance of considering stream water chemistry from a landscape perspective.
Biogeochemical cycling of P: Isotopic insights into the P-redox cycle

R.E. BLAKE
Yale University, Dept. of Geology & Geophysics New Haven, CT USA (ruth.blake@yale.edu)

Phosphorus occurs primarily as PO₄ in the +5 oxidation state and is conventionally thought of as having no significant redox chemistry. The recent discovery of several bacteria capable of using phosphate (PO₄, +5 valence) and hypophosphite (PO₃, +1 valence) as a sole source of P via oxidation to PO₄, however, led to the hypothesis that an active "P-redox cycle" exists in natural Earth systems (Metcalf and Wolfe, 1998). Subsequent investigations reveal that ca. 1% of all microorganisms are capable of Pt oxidation. More recently, a sulfate-reducing bacterium, Desulfotignum phosphitoxidans, that uses Pt as an electron donor has been isolated from marine sediments (Schink and Friedrich, 2000). Pt and other reduced-P compounds although not abundant, are very widespread as is the ability to metabolize these compounds. It has been put forth that on an oxygen-free early Earth, reduced-P compounds were more abundant and that Pt may have been the first water-soluble, bio-available form of P. It has been recently demonstrated for organic P-org compounds that specific phosphoenzymes have specific isotope effects that are distinguishable in laboratory and natural systems, and that PO₄ derived from P-org compounds inherits O from the Porg source (Blake et al., 2005). In effort to identify and further elucidate sources and reactions of reduced-P compounds, a study of the O-isotope systematics of Pt oxidation was undertaken. The reaction mechanisms and isotopic fractionations accompanying Pt oxidation by 2 different enzymatic pathways have been investigated: (1) non-respiratory PO₃ oxidation by Pt-dehydrogenase (PtxD); and (2) Pt oxidation by D. phosphitoxidans. Results from these studies provide new insights into PO₃ oxidation mechanisms and specific isotopic signatures that may be used to elucidate processes in the P-redox cycle operating in modern systems and possibly on early earth.

Boron isotopic composition correlates with ultra-structure in the deep-sea coral Lophelia pertusa: Implications for biomineralization processes and paleo-pCO₂

D. BLAMART¹, C. ROLLION-BARD², J.-P. CUIF³, A. MEIBOM⁴, A. JUILLET-LECLERC⁵ AND Y. DAUPHIN³

⁴Museum National d'Histoire Naturelle, Paris, France

Using the CRPG-CNRS Cameca 1270 ion microprobe facility we have measured B isotopic compositions in different ultra-structural components in the deep-sea scleractinian coral Lophelia pertusa. We observe a systematic difference in the B isotopic composition of Early Mineralization Zone (EMZ) and adjacent fibrous aragonite skeleton. In EMZ, the measured δ¹¹B values are consistently low. Fibrous aragonite is characterized by systematically higher δ¹¹B values, but also display B isotopic heterogeneity associated with specific growth bands in the calyx wall. The magnitude of the observed B isotopic variations cannot be explained by changes in environmental conditions (such as seawater temperature) and are to be considered the result of biological processes involved in the biomineralization of new skeleton; i.e. ‘vital’ effects. The observed B isotopic variations are directly opposite to the predictions of existing geochemical models for vital effects, which are based on the idea that stable isotopic fractionations (including C and O) in coral skeleton are driven by changes in pH of the fluid from which the skeleton is presumed to precipitate. Our data indicate that pH variations are not responsible for the observed stable isotopic fractionations. Existing geochemical models therefore do not provide an adequate framework within which to understand coral skeletal formation. Furthermore, our observations cast in doubt efforts to reconstruct paleo-pH variations in the oceans on the basis on coral skeletal B isotopic composition.
**Impact related and late crystallisation products of Shergotty**

**U.W. BLÄß AND F. LANGENHORST**

Institute for Geosciences, Burgweg 11, 07749 Jena, Germany
(Ulrich.Blaess@uni-jena.de)

Shergotty is one of the historic (fall in 1865) type meteorites, after which the SNC meteorite group is named. This group is nowadays accepted to be of Martian origin. Shergotty belongs to the basaltic subgroup of SNCs and is predominantly composed of large zoned clinopyroxene crystals intergrown with original plagioclase, which was subsequently converted into maskelynite upon shock compression. The coexistence of fayalite with silica, ilmenite, titanomagnetite and phosphates point to late crystallisation of a highly evolved residual melt fraction that crystallised at relatively high oxygen fugacity. Stöffler et al. (1986) concluded all shock features can be produced by a single shock event causing equilibrium shock pressure of $29 \pm 1$ GPa, whereas local stress and temperatures might have reached $60 - 80$ GPa and $1600 - 2000^\circ$C resulting in the formation of melt pockets. In our study we investigate fine-grained crystallisation products in order to distinguish whether they are the result of shock metamorphism or a late-stage product of magmatic crystallisation.

Thin sections of Shergotty have been analysed in detail by optical microscopy, scanning electron microscopy and transmission electron microscopy (TEM). In contact to Ti-bearing phases and phosphates, symplectites of fayalite and a SiO$_2$ polymorph or fayalite and hedenbergite occur with grain sizes ranging typically in the order of a few microns. They are similar to symplectites described first by Aramovich et al. (2002), who suggested that these symplectites are rather break-down products of former pyroxferroite and ferrosilite than crystallisation products. In interstices between clinopyroxene and maskelynite we observe several areas composed of a micrometer sized intergrowth of potassium-rich maskelynite, a SiO$_2$ polymorph, which shows a similar lamellar microstructure than those described by El Goresy et al. (2004) as post-stishovite phases, and a residual titanium-rich mafic silicate. TEM analyses indicate that these areas may have originated from shocked quartz-orthoclase symplectites reflecting a very late differentiation product of the magmatic melt.

A geochemical-mineralogical approach for the reconstruction of past flood events

S. BLEECK-SCHMIDT, Z. BERNER AND D. STÜBEN
Institute for Mineralogy and Geochemistry, University Karlsruhe, Germany
(stephanie.bleeck@img.uni-karlsruhe.de)

The increasing frequency of extreme flood events is a subject of debate for many years and it is speculated that this is a possible consequence of climatic change and/or recent river regulation operations. However, a well-founded discussion on the cause(s) of extreme flood events requires a more accurate record of their frequency and magnitude till a more distant past.

In looking for an adequate approach for the reconstruction of paleo-flood events we act on the assumption that the specific hydrological conditions during high water levels will entail a change in the grain size of the transported suspended matter and consequently, will also cause a change in its mineralogical and geochemical composition due to varying sources. Preliminary investigations on the suspended load of the River Rhine show that the amount of particles transported during a flood is not only much higher, but the grains are also larger in size and hold other geochemical-mineralogical features as compared to such particles transported during normal water levels. Indeed, it could be shown that the particulate matter transported during inundations is marked by a higher portion of coarse carbonate and a lower portion of fine grained fraction enriched in iron oxides.

During a flood event the suspended load is deposited on the floodplain, forming up to several centimetres thick accumulations. This material was cored on the floodplains of the Rhine close to Elchesheim-Illingen and on that of the Danube at Pfatter, by carrying out several short (up to 3 m deep) drillings which were sampled every centimetre. The relationship among the geochemical and mineralogical parameters was studied by means of factor analysis.

Results from the Rhine floodplain sediments clearly indicate a connection between individual mineral phases and specific grain size ranges. Thus the fraction < 20 µm correlates significantly with the iron oxide content, the grain size fraction 20 to 100 µm with the carbonate content, while the fraction > 100 µm is correlated with the amount of the siliciclastic components. It still has to be verified, whether the dominance of the fraction 20 to 100 µm during flood events is a local feature or if it can be extended also to larger sections of the Rhine.

These results demonstrate that a systematic and detailed study of the distribution of grain size and geochemical-mineralogical features of flood plain sediments may yield valuable insights in the occurrence of past flood events. The age of the sediments and hence the inundation can be dated e.g., by means of thermo luminescence and thus information could be obtained about the frequency and magnitude of extreme flood events far beyond historical records.

The age of the earliest continental crust and onset of plate tectonics

J. Blichert-Toft1, T. M. Harrison2 and F. Albarede1
1Ecole Normale Supérieure, 69007 Lyon, France
(jblichert@ens-lyon.fr; albarede@ens-lyon.fr)
2Institute of Geophysics and Planetary Physics, UCLA, Los Angeles, CA 90095, USA (tmh@oro.ess.ucla.edu)

We present bulk Hf and Pb isotope data obtained by solution chemistry and, respectively, MC-ICP-MS and ICP-MS for 60 new leached single Jack Hills zircons determined by SIMS spot analysis to be between 3.9 and 4.35 Ga in age. We also present bulk Pb isotope data corresponding to the MC-ICP-MS Hf isotope data of Harrison et al. (2005). Because abundant 235U was still extant during the Hadean, the 208Pb/206Pb ratio of radiogenic Pb varied extremely fast in the young Earth. Measurements with even modest precision thus provide reasonably accurate estimates of the age of old samples, provided adequate correction for common and contaminant Pb is applied. For this we used the strong correlation between 207Pb/206Pb and 208Pb/206Pb (r² = 0.985) on the assumption that Th/U of concordant zircons vary within only a narrow range (0.7±0.2). If so, the Pb isotope data show that most of the zircons have bulk ages of 4.08±0.15 Ga with a small tailing to younger ages and that no analyzed grains have bulk Pb-Pb ages older than 4.25 Ga. None of the zircons qualified by SIMS to be older than 4.3 Ga have bulk Pb isotope values consistent with such high ages, indicating these ages are overwhelmed by younger U-Th-Pb domains. Although the majority of the ICP-MS bulk Pb ages are in agreement within ~100 My with the associated SIMS spot ages, the former portray a younger and more restricted age range of Jack Hills zircons than the latter. However, this does not affect the conclusion reached by Harrison et al. (2005), based on Jack Hills zircon Hf isotope systematics and reinforced here by our new Hf isotope data (which are equally heterogeneous and exhibit both negative and positive epsilon values), that at least some continental crust began forming very early. Assuming a 176Lu/177Hf ratio of 0.015, typical of sediments and granites and low enough for our age assessments to be minimum rather than maximum estimates, and that all bulk zircon ages are ~4.1 Ga, the CHUR and DM model ages for the source (protolith) of the granites hosting the Jack Hills zircons are, respectively, 4.3-4.4 and 4.4-4.5 Ga. Because granites are the hallmark of modern plate tectonics, our Jack Hills data strongly suggest this process was active by at least 4.1 Ga. Demonstrating that it started even earlier requires independent evidence that the protolith itself was also granitic, an enticing interpretation given the heavy oxygen of a significant fraction of the Jack Hills zircons, their low crystallization temperatures (680±25°C), and the nature of their mineral inclusions.

Regulation of acidity generation and consumption in sediments of acidic mine lakes

C. BLODAU, C. GATZEK AND K.-H. KNORR
Limnological Research Station and Department of Hydrology, University of Bayreuth, 95440 Bayreuth (christian.blodau@uni-bayreuth.de)

In acid mine drainage (AMD) polluted lakes, acidity generation and consumption in sediments are regulated by geochemical factors and by seepage of groundwater. We tested the hypothesis that increased inflow of groundwater can shift the sediment from an acid generating to an acid consuming state and examined the chemical factors that control iron and sulfur transformations. In columns experiments, schwertmannite bearing sediment, rich in iron, sulphur, and carbon, was percolated (0, 5 and 20 L m⁻² a⁻¹) with two solutions (1/1 mmol L⁻¹ vs. 10/15 mmol L⁻¹ sulphate/ferrous iron, pH 5). A DOC source was added after 46 days (~2.5 mmol C L⁻¹) to ease the carbon limitation of reductive processes. The sediment remained in an iron reducing and acidic state during percolation without DOC. Percolation at a high rate and addition of DOC raised pH values in schwertmannite rich layers from 2.8 to 4.5 – 5. Percolation at a high rate and addition of DOC raised pH values in schwertmannite rich layers from 2.8 to 4.5 – 5. Schwertmannite transformation to goethite partly accelerated by a factor of >2 but effectively buffered proton consumption only at the low percolation rate. With pH increase, iron reduction slowed relative to CO₂ production, sulphate was reduced, and iron sulphides were formed.

In batch experiments we examine the effects of iron sources (schwertmannite, goethite, dissolved Fe³⁺), peat humic acid, and pH (3 – 6) on iron reduction rates. At pH 3, addition of schwertmannite and goethite and dissolved ferri-c iron strongly increased, and addition of the humic acid decreased iron reduction rates. Goethite promoted iron reduction more strongly than schwertmannite. Raising pH from 3 to 4.5 – 6 strongly decreased iron reduction rates. When the pH was not fixed, addition of schwertmannite increased (6.3 mmol g⁻¹ d⁻¹) and addition of goethite decreased (1.9 mmol g⁻¹ d⁻¹) iron reduction compared to a control (3.9 mmol g⁻¹ d⁻¹). This effect can be attributed to pH values being higher and dissolved ferric iron concentrations being lower in the goethite amended samples, compared to control and schwertmannite treatment. The acidifying effect of schwertmannite was more critical for maintaining high rates of iron reduction than bulk mineral properties.

The study showed that the input of alkalinity and electron donors by percolation may shift the biogeochemical regime from acidity production to acidity consumption. However, the acidifying capacity of schwertmannite transformation is substantial and its kinetics is fast, thus stabilizing the sediments in a acidic state.

Fo 99.8 olivine in basalts:
Assimilation of meta-serpentinites or oxidation of magmatic phenocrysts?

M. S. BLONDES¹, M. T. BRANDON¹, P. W. REINERS², N.T. KITA³, F.Z. PAGE³ AND J.W. VALLEY³
¹Dept of Geology and Geophysics, Yale University, New Haven, CT, USA (madalyn.blondes@yale.edu)
²Dept. of Geosciences, Univ. of Arizona, Tucson, AZ, USA
³Dept. of Geology, Univ. of Wisconsin, Madison, WI, USA

Rare occurrences of near endmember forsterite (> Fo 95) exist in volcanic lavas, skarns, and metamorphosed serpentinites. We identify olivines, more forsteritic than any published value, in multiple primitive basalt flows of a monogenetic vent in the Big Pine Volcanic Field, CA USA. Here, to provide a framework for understanding the effects of assimilation and alteration processes in basalts, we analyze two competing hypotheses of pure forsterite formation in lavas: incorporation of regenerated olivine from metamorphosed serpentinite or crystallization/alteration in a high fO₂ environment. Olivine compositions are bimodal, with flows either having all normal (Fo₉₇.₂–Fo₉₉.₈) or all forsteritic (Fo₉₉.₂–Fo₉₉.₃) olivine. Fo composition correlates with increased flow vesicularity but not with the systematic whole rock composition. In many grains, the nearly euhedral forsterite has a hematite and cpx rim, and internal parallel oriented planes of hematite, cpx, and opx.

During peridotite serpentinization and subsequent dehydration, Fe partitions into associated oxides and Ni remains in the serpentine. Thus, regenerated olivines commonly have both low Fe and Ni concentrations. In these lavas, there is a correlative bimodal distribution of NiO. With increasing Mg#, the normal olivines show an increase in NiO whereas it decreases in forsterites to 0.04 wt.%. We therefore can consider a scenario of dehydrated serpentinite originally from the mantle lithosphere incorporated into the ascending melt, with only the forsterite and related oxides remaining.

However, several lines of evidence are inconsistent with an assimilated serpentinite origin, and instead call for late stage oxidation of the melt in air. If metamorphosed serpentinites were selectively incorporated into certain flows, we would expect to see changes in whole rock chemistry as well as a bimodal distribution of both xenocrystic forsterites and phenocrystic normal olivines within single flows, which we do not. A closed system (other than fluids) is also likely because the reintegrated composition of the oxidized assemblage is a normal Fo₉₉ olivine. In addition, four δ¹⁸O analyses by CAMECA 1280 ion microprobe within one forsterite have typical mantle olivine values of 5.42 ± 0.3 % (1σ, 10 μm spots). Continuous oxidation of pre-existing olivine is known to generate pyroxene and oxide symplectites in an increasingly magnesian olivine that exhibit a topotaxial relationship. The BPVF olivines show these requisite reactive phases with the [100] direction of olivine parallel to the [0001] direction of the hematite, and with the symplectite planes parallel to the weak olivine cleavage planes.
Measurement and reporting of natural mercury isotopic variability

Magma generation and ascent beneath arc volcanoes

JON BLUNDY 1, KIM BERLO 2 AND KATHY CASHMAN 3

1Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (jon.blundy@bris.ac.uk)
2Earth & Planetary Sciences, McGill University, Montreal, Canada H3A 2A7 (kimberlo@eps.mcgill.ca)
3Geological Sciences, University of Oregon, Eugene, OR 97403-1272, USA (cashman@uoregon.edu)

Explosive eruptions of andesite arc volcanoes are driven by the generation and subsequent ascent of magma from the deep crust. Magma generation involves a combination of crystallisation of H2O-rich basalt derived from the mantle wedge and partial melting of pre-existing crustal rocks in deep crustal hot zones. Magma ascent can be divided into two regimes. The first regime involves the segregation and ascent of silicic magma through the crust. The H2O-rich magma is buoyant and inviscid and likely to ascend rapidly along dykes. The magma is, however, H2O-undersaturated and therefore will develop superheat during ascent, enabling it to partially digest residual source material and/or wall rocks. The corroded cores of many plagioclase phenocrysts may have originated in this way. Crystal retention and partial resorption by silicic melts leads to linear trends in whole-rock chemistry. We suggest that relatively few andesites represent true liquid compositions; most have an entrained cargo of ancestral crystal residues or accidental passengers acquired en route.

The second regime begins when the magma attains volatile saturation and degassing begins, preferentially removing CO2 relative to H2O. Crystallisation begins at slightly lower pressures when the volatile-saturated liquidus is encountered. The ensuing crystallisation and volatile loss due to decompression lead to a sharp increase in viscosity and density, which serve to slow magma ascent dramatically. We refer to this process as “viscous death” with the consequence that most andesite magmas are destined to form plutons. Decompression crystallisation releases latent heat and results in the paradoxical situation of magma both crystallising and getting hotter by ≤100°C. Because decompression crystallisation continues to low pressures melt SiO2 contents can be up to 80 wt% (anhyd.). Such melts are too viscous to segregate from crystals on volcanic timescales. As a consequence rather little chemical differentiation occurs at shallow levels; most of a magma’s chemistry is defined by differentiation processes in the hot zone and the entrained crystal cargo. Nonetheless, low-pressure cumulates do occur in many andesites, testifying to some crystal deposition within the sub-volcanic edifice. Exposures of sub-volcanic complexes support the idea that successive magma batches may deposit a small fraction of their cargo en route to the surface and, in a complementary way, can entrain fragments of the cargoes of antecedent magmas. An individual phenocryst in an andesite may preserve snapshots of the entire complex magmatic evolution.
Volatile fluxing and magma storage at Mount St. Helens volcano

JON BLUNDY1, KATHY CASHMAN2 AND KIM BERLO3

1Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK
(jon.blundy@bris.ac.uk)
2Geological Sciences, University of Oregon, Eugene, OR
97403-1272, USA (cashman@uoregon.edu)
3Earth & Planetary Sciences, McGill University, Montreal,
Canada H3A 2A7 (kimberlo@eps.mcgill.ca)

A major challenge of volcanology is linking the pre-eruptive movement of magma beneath a volcano to monitored signals such as seismicity and gas emissions. We have used analyses of over 210 melt inclusion (MI) and groundmass glasses from the 1980-86 eruption of Mount St. Helens to create a petrological dataset for comparison to the contemporaneous monitoring record.

H2O in MI ranges from 0 to 6.8 wt%, with the highest values from the Plinian phase of May 18th, 1980. CO2 contents indicate XH2Ovap ≈ 0.80, irrespective of H2O, suggestive of closed system degassing with high bubble fraction. Fluctuation in XH2Ovap suggests fluxing of the magma reservoir by gases exolved from below. Fluxing may play a key role in the development of oscillatory zoning in plagioclase phenocrysts.

Elevated Li in MI and plagioclase phenocrysts from the cryptodome and post-May 18th samples requires transport of Li in an exsolved H2O-rich vapour phase from deeper to shallower portions of the magma system. Maximum Li enrichment occurs at Ptot = 120-180 MPa, possibly due to condensation of a single vapour phase to H2O-rich gas and Li-rich brine. Decreasing Li contents at lower Ptot result from continued degassing during ascent. This degassing occurs on timescales slow enough to allow Li diffusion out of the melt and into the vapour, but fast enough to inhibit significant diffusive loss of Li from plagioclase.

MI evidence for gas fluxing is supported by 210Pb,226Ra disequilibrium resulting from loss and accumulation of 222Rn-bearing vapour. The magnitude of the 210Pb deficits indicate that the deeper reservoir was degassing for at least a decade prior to eruption, while 210Pb excesses in the shallow reservoir are confined to periods of elevated gas flux, as evinced by SO2 measurements.

Pre-eruptive magma storage depths, derived from MI saturation pressures, change systematically with time. The May 18 Plinian eruption discharged magma stored 5 to 11 km below sea-level (bsl). Preceding eruptions, including the lateral blast, and subsequent episodes involved shallower-stored magma. Tapping of magma from ≥2 km bsl stopped abruptly in Dec 1980, coincident with the onset of extensive shallow seismicity and a change from dominantly explosive to dominantly effusive eruption. This transition is likely a response to choking of the conduit system by highly crystallised magma. The close correspondence between petrological and monitoring records at MSH augurs well for an improved understanding of pre-cursory signals at explosive volcanoes.

Experimental Constraints on Trace Element Fluxes from Slab to Wedge

JON BLUNDY1, KEVIN KLIMM2 AND TREVOR GREEN3

The characteristic trace element signature of arc magmas is a consequence of the chemical flux from subducted slab to mantle wedge. The nature of this flux is determined by the different subducted lithologies, the subduction geotherm and the partitioning behaviour of trace elements between fluids, melts and slab residues. In an attempt to constrain the trace element flux that can be derived from subducted basalt we carried out H2O-saturated experiments on a trace element-doped MORB composition at 2.5 GPa, 750-900 °C and fO2=NO.

Garnet, omphacite and rutile occur at all temperatures. Amphibole, staurolite and epidote disappear above 750 °C; allanite appears above 750 °C. The tronnjemitic glass present at all temperatures was quenched from supercritical fluid. Trace element analyses of glasses demonstrate the control exerted by residual minerals on fluid chemistry: garnet controls HREE; rutile controls Ti, Nb and Ta; and allanite buffers LREE contents of fluids to low levels and preferentially holds back Th and, to a much lesser extent, U. We agree with previous experimental [1] and metamorphic [2] studies that residual allanite has a key role in selectively retaining trace elements during subduction.

Experiments and allanite-bearing rhyolites are used to derive a model for allanite solubility in melts or fluids as a function of P, T, composition and LREE (La-Sm) content. Our model reproduces LREE concentrations in allanite-saturated melts and fluids to within a factor of 1.4 from 650-1100°C, 0-4 GPa. The extreme T-dependence of allanite solubility is very similar to that of monazite [3]. Silicic fluids from basaltic (or sedimentary) protoliths will be saturated in allanite (or monazite) except at very high temperatures. For conventional subduction geotherms the low solubility of LREE (+Th) in allanite-saturated fluids raises questions about the mechanism of LREE+Th transport from slab to wedge. We suggest either that (i) locally temperatures experienced by the slab are appreciably higher than normal, e.g. by mechanical incorporation of thin slivers of sediment into the mantle wedge, or that (ii) substantial volumes of H2O-rich fluids must pass through the mantle wedge prior to melting. The solubility of accessory phases in fluids derived from subducted rocks clearly provides important geochemical constraints on subduction zone thermal structure.

Volatile abundances and H isotope signatures of melt inclusions and nominally anhydrous minerals in the nakhlites and chassignites

N.Z. Boctor AND C.M.O. D’Alexander
Carnegie Institution of Washington, 5251 Broad Branch Rd., NW, Washington, DC 20015, USA (boctor@ciw.gl.edu, alexander@ciw.dtm.edu)

Water and other volatiles play an important role in partial melting of mantle sources of primary magmas and their eruption and crystallization histories. The lack of pervasive alteration or shock melting in nakhlites and chassignites suggests that their nominally anhydrous minerals and melt inclusions may provide clues to the volatile abundances and H isotope compositions of their parent magmas. The abundances of H$_2$O, CO$_2$, F, S, and Cl and the H isotope signatures of nominally anhydrous minerals and the melt inclusions were measured in 7 nakhlites and 2 chassignites using standard SIMS techniques. The volatile abundances in the olivine and pyroxene in the nakhlites are lower than those of typical terrestrial basalts, mantle xenoliths, and megacrysts. The $\delta^D$ values for olivine are low and overlap with the terrestrial range (-350 to +100‰). The clinopyroxene shows a wide range of $\delta^D$, the largest in Governador Valadares (+200 to 1250‰). The olivines in chassignite have water abundances that are similar to those of mantle olivine (140 to 280 ppm) and low $\delta^D$ values (-67 to +86‰). Most inclusions in the nakhlites and chassignites have low water abundances and, by Martian meteorite standards, modest D enrichment. If the compositions of the nominally anhydrous minerals are primary, then the $\delta^D$ value of the parent magma is low. H isotopes provide clues to why the water contents of the melt inclusions are low. Degassing reduces the $\delta^D$ of the magma due to vapor-liquid equilibrium isotopic fractionation. The positive correlation between water and $\delta^D$ in melt inclusions in Governador Valadares suggests that its parent magma degassed. The negative correlation between H$_2$O and $\delta^D$ in Yamato 000593 suggests diffusive H loss. In the majority of the meteorites studied, however, there is no significant correlation between H$_2$O and $\delta^D$. Given the low water contents, any contamination may be complicating the interpretation of $\delta^D$ values. The low volatile abundances in the nakhlites and chassignites suggest that either the parent magmas degassed or volatiles were depleted in the source region of their parental melts.

Identification, interpretation and significance of fluid inclusions trapped in immiscible fluid systems

Robert J. Bodnar
Fluids Research Laboratory, Department of Geosciences, Virginia Tech, Blacksburg, VA 24061 (rjb@vt.edu)

Fluid immiscibility is an important process in the Earth’s crust and upper mantle and fluid inclusions provide the most direct evidence for the occurrence of fluid immiscibility. Fluid inclusions trapped from immiscible fluids provide information concerning the physical and chemical environment attending various geological processes. However, the identification of fluid inclusions trapped from immiscible fluids and their interpretation remain topics of discussion. Here we summarize techniques that should be used to identify and confirm that fluid inclusions were trapped from immiscible fluids, and outline techniques that should be used to obtain useful information from these inclusions.

The experienced inclusionist always envisions a phase diagram when observing fluid inclusions with the microscope, and uses this diagram to place constraints on the composition and homogenization temperature and trapping conditions of the inclusions. Thus, it is important that inclusionists be familiar with the phase relations of the more common fluid systems that serve as models for many fluids that occur in nature, including H$_2$O, H$_2$O-NaCl, H$_2$O-CO$_2$, and H$_2$O-NaCl-CO$_2$. Phase equilibria for these simple fluid systems provide the basis to understand the physical and chemical environment of inclusions trapped in immiscible fluid systems. In this presentation the PVTX properties of these systems will be reviewed using examples of the correct techniques for recognizing and interpreting fluid inclusions trapped in immiscible fluid systems.
New experimental data on Fe and Fe-S melting and the temperature at the core-mantle boundary

R. BOEHLER\textsuperscript{1}, D. SANTAMARIA-PEREZ\textsuperscript{1},
D. ERRANDONEA\textsuperscript{2} and M. MEZOULAR\textsuperscript{3}

\textsuperscript{1}MaxPlanck Inst. für Chemie, Postfach 3060, 55020 Mainz, Germany
\textsuperscript{2}Departamento de Física Aplicada, Universidad de Valencia, C/Dr. Moliner 50, Burjassot E-46100, Valencia, Spain
\textsuperscript{3}ESRF, BP 220, F-38043 Grenoble Cedex, France

Using a new method of rapid data acquisition in a double-sided laser-heating system at ESRF we measured X-ray diffraction patterns of laser heated iron to above its melting temperature in an argon pressure medium to 114 GPa, and in Al\textsubscript{2}O\textsubscript{3} to 150 GPa. Only the fcc and hcp phases were observed. Fcc iron is stable to at least 68 GPa and at higher pressures only hcp was observed making this phase again the most likely candidate for the solid-inner core. The room-temperature equation of state of these fully annealed iron samples is identical to that previously measured in a helium pressure medium (Dewaele et al., 2006). The highest P-T conditions at which melting was documented were 150 GPa and 3400 K, in excellent agreement with previous optical measurements (Boehler, 1993).

In the Fe-S system we reinvestigated the melt depression of iron using recovery experiments and electron microscopy. In contrast to our previous visual measurements there exists still a substantial melt depression of 1000 K at 50 GPa (Chudinovskikh and Boehler, 2007).

Both studies strongly suggest low core temperatures. The temperature at the core-side of the core-mantle boundary (at 135 GPa) would be substantially below 4000 K and thus, significantly decreasing the previously predicted large temperature jump across this boundary.

\textsuperscript{7}Universität Erlangen, Germany

We present a new Early Ordovician to Late Triassic Ca isotope record measured on brachiopods. In combination with published and new Mesozoic-Cenozoic data (Late Jurassic-Early Cretaceous belemnites and brachiopods, Late Cretaceous brachiopods, Neogene foraminifera) our $\delta^{44/40}$Ca record covers most of the Phanerozoic history. The data show significant variability on several timescales: An overall 0.5 \% increase in $\delta^{44/40}$Ca from the Ordovician to the Pleistocene is mainly due to rising values during the Mississippian followed by a drop to intermediate values in the Permian-Triassic and a second increase during the Jurassic to a Cretaceous maximum. Neogene $\delta^{44/40}$Ca values are in the same range as the Cretaceous values. Superimposed on these long-term (ca. 100 Ma) trends are several higher order oscillations (ca. 5-30 Ma) with magnitudes of up to 0.4 \%. Well documented examples of the latter occurred during the Neogene [1] and the Jurassic-Cretaceous [2].

There is currently no simple explanation for the reconstructed isotope variability of seawater calcium. Variable continental weathering fluxes and carbonate deposition in the oceans cannot explain the isotope variations. These mechanisms only influence the ocean carbon cycle, which operates on a much shorter timescale than the Ca cycle. Variable Ca isotope fractionation on the continents also is unlikely to cause significant variability in ocean $\delta^{44/40}$Ca, due to the huge size of the ocean calcium reservoir compared to terrestrial Ca sediments (e.g. in soils or travertine). The most likely mechanism to explain ocean $\delta^{44/40}$Ca variations is variable input of hydrothermal Ca and of Ca from dolomite formation. In addition, we observe a correlation of $\delta^{44/40}$Ca and seawater Mg/Ca ratios during the Paleozoic, which can be best explained by a shift from calcite dominated sedimentation during the Early Paleozoic to aragonite dominance in the Late Paleozoic and Triassic. Aragonite is stronger fractionated than calcite, so sedimentation dominated by aragonite leads to an enrichment of seawater in $^{44}$Ca. However, this correlation breaks down after the Carboniferous, possibly due to the evolutionary shift to mineralogy-independent fractionation of modern carbonate producers [3].

Nd isotope initials of Turku Migmatite Complex: Contemporaneous production of contrasting felsic melts

I. BOETTCHER1, K. MENGEL1 AND I.C. KLEINHANNS2

1Institut für Mineralogie, TU-Clausthal, D-38678 Clausthal-Zellerfeld (ingo.boettcher@tu-clausthal.de)
2GZG Isotopengeologie, Universität Göttingen, D-37077 Göttingen

Within the Turku Migmatite Complex (TMC) in S-Finland two types of in-situ partial melts are observed: akf-quartz-dominated melts and leucosomes comprising ‘small-scale granites’. These and the respective restites and precursors have been interpreted in a common genetic model (Johannes et al. 2003). In order to test the hypothesis of contemporaneous production of contrasting felsic melts within the same educt, Nd-isotope analyses were performed on garnet separates. U-Pb dating of zircons of the TMC indicate a 1.83 Ga partial melting event. If both types of leucocratic melt were generated at this stage, garnets of both leucosome types and of the respective restites should reveal identical initial Nd isotope compositions.

Clean garnet separates of leucosomes and restites from two different outcrops (R, L) were prepared and analyzed for their Sm-Nd isotope signatures by TIMS. Resulting present-day εNd values of garnets derived from akf-q-leucosomes are +373 and +288, from restites are +173 and +76 and from small-scale granites are -6 and +76. Recalculation of the Nd isotope composition to the zircon age of 1.832±11 reveal identical εNd (1.83Ga) of +4.2 for outcrop L and +7.0 for outcrop R for leucosomes and restites, respectively. The observed difference of 3 ε-units in the calculated initial Nd isotope compositions is probably due to local heterogeneity within the thick meta-pelite precursor. Considering the peak P-T-conditions in this area with ~800°C and 6 kbar (Johannes et al. 2003) it seems obvious that isotopic equilibration had been achieved at each outcrop during mid-crustal partial melting resulting in contemporaneous production of the contrasting types of leucosomes. The akf-q-leucosomes and the ‘small-scale granite’-leucosomes have different major and trace element composition including highly fractionated REE patterns. Akf-q-leucosomes are interpreted as cumulates formed of in-situ partial melts leaving behind an evolved liquid which crystallized to form the ‘small-scale granites’.

High-pressure behaviour of CaIrO3 perovskite and post-perovskite phases

T. BOFFA BALLARAN1, R.G. TRONNES2 AND D.J. FROST1

1Bayerisches Geoinstitut, Universitaet Bayreuth, D-95440 Bayreuth, Germany
(tiziana.boffa-ballaran@uni-bayreuth.de;
dan.frost@uni-bayreuth.de)
2Natural History Museum, Geology, University of Oslo, Box 1172, Blindern, N-0318 Oslo, Norway
(r.g.tronnes@nhm.uio.no)

CaIrO3 perovskite and post-perovskite phases might be used as low pressure analogues of the correspondent MgSiO3 phases in experiments that are currently impossible at conditions of the MgSiO3 perovskite to post-perovskite transformation, provided that their high-pressure behaviour is well characterised.

Single crystals of CaIrO3 perovskite and post-perovskite phases were synthesised in a piston-cylinder apparatus at 2.5 GPa and 1525 °C and 1GPa and 1435 °C, respectively. Two single-crystals, one with the perovskite and the other with the post-perovskite structure have been loaded together in a diamond anvil cell with ruby chips as pressure calibrant and a methanol:ethanol 4:1 mixture as a pressure transmitting medium. Unit-cell lattice parameters have been measured for both crystals up to 8 GPa. The CaIrO3 post-perovskite is more compressible than the perovskite structure. The equation of state parameters determined using a second-order Birch-Murnaghan expression are $V_0=229.47(1)$ and $K_0=189.4(6)$ for the perovskite and $V_0=226.38(2)$ and $K_0=176.0(6)$ for the post-perovskite phase. The compressibility of the unit-cell axes of the perovskite structure is anisotropic with $\beta_a>\beta_c>\beta_b$. The smaller compressibility of the $b$ axis also has been reported for MgSiO3, however in the latter compound the compressibility of the $a$ and $c$ axes is practically the same. In contrast the $b$ axis is the most compressible in the post-perovskite structure, whereas the $a$ and $c$ axes have similar compressibilities and are much stiffer.

Intensity data collections at high-pressure and structural refinements are underway in order to characterise the compression mechanism of these phases.
Temperature-programmed desorption of oxalate from the goethite surface

JEAN-FRANÇOIS BOILY
Pacific Northwest National Laboratory, P.O. Box 999, Richland, WA 99352, USA. (boily@pnl.gov)

The TPD-FTIR technique was used to investigate the relative thermal stabilities and decomposition reactions of different oxalate complexes adsorbed on the dry goethite surface. The measurements showed that important differences in coordination have a considerable impact on the thermal stability of the surface complexes.

Three important stages of desorption were identified from both TPD (Figure 1) and FTIR data in the 300-900 K range. Stage I (300-440 K) corresponds to the desorption of weakly-bound oxalate molecules with decomposition pathways characteristic of oxalic acid. Stage II (440-520 K) corresponds to the dehydration of key surface OH2 groups responsible in stabilizing hydrogen-bonded surface complexes. These species can either decompose via typical oxalic acid decomposition pathways or convert to metal-bonded surface complexes. Finally, Stage III (520-660 K) corresponds to the thermal decomposition of all metal-bonded oxalate complexes, proceeding through a two-electron reduction pathway that converts oxalate to CO2. Experiments in the absence of oxalate were used to assess the contributions from dehydration, dehydroxylation and decarbonation reactions from the goethite bulk.

Figure 1: TPD trace of goethite in the presence of 1.7 µmol/m² adsorbed oxalate. The dry powder was prepared from an aqueous suspension of goethite equilibrated in the presence of sodium oxalate at pH 6.5 and dried at room temperature.

Trace Elements and radio nuclides in Zegrze reservoir sediments (Poland)

I. BOJAKOWSKA, T.GLIWICZ AND S. WOŁKOWICZ
Polish Geological Institute, Warsaw, Poland (izabela.bojakowska@pgi.gov.pl; tomasz.gliwicz@pgi.gov.pl; stanislaw.wolkowicz@pgi.gov.pl)

The Zegrze Reservoir (Poland) is located just north of Warsaw. It is formed by a dam constructed on the lower course of the Narew and the Bug rivers, near their flow in the Vistula river. Its surface area is about 33 km².

Material and methods
64 drilling cores sampled were collected from the reservoir. The cores were divided into 178 samples. Analyses of concentrations of Ag, As, Ba, Cd, Cr, Co, Cu, Hg, Pb, Se, Sr, Sn, Ti, V, and Zn and as well U (eU), Th (eTh), 40K and 137Cs were performed for the sediment grain fraction <1mm.

Results
It results that the concentration of the most trace elements in the sediments accumulated at the bottom of the reservoir are diversified. The silt sediments characterized higher contents of trace elements than the geochemical background while sand sediments show low concentrations. In sediments maximum concentration (mg/kg) of antimony was 4.3, arsenic – 17, barium – 355, cadmium – 11.9, chromium – 95, cobalt – 8, copper – 74, mercury – 0.72, nickel – 36, lead – 48, selenium – 1.2, silver – 3.4, strontium – 342, thallium – 0.4, tin 4.8, vanadium – 45 and zinc – 538. In Zegrze reservoir radio nuclides occur in concentrations similar to characteristic values for that type of sediments.

Silts with high contents of heavy metals were accumulated in reservoir near Nieporęt, nearby mouth of Żerań channel (chromium, zinc, cadmium, copper, nickel, lead, mercury), which is connected with Vistula river in industrial part of Warsaw. And silts with distinctly high contents trace metals occur near some touristic sites localized on reservoir rim.

Conclusion
The estimated volume of silts accumulated in reservoir was 7860000 m³ and their tonnage – 13.36 mln t. It was calculated that these silt sediments contain about 2.6 t antimony, 13.4 t arsenic, 227 t chromium, 9.4 t tin, 561 t zinc, 3.2 t cadmium, 94 t copper, 107 t nickel, 134 t lead and 0.7 t mercury.
Pressure and temperature dependence of water solubility in forsterite: Implications for the activity of water in the Earth’s mantle

N. Bolfan-Casanova¹, E. Bali² and K. Koga³

¹Laboratoire Magmas et Volcans, CNRS, Universite Blaise Pascal, Clermont-Ferrand, France
(N.Bolfan@opgc.univ-bpclermont.fr)
²Bayerisches Geoinstitut, Universitat Bayreuth, Germany (Eniko.Bali@uni-bayreuth.de)
³Laboratoire Magmas et Volcans, CNRS, Universite Blaise Pascal, Clermont-Ferrand, France (K.Koga@opgc.univ-bpclermont.fr)

The storage capacity of water in the upper mantle largely depends on water solubility in mantle olivine. Such solubility provides a fundamental information required for petrological, geophysical and geochemical models of the mantle. Previous experimental studies have shown that the water solubility in olivine increases with increasing water fugacity up to 12 GPa at 1100°C (Kohlstedt et al., 1996) and with increasing temperature at 0.3 GPa (Zhao et al., 2004). This latter contrasts with the incorporation of water in transition zone phases such as wadsleyite and ringwoodite for which water solubility decreases with increasing temperature.

The goal of this study was to determine the dependence of water maximum concentration on temperature at pressures higher than 0.3 GPa. We performed experiments at 3, 6 and 9 GPa, and temperatures ranging from 1000 to 1400°C in the MgO-SiO₂-H₂O system using a multi-anvil apparatus. The starting material consisted of forsterite and enstatite in the 1:1 molar ratio with 1 to 5 wt% H₂O. The samples were analyzed using scanning electron microscopy, electron microprobe and polarized Fourier transform infrared spectroscopy. Results show that water solubility in olivine increases with temperature only at 3 GPa. At 6 and 9 GPa, the water solubility reaches a maximum at low temperatures then decreases at high temperatures. These results agree with recent observations at 12 GPa in the MgO-SiO₂-H₂O system (Smyth et al., 2006). Such behaviour is explained by the change in water fugacity as a function of pressure and temperature due to dissolution of silicate component in the fluid. The solubilities determined in this study allow to correct for this effect and permit to establish a new model of water activity in the mantle for silicate-water fluid coexisting with olivine and enstatite.

Compared Mg isotope compositions of plants, rocks and waters

E. B. Bolou Bi¹, ², N. Vigier¹, A. Poszwa² and A. Brenot¹

¹CRPG-CNRS, Vandoeuvre les Nancy Cedex, France
²LIMOS-CNRS, Univ. Nancy, Vandoeuvre les Nancy Cedex, France (emile.boloubi@limos.ujf-nancy.fr)

Magnesium is directly involved in the biological cycle. Mg plays a major role in photosynthetic processes, as it is the central core of the chlorophyll molecule. It activates many specific enzyme systems, and helps to regulate internal transport of other major ions such as P and K. Mg in plants comes from soil minerals and atmospheric deposits. Mg absorbed from soil solution by roots is transferred to shoots where it can be stored for months to hundred of years. Plants can therefore be responsible for considerable Mg mobilization on a basin scale (mean plant Mg content is ~2000ppm). Chlorophyll can be significantly enriched in light isotopes [1]. The aim of this study is to determine Mg isotope fractionation during Mg uptake by roots and Mg translocation within the plant, and to estimate their potential impact on the isotope signature of continental waters.

We first developed a new chemical procedure to separate Mg from both geological and biological matrices. Plants, clays and granites can display significant contents in alkali, Al and some transition elements such Fe, Mn and Zn which are difficult to separate from Mg with a typical cation exchange resin. We then investigated Mg isotope fractionation induced by two plants (clover, ray grass), grown under experimental conditions, on various Mg-rich substrates (phlogopite, magnesia, nutritive solution). δ²⁵Mg and δ²⁶Mg were measured using the MC-ICP-MS.

Regular measurements of Cambridge-1 standard solution indicate long term reproducibility for δ²⁶MgDSM better than 0.15‰ (2σ). δ²⁶Mg for Cambridge-1 (-2.61‰), as well as for silicate (BE-N, -0.28‰), carbonate (CaLs, -4.59‰), seawater (BCR-403, -0.93‰) and river water (SRM1640, -1.28‰) reference materials are in agreement, within errors, with published values [2, 3]. δ²⁶Mg for plant, soil and granite reference materials are presented for the first time. The plants and organic matter analysed (rye flour BCR-382, sealetuce BCR-279 and natural wavy hairgrass) display δ²⁶Mg ranging between -0.58‰ and -1.15‰, greater than published values for chlorophyll [4]. A forest soil (TILL-1) yields a δ²⁶Mg of -0.40‰. The two granites (DR-N and GA) display δ²⁶Mg of -0.50‰ and -0.75‰ respectively.

Preliminary results for experimentally grown plants highlight different Mg isotope signatures of different organs of plants. A decrease of δ²⁶Mg from roots to shoots is observed, demonstrating isotope fractionation during Mg internal transfer. The respective roles of plant species, Mg internal recycling, and soil Mg biodisposable will be discussed.

Petrological features of lithospheric mantle beneath Santo Antao (Cape Verde Archipelago)

C. Bonadiman1, L. Evans2, M. Coltorti1, H. Downes3 and F. Wall2

1Department of Earth Sciences, Ferrara University (bdc@unife.it)  
2National History Museum, London (F.Wall@nhm.ac.uk)  
3School of Earth Sciences, University College London (h.downes@ucl.ac.uk)

Spinel peridotites in basanites from Sao Antao were studied with the aim of characterising the lithospheric mantle beneath this island, and working towards a better understanding of the nature of the mantle under the Cape Verde archipelago. Most samples examined are four-phase lherzolites with modal clinopyroxenes up to 18% and no evidence of modal metasomatism. A few are characterised by the presence of metasomatic textures such as i) glassy patches with tiny subidiomorphic crystals of secondary olivine and clinopyroxene, and ii) rare spongy pyroxenes. Texturally, clinopyroxene often occurs as clusters of small crystals (<200 microns), whereas olivine and orthopyroxene are larger (up to 1 mm), suggesting a secondary origin for this clinopyroxene. A few samples show clear evidence of host magma infiltration, allowing us to discriminate the chemical effects of this process against processes related to mantle metasomatism, i.e. magma interaction at depth. Olivine, ortho- and clinopyroxene near basalt or in contact with basaltic veins crossing the samples systematically present lower mg# and Cr2O3, and higher TiO2 and Al2O3 contents between 59.6 wt% and 66.0 wt%, whereas the orthopyroxene has a more restricted mg# range (91.2-92.2). Clinopyroxene has mg# varying from 91.7 to 93.0, with Al2O3 from 0.98 to 4.43 wt%, without any correlation between the two parameters, which rules out the idea that it results from a simple depletion event. REE clinopyroxene patterns vary from ‘humped’ to ‘spoon-shaped’ at Yb at 3-6 x Ch, with strong LREE enrichment (La 7-117 x Ch). Silicate glasses, unrelated to host basalt infillations are present just in one sample. They are rather homogeneous in composition with silica contents between 59.6 wt% and 66.0 wt%, and alkali contents up to 15 wt% with Na/K < 1. On the whole they show fractionated trace element profiles with (La/Yb)N varying from 34 to 102. These preliminary petrographic and geochemical data for Sao Antao spinel lherzolites allow a comparison with the data and model proposed for Sal, an island to the east where lherzolites contain a sub-continental mantle component, and Santiago and Fogo to the south where the lherzolite is interpreted as the result of carbonatic metasomatism and wehrlite is probably cumulate from a large magma chamber system, again involving carbonatic activity.

Polymetamorphism in the Paleoproterozoic Ubendian Belt, Tanzania

Nelson Boniface and Volker Schenk

Institute für Geowissenschaften, CAU, 24098 Kiel, Germany (nb@min.uni-kiel.de, vs@min.uni-kiel.de)

The Paleoproterozoic (ca. 2.0-1.8 Ga) Ubendian-Usagaran orogens surrounding the SE and SW margins of the Archaean Tanzania craton contain eclogites of MORB-like chemistry which are among the oldest eclogite occurrences exposed in orogenic belts on Earth. Our study of metamorphic events by petrology and U-Pb SHRIMP dating of zircons is aimed to unravel the orogenic history of the Ubendian Belt southwest of the Tanzania Craton.

The Ubendian Belt has been subdivided into eight NW to SE elongated lithotectonic blocks the formation of which is interpreted to be of late Paleoproterozoic or Pan-African age. Lithologically the belt consists, besides minor eclogites, mainly of granitic gneisses, metapelites, some mafic granulites and amphibolites, i.e. rocks attributed to a continental environment. Melanite samples from the Wakole, the Ufipa and the Ubende terranes all revealed the same type of clockwise P-T path and thus a crustal thickening event dated with zircons (SHRIMP) at 1900±14, 1901±37, 1949±16 and 1817±26 Ma. Metamorphic mineral assemblages include biotite-muscovite-garnet-staurolite-kyanite and garnet-biotite-K-feldspar-kyanite (partly replaced by sillimanite). Peak metamorphic conditions were calculated for rocks of different parts of the belt and of different blocks. They range from 7kbar / 640°C over 9.4kbar / 670–800°C to 12.4kbar / 800°C, indicating low geothermal gradients during the crustal thickening event that was followed by a strong erosion of the crust.

Locally, metapelites of different parts of the Ubende block experienced a mylonitic overprint within the kyanite stability field. Zircon rims in these mylonites revealed a Kibaran overprint (1086±21 Ma), an age that is also found in metamorphic zircons of some non-mylonitic schists (1166±14 Ma) of that block.

Lenses of eclogites (meter to 100 meter scale) occur widespread in the Ubende and Ufipa blocks (over a distance of ca. 200 km). Some of these eclogites contain metamorphic zircons grown during a Pan-African eclogite-facies metamorphism at 520 to 590 Ma. However, at three localities the eclogite zircons contain inner metamorphic growth zones that revealed a Paleoproterozoic age (1877±20, 1886±16 Ma) in addition to the Pan-African age of the outermost rims (596±41, 548±39 Ma).

Neither the Kibaran mylonitic overprint nor the Pan-African eclogite-facies subduction metamorphism have been described so far. Their discovery demands major revision of the interpretation of the Proterozoic evolution along the southwestern margin of the Tanzania Craton.
Nano-scale interactions of fungi with mineral surface

S. BONNEVILLE AND L.G. BENNING
School of Earth and Environmental Sciences, University of Leeds, LS2 9JT, Leeds, UK
(s.bonneville@earth.leeds.ac.uk).

Classical studies of biotic weathering have mainly focussed on solution phase interactions with minerals and on the ability of plants and microorganisms to influence soil solution composition. Only recently, has the relevance of direct (contact) interactions between fungi and minerals been recognized as an important driver in weathering environments. This can be exemplified by the fungal components of lichen symbioses or the ectomycorrhizal association between plants and fungi.

For ectomycorrhiza, the distal tree roots are closely interconnected with a dense fungal mycelium network in which hyphal strands interact directly with soil organic and/or mineral surfaces. These fungal extensions are sustained by the photosynthate of the trees, and in return, they solubilize minerals and directly aid the mass transfer of a large array of elements (e.g. P, N, K, Zn, Fe, Cu etc) towards the tree roots. The exudation of protons, ligands and siderophores by hyphae tips has been suggested as the main factor controlling the weathering of minerals. However, the fungi are in close contact with the mineral surface and therefore may destabilize the lattice structure of the mineral surface, yet this dissolution process has been largely overlooked and our contribution intends to fill that gap.

In this study, we investigated the weathering of biotite induced by Sullus bovinus hyphae grown in symbiosis with Pinus sylvestris trees grown on biotite substrates within agar-perlite systems. The fungal-mineral systems were maintained under sterile conditions and fungal hyphae were allowed to colonize the biotite surface (around one cm²) for about ~ three months before removal of the mineral substrate for analysis. Half of the biotite sample was treated with a detergent to remove the fungal material and expose the weathered surface. This exposed surface was subsequently analysed by Vertical Scanning Interferometry (VSI) to quantify any changes in the biotite surface microtopography and to determine the weathered biotite volume. The other half of the biotite sample, was used for Focus Ion Beam (FIB) sections (~ 100 nm thick, 15 µm long by 5 µm wide) with sections cut across several mature filaments or across terminal hyphae segments. These sections were transferred onto TEM grids and characterized using Electron Energy Loss Spectroscopy (EELS), Energy Dispersive Spectroscopy (EDS) and Energy-filtering TEM (EFTEM). These techniques allows (i) the determination of the mass loss upon hyphae-mineral surface interaction (ii) the quantification of chemical bonds between hyphae and the biotite surface, (iii) the imaging of secondary mineral phases at the interface and (iv) quantification of uptake of elements from mineral to fungi at the molecular scale.

Dolomite nucleation on extracellular polymeric substances

TOMASO BONTOGNALI, CRISOGONO VASCONCELOS, ROLF WARTHMANN AND JUDITH A. MCKENZIE
ETHZ, Geological Institute, 8092 Zurich, Switzerland
(tomaso.bontognali@erdw.ethz.ch)

Research in natural environments, in conjunction with laboratory culture experiments, has demonstrated that microbes can induce low-temperature dolomite formation. Nevertheless, the exact mechanism and the ecological significance of the process remain unclear.

Here, we present a laboratory experiment designed to determine whether dolomite nucleation is an active microbial process at the cell wall or a passive process associated with microbially produced organic compounds. Pure strains of Desulfovibrio brasiliensis, a dolomite producing bacterium, were initially grown at 30°C under anoxic conditions in a medium whose chemical composition prevents dolomite formation. The cultures were subsequently sterilized and the chemical composition of the medium modified to permit carbonate precipitation. At this time, nucleation of Ca-dolomite occurred in the absence of living bacteria, but in the presence of fresh extracellular polymeric substances (EPS) previously produced by D. brasiliensis.

Our results suggest a key role for EPS in dolomite formation. In contrast, excretion of metabolites and nucleation on the cell wall appear less important for the process. We propose that EPS acts as a structural template at the molecular scale which, absorbing and ordering ions in a preferential way, promotes dolomite formation at 30°C. Our experiments show how microbial activity may induce biomineralization through the excretion of specific organic molecules in the environment. The occurrence of such biominerals may be unexpected if only the inorganic chemistry of the solution were considered.
Partitioning of Rb and Sr between haplogranitic melts and aqueous fluids: Information from in situ experiments using SR-XRF

M. BORCHERT1, M. WILKE1, C. SCHMIDT2, K. RICKERS-APPEL3 AND J. KOEPKE4

1Universität Potsdam, Karl-Liebknecht-Str. 24, 14476 Potsdam-Golm (manu@geo.uni-potsdam.de)

3HASYLAB/DESY, Notkestr. 85, 22607 Hamburg
4Universität Hannover, Callinstr. 3, 30167 Hannover

Knowledge of the partitioning of trace elements between silicate melts and coexisting aqueous fluids is essential for the understanding of mass transfer during late stage magmatic processes. Fluid-melt partitioning depends on numerous parameters such as temperature, pressure, chlorinity and pH of the fluid, and the composition of the melt. Although there are several experimental studies on trace element partitioning in various fluid-melt systems [e.g. 1, 2, 3], the effect of many compositional parameters is still insufficiently known.

We investigated the partitioning of Rb and Sr between synthetic haplogranitic melts and an aqueous NaCl fluid at 750°C and 200 MPa using cold-seal pressure vessels. The resulting partitioning coefficients (Df/m = Cf/Cm) scatter up to a factor of 5. This scatter may be caused by 1) changes in the fluid composition during quenching, 2) fluid loss during extraction from the capsules or 3) feldspar formation during the runs. Therefore, we determined the concentrations of Rb and Sr in the aqueous fluid coexisting with the melt directly at high P and T using a hydrothermal diamond-anvil cell (HDAC) and SR-XRF analyses [4]. The in-situ experiments were done at the SR-XRF microprobe at beamline L of DORIS III at HASYLAB/DESY. A glass chip doped with 2500 ppm Rb and Sr and an aqueous solution were loaded into the sample chamber of the HDAC, which was then heated to 750 °C. Equilibrium was attained in less than 20 min, as indicated by consecutive XRF spectra of the fluid. Because it was not possible to analyse the melt droplets without a contribution from the aqueous phase to the XRF signal, the Rb and Sr concentrations in the melts were measured on the quenched glass using EMP. For pure water as starting fluid, a Rb concentration of 322 ± 23 ppm was obtained in situ at 750°C and 200 MPa in the aqueous phase, which resulted in a Df/m of 0.129 ± 0.013. This is much higher than a Df/m of 0.006 at 750°C and 200 MPa reported in the literature [5] obtained from analyses of quench fluid and glass.

Dissolution of iron (hydr)oxides by siderophores is a process that potentially contributes to the generation of bioavailable iron in marine waters. We have recently shown that the ligand-promoted dissolution of lepidocrocite (γ-FeOOH) by model siderophores (aerobactin and desferrioxamine B) is enhanced at pH 6 under simulated sunlight [1]. Based on that study we hypothesized that the photoreactive α-hydroxycarboxylic acid moiety within aerobactin is not involved in the inner-sphere coordination at the surface of lepidocrocite. The enhanced dissolution of lepidocrocite was explained in terms of the intrinsic photoreactivity of the oxide phase itself and not by a light-induced photolysis reaction of adsorbed aerobicactin. To verify the above hypothesis, extensive batch dissolution experiments with aerobactin and the non-photoreactive desferrioxamine B were conducted between pH 3 and pH 8 in the dark as well as under irradiation. Adsorption isotherms were determined and the potential readsorption of Fe(III)-siderophore complexes was evaluated. Based on these results a kinetic rate law for the dissolution of lepidocrocite was formulated for both desferrioxamine B and aerobactin. The calculated dissolution rate constants for the two model siderophores between pH 5 and pH 8 were very similar. This is a strong indication that aerobactin forms inner-sphere surface complexes by the coordination of the terminal hydroxamic acid moieties (as is the case for desferrioxamine B) and not by the photoreactive α-hydroxycarboxylic acid moiety.

³Pakistan Museum of Natural History, 44000 Islamabad, Pakistan.

The Kohistan Arc complex (KAC), in northern Pakistan, represents the exhumed section of an island arc formed within the Neo-Tethys ocean during the Mesozoic. This complex has been obducted during the Late Cretaceous-Palaeocene onto the Indian plate along the Indus Suture. Lower to mid-crustal level rocks of the Jijal and Patan-Dasu metaplutonic complexes represent the plutonic roots of the KAC section studied, accreted during the ~115-85 Ma time interval. The Jijal sequence, the deepest exhumed part of the KAC, is subdivided into a basal ultramafic section and an upper gabbroic zone of granulite facies rocks. The Patan-Dasu metaplutonic complex, more than 22km-thick, is mainly composed of gabbros and amphibolites more or less metamorphosed. Field and petrological investigations combined with detailed Sr-Nd-Pb isotopic and REE analyses performed on whole rocks, plagioclase and clinopyroxene from representative samples across the Jijal and Patan-Dasu sequences allow us to propose a three-stage geodynamical model covering the complete arc evolution through ~30 Ma. The present work is mainly focused on the temporal constraints of this model. The “in-situ” LA-ICPMS U-Pb analyses have been performed on zircons separated from the different lithologies belonging to the three identified steps of the KAC evolution and they provide temporal constraints of the main stages of this model. The model starts with the onset of the subduction at 118±7 Ma [1, 2] and is followed by the building of the volcanic arc. The 2nd stage corresponds to a major thermal event, characterized by abundant magma underplating and by granulitisation of the arc base at 95.8±1.3 Ma. The last stage, between ~95 and 88 Ma seals the end of the intra-oceanic subduction and corresponds to a limited magmatic period. A voluminous, but short, magmatic pulse occurred at ~88-80 Ma and corresponds to the Chilas complex emplacement.

The Cabo Verde archipelago, located in the Atlantic between 15 and 17°N, is composed of 10 principal volcanic islands forming two lineaments converging eastward (the Northern and Southern Islands). It occurs over the Cabo Verde Rise, an oceanic mega-swell, considered as the result of a mantle plume (Montelli et al. 2006). Those two groups of islands have been considered distinct based on the geochemical (elemental and isotopic) characteristics of the magmatic rocks (Gerlach et al., 1988; Doucelance et al., 2003). Morphological observations and historical volcanic activity argue in favour of a westward migration of the magmatism during the last 20 Ma. However, to date, the age progression of the Cabo Verde islands has not been yet clearly demonstrated by detailed geochronological studies at the scale of the whole archipelago.

We present here 15 new ⁴⁰Ar-³⁹Ar ages obtained on volcanic rocks from São Vicente, São Nicolau, Northern Islands, on one hand, and from Santiago, Southern Islands, on the other hand. Analyses were performed on whole rock samples for which chemical and isotopic characteristics have been previously studied in details. ⁴⁰Ar-³⁹Ar ages range from 6 Ma to 700 ka, from 2.6 Ma to 700 ka and from 3.8 to 1.5 Ma in São Vicente, São Nicolau and Santiago, respectively. Together with previous published ⁴⁰Ar-³⁹Ar and K-Ar studies, these new geochronological results show that the age distribution cannot only be related to the spatial distribution of the islands along the Northern and the Southern segments. We will discuss the temporal evolution of volcanic activity considering the following spatial scales: 1) single island, 2) Northern and Southern segments, 3) whole archipelago.

The late-stage evolution of oceanic gabbros - Combined experimental and in situ isotope study on gabbros from Southwest Indian Ridge

R.E. BOTCHARNIKOV, J. KOEPKE, I. HORN AND F. HOLTZ
Institut Mineralogie, Callinstr.3, Leibniz Universität Hannover, 30167 Hannover, Germany
(r.botcharnikov@mineralogie.uni-hannover.de)

Gabbroic rocks from Hole 735B at the Southwest Indian Ridge (SWIR; Legs 118 and 176), represent the longest continuous section of oceanic lower crust ever drilled by ODP (Ocean Drilling Program). About 25% of the core is strongly influenced by late-stage magmatic processes leading to Fe-rich (ferrogabbros) and Si-rich (plagiogranites) compositions as end-members. The study of natural ferrogabbros from SWIR reveal that the typical ferrogabbroic paragenesis is ilmenite ± pargasite ± magnetite ± apatite ± orthopyroxene. Phase equilibria experiments at P=200 MPa and T=900-1050°C show that Fe-Ti oxides are the liquidus phases, even at reducing conditions, leading to dramatic depletion of residual melts in FeO and TiO₂ from the beginning of crystallization. Thus, it is very unlikely that the ferrogabbroic assemblages are formed by simple differentitation of Fe-rich basaltic melts. Remarkable is that plagioclase and clinopyroxene are normally absent in natural paragenesis while these phases are stable in phase equilibria experiments. On the other hand, amphibole and orthopyroxene are typical for natural late-stage gabbros and completely absent in our experimental products. However, amphibole + orthopyroxene + An-rich plagioclase are main phases formed in partial melting experiments on gabbros [1]. These observations indicate again that the late-stage high-temperature evolution of the gabbroic suites in the lower oceanic crust can not be simply related to the differentitation of basaltic liquids but requires additional mechanisms operating in the still-hot gabbroic rocks. Potential processes responsible for the formation of mineral assemblages in ferrogabbros could be: impregnation of gabbroic protolith with accumulated phases crystallized in a late-stage melt, partial melting of gabbroic cumulates due to reaction with water-rich fluids and/or precipitation from an immiscible iron-rich silicate liquid.

In situ LA-MC-ICPMS analyses of Sr isotopes in late-stage parageneses in natural rocks were applied to discriminate between hydrous primary magmatic, and seawater-induced late-stage processes. First in situ Sr isotope analyses on An-enriched plagioclases, which are regarded to be formed during late-stage hydrous partial melting process, show seawater signatures. However, the Sr isotope analysis in such phases is a challenge due to the very low Sr contents of the plagioclases (less than 100 ppm Sr). Therefore, additional efforts are required to improve the reliability of this method.

4Department of Geosciences, University, D-28359 Bremen

Reduced carbon is mineralized in marine sediments by microbial activity using predominantly oxygen, sulfate, and metal oxides as electron acceptors. Besides DOC compounds, methane can be oxidized to carbon dioxide. Both, CO₂ and CH₄ are strong green-house gases that may be liberated from the sediments into the bottom waters or the atmosphere. The partitioning of stable carbon isotopes is useful for the biogeochemical transformations of different C sources and is used here to identify the key reactions in the C-S cycles of intertidal surface sediments. Sediments and pore waters (top 20 cm) from intertidal sands of the back-barrier tidal areas of Spiekeroog and Sylt islands (southern and eastern North Sea) have been investigated on a seasonal base, and are analyzed for a number of geochemical parameters as, for instance, TOC, TIC, DIC, TA, methane, SRR, salinity, pH, sulfate, sulfide, and the carbon isotopic compositions of substrates and products.

Results indicate that DIC is dominated by products derived from organic compounds besides exchange via the sediment-water interface, with bioturbation having important effects. Below reduced sulfidic sediment surfaces, the isotopic composition of DIC down to -40 per mil indicates CH₄ (60 per mil) derived from the oxidation of methane as an important source. These sites promote an energy transfer from the sediments to the bottom waters.

Weathering over a large range of erosion solid products: Insights from Amazon river depth-samplings

J. BOUCHEZ¹, J. GAILLARDET¹, C. FRANCE-LANORD², V. GALY² AND L. MAURICE-BOURGOIN³

¹IPGP, 4, Place Jussieu, 75252 Paris cedex 05, France (bouchez@ipgp.jussieu.fr)
²CRPG, BP 20, 54501 Vandoeuvre les Nancy, France
³LMTG, 14 Avenue Edouard Belin, 31400 Toulouse, France

Continental erosion processes produce dissolved material plus sediments. The latter are heterogeneous in terms of mineralogy, grain size, chemical composition and weathering intensity. Within large rivers, these particles are vertically sorted during their transport to the oceans, following their physical properties and stream hydrodynamics.

In order to take in account this internal variability, we sampled the Amazon along depth profiles, and carried out granulometric and chemical analysis of suspended sediments as well as bedload.

The vertical profiles of suspended sediments concentration increase exponentially downward, and can be explained by a simple sedimentary transport model, based on an equilibrium between sedimentation velocity and bedload turbulent diffusivity. This model allows depth-integrated estimates of Amazon suspended matter fluxes (total and elemental) to the oceans.

Major elements composition, along with microscopic and mineralogic analysis, shows a rather strong evolution from clay-dominated sediments near the surface towards quartz and other silicon-rich minerals downward.

The weathering indexes of Na, K and Ca (as defined by Gaillardet et al. (1999)) in the sediments of the Solimoes river, show respectively a three-fold, two-fold and two-fold increase from the bottom to the surface. In Madeira surface sediments, the apparent depletion in soluble elements is amplified by a factor of two by the granulometric sorting with respect to the integrated weathering index.

The results obtained on the Amazon system are compared with those from the Ganga-Brahmaputra system (Ga by et al., submitted) and are interpreted in terms of weathering/erosion intensities, bedrock lithology and rivers hydrodynamics.

Root zone of sheeted dike complex in Oman ophiolite-petrological model

F. BOUDIER¹, J. KOEPKE², L. FRANCE¹ AND C. MEVEL³

¹Univ. Montpellier II, France (boudier@gm.univ-montp2.fr)
²Institut fuer Mineralogie der Universitaet Hannover, Germany (koepke@mineralogie.uni-hannover.de)
³IPGP, Paris (mevel@ipgp.jussieu.fr)

Recently, IODP (Integrated Ocean Drilling Program) has penetrated in the eastern Pacific Ocean (Hole 1256D) the root zone of the sheeted dike complex (RZSDC). In Oman ophiolites, it is a well exposed horizon ~100m thick between the main gabbro unit and above, the crustal lid (sheeted dikes and lavas). To compare with the IODP hole, a new petro-structural study was conducted in Oman. We explain this complex zone by interference between the magmatic system of the melt lens present in fast spreading ridges, and a hydrothermal system operating at very high temperatures penetrating down to the roof of this lens where it induces successive stages of hydrous anatexis. This results in a crude stratigraphy throughout the RZSDC with doleritic isotropic gabbros evolving upwards in vari-textured, pegmatitic gabbros and trondjhemite intrusions. New melt intrusions from the melt lens proceed through basaltic ‘protodikes’ which are, in the RZSDC, a relay to the overlying sheeted dikes. Injected in gabbros still at solidus temperature, protodikes develop against these gabbros a typical microgranular margin. The following phase diagram constructed for pressure 50MPa, issued from Feig et al., 2006 allows to follow the sequence of formation of the successive magmatic facies described in the RZSDC.

Disturbance of the monazite U-Th-Pb chronometer by fluids: A study combining stable isotopes and in situ dating

P. BOULVIAI, V. BOSSE, P. GAUTIER, M. TIEPOLO, G. RUFFET and J. L. DEVIDAL

1 Geosciences Rennes (UMR 6118, CNRS), Université de Rennes 1, France (Philippe.Boulvais@univ-rennes1.fr, Pierre.Gautier@univ-rennes1.fr)
2 Laboratoire Magmas et Volcans (UMR 6524 CNRS), Observatoire de Physique du Globe de Clermont Ferrand, France, (V.Bosse@opgc.univ-bpclermont.fr, J.L.Devidal@opgc.univ-bpclermont.fr)
3 CNR - Istituto di Geoscienze e Georisorse, Università de Pavia, Italia (tiepolo@crystal.unipv.it)

The monazite U-Th-Pb chronometer is extensively used to date metamorphic rocks because it is usually considered to be resistant to diffusive Pb loss at temperatures as high as 800°C. However, age perturbations are sometimes documented in monazite grains showing distinct compositional and age domains. The mechanism by which Pb is lost is not well understood. Fluid-assisted recrystallization has been shown to constitute an efficient mean to reset the monazite chronometer in experimental conditions (Seydoux-Guillaume et al. 2002). Whether the same holds true in natural systems remains to be documented.

Here we present in situ U-Th-Pb ages on monazite from foliated pegmatitic veins from highly strained levels of the Central Rhodope metamorphic pile (Greece, Bulgaria), together with oxygen isotopic characterization and 40Ar-39Ar data. U-Th-Pb ages were obtained by (LA)-ICPMS on 8 monazite grains from three samples. In one sample from Bulgaria, the ages are concordant at 35 Ma, and no chemical zonation is observed. Quartz and feldspar have δ18O values consistent with equilibration at high temperatures. Microfabrics in the vein and the host rocks indicate high grade conditions of deformation. In the two other samples, from Greece, monazite grains show distinct chemical domains and yield discordant U-Th-Pb ages ranging from 52 to 36 Ma. Strong oxygen isotope disequilibrium between quartz and feldspar argues for a complex fluid history: high-δ18O fluids first invaded rocks and were followed by low-δ18O fluids at lower temperatures. Low temperature fluid circulation at around 36 Ma is consistent with 40Ar-39Ar dating of both samples at 33-34 Ma (mica plateau ages) and with microfabrics documenting a transition from high grade to greenschist facies conditions of deformation during intense shearing. These data confirm the capacity of fluids in disturbing significantly the monazite chronometer.

Uranium isotope ratios determined by MC-ICP-MS and the assessment of total combined uncertainty budgets

S.F. BOULYGA, U. KLÖTZLI and T. PROHASKA

1 Department of Chemistry, Division of Analytical Chemistry-VIRIS Laboratory, University of Natural Resources and Applied Life Sciences, Vienna, Austria (sergei.boulyga@boku.ac.at)
2 Center of Earth Sciences, University Vienna, Vienna, Austria (urs.klotzli@univie.ac.at)

Precise determination of uranium isotopic composition is required in nuclear environmental and geologic studies. Particular applications imply determination of extremely low 234U/238U quantities in the presence of a large excess of 235U and 236U which represent severe sources of interference in determinations of 238U.

A multi collector inductively coupled plasma mass spectrometer (MC-ICP-MS) - Nu Plasma HR - equipped with an ion deceleration filter was applied for rapid and sensitive determination of 234U/238U, 235U/238U and 236U/238U isotope ratios in aqueous samples on a concentration level typical for digested environmental samples. Application of the ion deceleration lens system in Nu Plasma ICP-MS improved significantly the abundance sensitivity and made possible the analysis of 238U/238U isotope ratios in the 10⁻⁸ to 10⁻⁷ range. On the other hand, using the ion deceleration lens for determination of 236U/238U isotope ratios above 10⁻⁵ was found disadvantageous because it might introduce additional uncertainty. Accuracy of uranium isotope ratio measurements by MC-ICP-MS was evaluated by analysis of unknown samples obtained in the frame of a round robin exercise as well as by comparative measurements using sector-field ICP-MS with single ion detector and thermal ionization mass spectrometry (TIMS). Combined uncertainty of measured ratios ranged from 0.17% to 0.20% for 235U/238U, from 1.0% to 1.1% for 234U/238U and from 1.3% to 53% for 236U/238U. The main uncertainty contribution component to the 235U/238U ratio measured by MC-ICP-MS is the uncertainty of the applied isotopic standard. The uncertainty budget for 236U/238U strongly depends on the abundance of 238U. In particular, peak tailing and interference by 235U¹H⁺ ions increased the measurement uncertainty in the case of 236U/238U lower than 10⁻⁷. Nevertheless, accurate determination of 236U/238U isotope ratios as low as 3x10⁻⁸ was possible, which opens new possibilities for tracing this isotopes in environmental samples by using MC-ICP-MS, in particular with respect to its better time-effectiveness and lower labor expenses when compared to other highly sensitive mass spectrometric methods.
Weathering rates from top to bottom in a carbonate environment

BERNARD BOURDON\textsuperscript{1}, SARAH BUREAU\textsuperscript{1}, MORTEN ANDERSEN\textsuperscript{1,2} AND ERIC PILI\textsuperscript{3}

\textsuperscript{1}Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich CH-8092, Zurich, Switzerland (bourdon@erdw.ethz.ch, bureau@erdw.ethz.ch)
\textsuperscript{2}Dept. of Earth Sciences, University of Bristol, United Kingdom (morten.andersen@bris.ac.uk)
\textsuperscript{3}CEA Département Analyse Surveillance Environnement, 91680 Bruyères le Châtel, France (eric.pili@cea.fr)

It is generally thought that most of the weathering reactions take place near the surface of the Earth but the contribution from deeper water circulation is less well quantified. Yet, the groundwater fluxes needs to be assessed as a recent study has inferred that up to 20\% of the weathering flux could be coming from the base flow. To address this issue, we have investigated weathering rate in a double-porosity carbonate environment by measuring U-series isotopes from the soil’s surface down to a depth of \(~70\) m to determine the rates of dissolution. The samples we analyzed include soils, drill cores, fracture and matrix fluids. The samples were all analyzed by MC-ICPMS for U and Th isotopes. The solid samples were also analyzed for trace element concentrations by ICP-MS.

The results show quite clearly preferential mobility of U throughout the profile but with a much larger effect in the first meter below the surface. The surface samples show the greatest \(230\)Th excess together with moderate depletion in \(234\)U relative to \(238\)U. Accordingly, the \(230\)Th/\(232\)Th ratios and the relative abundance of mobile trace elements are lower in the surface layers, which can be interpreted by faster dissolution of carbonates near the surface together with an enrichment in residual silicates. In this environment, the dissolution of carbonates can be easily distinguished from silicate dissolution and the dissolution rates results in a net removal of Th (and U). Redeposition of Th derived from the carbonate by adsorption or precipitation in secondary phases is not effective.

The combined \(234\)U-\(238\)U and \(230\)Th-\(238\)U systematics also allows to quantify the relative dissolution rates in the soil horizons compared with deeper horizons in the bedrock. In the surface horizons, the U-series signature can be thought of as being dissolution-dominated while in the deeper layers, it indicates slower dissolution and larger effects of recoil on \(234\)U-\(238\)U systematics. Preliminary modelling suggests that dissolution rates can vary by a factor of 10 faster near the surface (with the slowest rate obtained for a clay-rich cap rock). At depth, there is generally slower dissolution and even reprecipitation of carbonates.

An isotope and PGE perspective on the mantle xenoliths from Marsabit Volcanic field (Kenya Rift)

ERWAN BOURDON AND ANGELIKA KALT
IGH, Université de Neuchatel, Emile Argand 11, CP 168, 2009 Neuchatel, Switzerland.

PGE and Os isotopes have been determined in 14 well-characterized spinel peridotite xenoliths from the Marsabit volcanic field (Kenya Rift) pertaining to 3 different groups previously distinguished based on their textural characteristics (porphyroelastic (I) and recrystallized (II) spl-lherzolithe and porphyroelastic hazburgites (III) (Kaeser \textit{et al.}, 2006).

The overall total PGE contents of Marsabit xenoliths (Total PGE between 14 and 32 ppb) shows a rather restricted range.

Whether coarse-grained, recrystallized, deformed, virtually anhydrous or modally metasomatized, all peridotites have Pd-depleted PUM-normalized PGE patterns probably inherited from an old (archean?) partial melting event. This is confirmed by the crude correlation existing between the Ol or Cpx modal content of the rocks and their total PGE, Pd/Ir ratio or Al\textsubscript{2}O\textsubscript{3} whole rock content. However the shape of PGE patterns can greatly vary between or within different peridotite groups and probably reflects differing recent magmatic history and/or ancient metasomatism.

Calculated Re depletion ages indicate 2 possible melting events around 2 Ga (Archean – for Group III) and around 650 Ma (Panafrican? for Group II and III). Group I consistently gives future ages and its Os isotope characteristics suggest some addition of radiogenic Os (either through metasomatism or mingling between peridotite and pyroxenite).

Preliminary Sr-Nd-Pb isotopic data show that the most refertilized lherzolithes (Group II and III) display unradiogenic signatures (cpx, or wholerock) incompatible with plume-type metasomatism enrichment.

High biological productivity takes place on the Kerguelen Plateau in the Indian sector of the Southern Ocean known to be a HNLC region. Natural iron fertilization is suspected in that area. One goal of the KEOPS project is to understand the mechanisms controlling iron fertilization. Ra isotopes that are produced in the sediment and diffuse in the water column may be a good analogue for tracing the input of sedimentary iron and its fate on the Kerguelen Plateau. We measured all four radium isotopes during KEOPS (\(^{224}\text{Ra},\) \(^{223}\text{Ra},\) \(^{228}\text{Ra},\) and \(^{226}\text{Ra}\)) in seawater in order to provide information on the water mass pathways on the Kerguelen plateau. We also measured dissolved Ba concentrations, Ba being a chemical analogue of Ra. Here we report \(^{226}\text{Ra}\) activities and \(^{226}\text{Ra}/\text{Ba}\) ratios obtained during repeated visits of station A3 located in the middle of the bloom area on the Kerguelen Plateau. We compare these data to those obtained outside the plateau, in the HNLC area. We observe a pronounced temporal variability in the \(^{226}\text{Ra}\) activities and \(^{226}\text{Ra}/\text{Ba}\) ratios found at station A3 suggesting that the dynamic system has changed during the repeated visits or that biological activity significantly impacts \(^{226}\text{Ra}\) activities and \(^{226}\text{Ra}/\text{Ba}\) ratios.

**Geochemistry of primary magmas of St Vincent (Lesser Antilles Arc) tracked by melt inclusions**

A.-S. BOUVIER\(^1\), N. MÉTRICH\(^2\) and E. DELOULE\(^1\)

\(^1\)CRPG-CNRS, Nancy, France (abouvier@crpg.cnrs-nancy.fr; deloule@crpg.cnrs-nancy.fr)

\(^2\)LPS, CNRS-CEA, Saclay, France (nicole.metrich@cea.fr)

The Lesser Antilles arc volcanism results from the subduction of the Atlantic plate beneath the Caribbean plate. Lavas are dominantly andesitic, but MgO-rich basalts are found in the south part of the arc (St-Vincent, Grenade islands). Major, trace elements and isotope geochemistry on whole rocks, as experimental works, suggest that magmas are generated by the melting of a N-MORB type mantle source contaminated by at least two components, involving fluids derived from subducted oceanic crust and sediments. However, the nature and the relative influence of each components and the importance of the crustal contamination are still debated (Macdonald et al., 2000). In order to discriminate the importance of these different contributions, we undertook the analysis of melt inclusions trapped in olivines of basaltic scoriae (MgO> 12.5 wt%) of St-Vincent. Major elements of more than 200 melt inclusions are measured by electron microprobe SX50, and \(\text{H}_2\text{O}, \text{Li, CI, F, } \delta^7\text{Li, } \delta^{11}\text{B, } \delta^{18}\text{O}\) of 50 melt inclusions are determined by SIMS 1270. Chemical and isotopic characterisations point out a broad variability for all the analysed elements. Major elements indicate a differentiation trend, and a second trend with lower SiO\(_2\) and higher CaO than whole rocks. B, CI and H\(_2\)O are variably enriched compared to MORB, \(\delta^7\text{Li}\) values range from -10 to +7‰, \(\delta^{11}\text{B}\) from -16 to +12‰, and \(\delta^{18}\text{O}\) from +3 to +10‰. These variations reflect addition of contaminants. Melt inclusions provide new data which confirm that primary magmas of St-Vincent are generated by melting of a N-MORB type mantle source weakly affected by the addition of fluids derived from the dehydration of AOC and the melting of sediments.

The Lu-Hf CHUR value

A. BOUVIER, J.D. VERVOORT AND P.J. PATCHETT

1Department of Geosciences, University of Arizona, Tucson, AZ, USA (abouvier@email.arizona.edu)
2School of Earth & Environmental Sciences, Washington State University, Pullman, WA, USA (vervoort@wsu.edu)
3Department of Geosciences, University of Arizona, Tucson, AZ, USA (patchett@email.arizona.edu)

Lu-Hf and Sm-Nd isotopic systems involve refractory and lithophile elements, so that the composition of Bulk Silicate Earth (BSE) should coincide with that of the Chondritic Uniform Reservoir (CHUR). BSE reference for Lu-Hf was first plotted within the terrestrial Hf-Nd isotopic array [1], and since 1997 lies just below it [2]. This raises questions of a possible hidden reservoir in the terrestrial mantle, or alternatively, a discrepancy with the CHUR parameters employed. Determination of CHUR Lu-Hf is hampered by the ~20% variation in Lu/Hf among the ordinary (OC) and carbonaceous chondrites (CC) analyzed previously [2-4], a contrast with Sm/Nd which varies by only ~3%. The Lu-Hf CHUR parameters were determined from a mean value for OC, mostly petrologic types 4 to 6, plus the two CC, Allende (CV3) and Murchison (CM2), and yielded $^{176}\text{Lu}/^{177}\text{Hf} = 0.0332 ± 2$ and $^{176}\text{Hf}/^{177}\text{Hf} = 0.282772 ± 29$ [2].

We analyzed 20 new chondrites for Lu-Hf and Sm-Nd isotope systematics. These included: (i) thirteen H, L, and LL OC of types 3.0 to 3.8, where their low degree of metamorphism limits the growth of phosphate (main carrier of REE) compared to the equilibrated types 4 to 6 OC; and (ii) seven CC of types 1 to 3 (CI, CV, CO and CK groups). We obtained mean values ($2\sigma$ SE) of $^{176}\text{Lu}/^{177}\text{Hf} = 0.0337 ± 3$, $^{176}\text{Hf}/^{177}\text{Hf} = 0.282802 ± 23$, $^{147}\text{Sm}/^{144}\text{Nd} = 0.1961 ± 6$, and $^{143}\text{Nd}/^{144}\text{Nd} = 0.512629 ± 16$ from the types 1 to 3 OC (n=11) and CC (n=11) from this study (n=18) and [4] (n=4). These values are our best estimates for CHUR and BSE. The CC alone give higher mean values of $^{176}\text{Lu}/^{177}\text{Hf} = 0.0341 ± 4$, $^{176}\text{Hf}/^{177}\text{Hf} = 0.282828 ± 38$, $^{147}\text{Sm}/^{144}\text{Nd} = 0.1966 ± 10$, and $^{143}\text{Nd}/^{144}\text{Nd} = 0.512639 ± 28$. These last values are concordant with the Sm-Nd CHUR parameters that have been widely used since 1980 [5], but CC may not provide the best approximation for BSE.

The $^{176}\text{Lu}/^{177}\text{Hf}$ range obtained from all the types 1 to 3 OC and CC is now constrained to ~4%, similar to Sm/Nd. The mean values of $^{176}\text{Lu}/^{177}\text{Hf}$ and $^{176}\text{Hf}/^{177}\text{Hf}$ are higher than the previous estimates and reconcile the chondrite composition with the mantle array, removing any need for a hidden reservoir affecting Lu-Hf systematics. The ~20% range of Lu/Hf observed in type 4 to 6 chondrites must reflect metasomatic processes on the OC parent bodies associated with their thermal metamorphism.

4Section des Sciences de la Terre, Université de Genève, Geneva, Switzerland (blair.schoene@terre.unige.ch)

One emphasis of the EARTHTIME project (www.earth-time.org) is understanding the power and limitations of high-precision U-Pb geochronology towards sequencing earth history at high precision. This involves establishing absolute chronologies both for sequences of fossil-bearing rocks and for testing models for astronomical forcing of sedimentation.

In the past decade, progress in imaging and microsampling of zircon domains prior to analysis, pre-treatment using the CA-TIMS method of Mattinson (2005), and the ability to make high-precision isotopic measurements on as little as 1-10 picograms of radiogenic Pb has revolutionized U-Pb geochronology.

With high precision and high spatial resolution has come recognition of previously underappreciated complexities that introduce both internal and systematic errors. These range from intermediate daughter product disequilibria, to distinguishing small amounts of Pb loss from protracted from intermediate daughter product disequilibria, to introduce both internal and systematic errors. These range recognition of previously underappreciated complexities that geochronology.

10 Ma. Integration of U-Pb and 40Ar/39Ar geochronology is necessary to address the above complexities. We are making differentials from simple one-stage mixing by the addition of the time dimension to the composition data. These crystals appear to have shared a considerable portion of their growth histories, with similar cores and growth patterns – up until a point when they diverged greatly, suggesting that crystals in various parts of the magma system record different but related versions of the magmatic volatile story.

A high resolution time-sequential record of magmatic volatiles from apatite phenocrysts

JEREMY W. BOYCE AND RICHARD L. HERVIG

School of Earth and Space Exploration, Arizona State University. Box 871404 Tempe, AZ, USA. (jwboyce@asu.edu)

Understanding the time-dependent variation of volatile elements in magmatic systems is essential to the study of the generation, evolution, and eruption of magmas. The mineral apatite is capable of recording volatile variations, commonly incorporating H, F, and Cl as major components, with smaller amounts of C and S usually present. Unlike melt inclusions, which are often difficult to place in a relative temporal context, apatite crystals grow from core to rim (in the absence of resorption) providing a sequential record of volatile changes in the coexisting magma.

Using Secondary Ion Mass Spectrometry (SIMS), we have analyzed H, F, and Cl in several apatite phenocrysts from the Cerro Galan ignimbrite, Argentina. For each crystal, a traverse of individual spots was performed on polished sections in the C-axis direction. A 10nA, ~20µm O primary beam was rastered ~20µm and used to sputter positive secondary ions: 1H, 12C, 19F, 28Si, 31P, 37Cl and 43Ca. Ions with initial kinetic energies of 75±20 eV, originating from the central 9µm region, were allowed into the mass spectrometer.

Traverses of 40-60 spots at 4-7µm spacing were obtained on several crystals. Most apatite phenocrysts contain homogeneous OH-rich cores (~4000ppm), mantled with oscillatory but generally lower OH concentrations. Chlorine data describe apparently related patterns, with homogeneous cores (~5000ppm) and oscillatory rims (~ up to 1500ppm), with similar patterns observed in several crystals. Fluorine variations are less well-resolved relative to analytical uncertainties, but are generally increasing towards the rim and inversely related to OH.

Relationships between OH, F, and Cl are most easily explained as parametric functions of relative time as defined by core-to-rim stratigraphy. Knowing volatiles as a function of time allows us to convert cryptic clouds of data into a history of the growth of this crystal, which give us clues as to the volatile evolution of the magma. Apatite core regions represent either growth in a stable magma chamber or residence in a stable magma chamber where any pre-existing volatile variations were homogenized. After this period of relative quiescence, these apatite crystals experienced cycles of magma mixing and or degassing – cycles which can only be differentiated from simple one-stage mixing by the addition of the time dimension to the composition data. These crystals appear to have shared a considerable portion of their growth histories, with similar cores and growth patterns – up until a point when they diverged greatly, suggesting that crystals in various parts of the magma system record different but related versions of the magmatic volatile story.
Early Lunar Differentiation and the Earth-Moon Connection

MAUD BOYET1,2 AND RICHARD CARLSON2

1Universite Jean Monnet, St. Etienne, France
2Carnegie Institution of Washington, Washington, DC, USA

Coupled $^{146}$Sm-$^{142}$Nd ($T_{1/2}=103$ Myr) and $^{147}$Sm-$^{143}$Nd ($T_{1/2}=103$ Gyr) systematics were analyzed on lunar samples that span the range of source compositions created in the early lunar differentiation event (ferroan anorthosites, high-Mg suite norite, KREEP, low- and high-Ti basalts). If fit with a single isochron, the data agree with previous suggestions of a ~200 Ma duration for lunar magma ocean (LMO) crystallization [1, 2], but with an initial $^{142}$Nd/$^{144}$Nd 20 ppm higher than chondritic, essentially the same as measured for terrestrial rocks [3]. Excesses in initial $^{142}$Nd ($\varepsilon^{142}$Nd = 0.27 to 0.38 relative to O-chondrites) in crustal rocks 60025 and 78236, coupled to positive initial $\varepsilon^{143}$Nd, measured in most of crustal samples, indicate that they derive from a source strongly depleted in light rare earth elements ($^{147}$Sm/$^{144}$Nd -0.23-0.24). The source reservoir for lunar crustal rocks thus would be the early depleted reservoir (EDR) formed on Earth during the first tens of Ma of Solar System history ($^{147}$Sm/$^{144}$Nd = 0.209) [3]. This geochemical signature cannot be reconciled with the current lunar magma ocean (LMO) models that suggest that the crust formed after approximately 70% crystallization of an LMO that initially had chondritic relative REE abundances. Two alternatives exist: 1) The lunar crust formed by post-magma ocean remelting and diairism of LREE-depleted cumulates from the lunar interior [see also 4]. A two-point isochron for the crustal rocks provides an age of 64 (+97, -58) Ma after the beginning of Solar System formation or 4.50 Ga. If the thick crust is a secondary product, there is no reason to invoke its insulating qualities for explaining a delay of the LMO crystallization. Fitting the Sm-Nd data for the different groups of lunar samples (crustal rocks, low-Ti and high-Ti basalts) independently allows rapid (~60-120 Ma) evolution of the LMO at the limit of lifetime of $^{182}$Hf [5, 6]. 2) If all the lunar igneous rock groups are considered together and related to crystallization of a single LMO, then the Sm-Nd data suggest a prolonged (~200 Ma) LMO crystallization interval and a bulk LMO with LREE-depleted character in common with the EDR of the Earth. This strengthens the Earth-Moon connection by requiring formation of the Moon from an already differentiated Earth.

Release of C-14 from a closed final repository for low-level radioactive waste to the biosphere

G. BRACKE AND W. MÜLLER

ISTec, Institute for Safety Technology GmbH, Schwertnergasse 1, 50667 Cologne, Germany
(guido.bracke@istec.grs.de; wolfgang.mueller@istec.grs.de)

Introduction
The contribution of C-14 to radiation exposure in the biosphere from a repository for low-level radioactive waste can be significant. The pathways and processes of C-14 relevant to its release from a closed final repository for low-level radioactive waste are under investigation. Because a conservative approach may lead to undue overestimation of the potential radiation exposure, a more realistic approach is outlined.

Results
A more realistic approach includes:
- a reference scenario including technical measures
- the inventory of C-14 with specification
- geochemical reactions in all compartments
- gas generation
- gas pathways
- isotope exchange reactions
- sorption, precipitation
- exposure scenario

Figure 1: Distribution of C-14

Summary
At the present level of refinement, a more realistic assessment of the release of C-14 after closure of a final repository for low-level radioactive waste in a mine shows a significantly lower release of C-14 than previously used conservative approaches. This assessment predicts a significantly lower potential radiation exposure, thus increasing the safety margins to federal limits.

With this approach it is possible to demonstrate that a repository in a mine complies with the ALARA (as low as reasonably achievable) principle, thus facilitating licence approval. Conservative approaches are unable to demonstrate compliance other than with the limits for radiation exposure.
Os-He isotope systematics of Iceland picrites: Evidence for a deep origin of the Iceland plume

ALAN D. BRANDON1, DAVID W. GRAHAM2, TOD WAIGHT3 AND BJARNI GAUTASON4

1NASA, Johnson Space Center, Houston, TX 77058, USA (alan.d.brandon@nasa.gov)
2College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR 97331
3Geological Institute, Øster Voldgade 10, 1350 Copenhagen K, Denmark
4Orkustofnun and University of Akureyri, Rangarvellir, P.O.Box 30, 602 Akureyri, Iceland

Recent work on the origin of the Iceland hotspot suggests that it may result from upwelling upper mantle material rather than a deep plume. To constrain the depths of origins of Iceland mantle sources, Os and He isotope systematics were obtained on a suite picrites that span the compositional range observed within the neovolcanic zones.

The Iceland picrites display a range in $^{187}$Os/$^{188}$Os from 0.1297 to 0.1381 (gOs = 0.0 to 6.5) and uniform $^{186}$Os/$^{188}$Os of 0.1198375±32 (2s). The value for $^{186}$Os/$^{188}$Os is within uncertainty of the present-day value for the primitive upper mantle of 0.1198398±16. These Os isotope systematics are best explained by ancient recycled crust or melt enrichment in the mantle source region. If so, then the coupled enrichments displayed in $^{186}$Os/$^{188}$Os and $^{3}$He/$^{4}$He from lavas of other plume systems must result from an independent process, the most viable candidate at present remains core-mantle interaction. While some plumes with high $^{3}$He/$^{4}$He, such as Hawaii, appear to have been subjected to detectable addition of Os (and possibly He) from the outer core, others such as Iceland, appear to have not.

A positive correlation between $^{187}$Os/$^{188}$Os from 0.1297 to 0.1381 and $^{3}$He/$^{4}$He from 9.6 to 19 Ra in Iceland picrites is best modeled as a two stage process. In stage 1, 500 Ma or older ancient recycled crust is mixed with a primitive-like mantle for Os and He systematics, creating a hybrid source region. In stage 2, the hybrid source mixes with the convecting MORB mantle during ascent and melting. This multistage mechanism to explain these isotope systematics is consistent with ancient recycled crust juxtaposed with more primitive, relatively He-rich mantle, in convective isolation explaining the $^{3}$He/$^{4}$He signature in Iceland lavas.

The lack of a resolvable seismic signature of conduit-like plume flow under Iceland at some depths may result from sporadic flow of material from depths near the core-mantle boundary, consistent with recent dynamical models (Farnetani and Samuel, 2005, GRL 32, L07311).

Modelling of phase diagrams for migmatitic paragneisses of the Epupa Complex, NW Namibia

SÖNKE BRANDT1 AND REINER KLEMD2

1Universität Würzburg, Institut für Mineralogie, Am Hubland, D–97074 Würzburg (brandt@min.uni-kiel.de) present address: Universität Kiel, Institut für Geowissenschaften, Ludewig-Meyn-Str. 10, D-24118 Kiel
2Universität Würzburg, Institut für Mineralogie, Am Hubland, D–97074 Würzburg (reiner.klemd@mail.uni-wuerzburg.de)

Mesoproterozoic (1.37-1.32 Ga) migmatitic metapelites and metagreywackes (Orue Unit) of the Epupa Complex, NW Namibia, record several melt-producing reactions. Partial melting of the paragneisses and the evolution of their mineral assemblages can be adequately interpreted by calculated phase diagrams in the Na2O-CaO-K2O-FeO-MgO-Al2O3-SiO2-H2O (NCKFMASH) system. The development of the different observed mineral assemblages reflects variations of the bulk-rock composition but also indicates regional differences in the metamorphic grade between the various structural parts of the Orue Unit. The evolution of the mineral assemblages is interpreted in terms of simple heating-cooling P-T paths at different crustal levels: early mineral assemblages of Bt-Sil-Qz in the paragneisses and of Bt-Qz in the metagreywackes, preserved as mineral inclusions in peak-metamorphic porphyroblasts, break down via melt-producing reactions to higher-temperature garnet-bearing and/or cordierite-bearing assemblages under upper-amphibolite facies conditions. According to the calculations, melting occurs at uniform temperatures of 650-700°C, close to the thermal peak of metamorphism. The relatively Fe-rich (XMg: 0.36-0.28) cordierite-bearing paragneisses with or without garnet which are restricted to the northern part of the study area equilibrated at peak-temperatures of 700-750°C and low pressures of 3-4 kbar as constrained from geothermobarometry and calculated mineral isopleths. The slightly more magnesian Grt-Bt-Sil greisses (XMg: 0.43-0.32) which are exposed in the southern part of the study area record similar peak-temperatures (670-750°C) but higher pressures of 5.5-6.5 kbar. Retrograde back-reactions between restite and in situ crystallising melts are recorded by the replacement of garnet by Bt-Sil (Al-rich samples) and/or Bt-Ms intergrowths (Al-poor samples).

The P-T axes are interpreted to result from a regional scaled thermal perturbation of the normal geotherm in mid-to-upper crustal levels induced by magmatic accretion of mantle-derived melts. This process is presumably related to the emplacement of the c. 1.38 Ga anorthositic Kunene Intrusive Complex. A contact metamorphic overprint is restricted to a narrow reaction zone along the margin of the Kunene Intrusive Complex and is recorded by highly aluminous metapelitic Grt-Crd-Sil hornfelses which equilibrated at peak-conditions of 700°C and 5-6 kbar.
Bedrock to soil: Earth’s weathering engine

SUSAN L. BRANTLEY
Center for Environmental Kinetics Analysis, Earth and Environmental Systems Institute, Penn State University, University Park, PA, USA (brantley@eesi.psu.edu)

Seawater chemistry responds to changes in terrestrial weathering over time in response to the forcing functions of tectonism, climate, and anthropogenic activity. Many researchers have attempted to read the effects of weathering solute fluxes in sediments in the rock record. For example, the Sr isotope record in marine limestones has been interpreted with respect to continental weathering fluxes due to changes in Earth’s weathering engine. Our ability to predict such fluxes forward in time is limited because of difficulties in calculating weathering fluxes and the rates of formation of soils on weathering or eroding bedrock.

Weathering solute fluxes are recorded in many areas as chemical and textural profiles imprinted on regolith. These profiles, when observed on noneroding regolith in the absence of significant deposition, propagate downward as the regolith pile thickens with time. Such a profile can be described as a quasi-stationary state. If the rate of erosion of such regolith is increased larger than the weathering advance rate, the regolith thickness must decrease with time. For such a condition, the regolith eventually disappears unless some process accelerates the weathering advance rate. During weathering, as regolith thins, the rate of weathering advance can increase because porefluid chemistry at the bedrock interface becomes more corrosive. Thus, the rates of erosion and weathering advance can be coupled through porefluid chemistry, maintaining regolith thickness at steady state values. Solute fluxes and regolith profiles can be predicted for simplified lithologies under these assumptions.

The weathering advance rate is not, however, observed to be the same when calculated at the watershed, soil profile, and hand specimen scales. Several phenomena contribute to this observation. Approaches will be described to understand the prediction and modeling of weathering advance rates across scales as well as the controls on weathering solute fluxes.

The role of impurity doping during oriented α-alumina-on-mullite growth

W. BRAUE
German Aerospace Center (DLR), Materials Research Institute, D-51147 Cologne (wolfgang.braue@dlr.de)

This work presents a recent case study on the benefits of impurity doping for producing unique ceramic microstructures which are difficult to process by other means.

Topotactic orientation relationships between thin α-alumina (00•1) platelets and Czochralski grown 2/1 mullite substrates are discussed in the light of annealing experiments of 2/1 mullite (001), (010) and (001) single crystals sections in the two-phase regime <mullite plus α-alumina> (1200-1650°C) in different atmospheres (dry vs. wet air) at normal air pressure.

Thermal decomposition of 2/1 mullite gives rise to the simultaneous formation of α-alumina platelets and an initially siliceous glassy phase completely wetting the platelets. Its chemical composition is shifted to a Na-Mg-Ca bearing aluminosilicate composition via uptake of network modifying cations from external impurity sources (kiln furnace material, alumina reaction tube) during the annealing experiments. It is this glassy phase modified via impurity doping which filled the mullite dissolution paths driven forward by the platelets and provided a build-in flux for platelet growth.

In wet annealing experiments employing higher gas velocities and temperatures the glassy phase is lost due to substantial silica and alumina volatilization. With no more sink for impurity doping provided, the unique corundum-on-mullite microstructure gives way to complex etching patterns of the mullite surfaces due to selective corrosion by the water vapor-rich atmosphere.
Bacterial interactions with solid substrates: Applications for microbial fuel cells, carbonate surfaces and metal oxide reduction

O. BRETSCHGER1, A. OBRAZTSOVA1, C. STURM2, L. ZHANG2, Y. GORBY3, I-S. CHANG4,5, B-H. KIM4, F. MANSFELD1, K. H. NEALSON1 AND A. LUTTGE2

5Gwangju Institute of Science and Technology, Gwangju, South Korea

*Shewanella oneidensis* MR-1 is a flexible microorganism that can use a broad range of electron acceptors, including several solid substrates. MR-1 reduces Mn(IV), Fe(III) oxides, impacts the surface morphology of carbonates, and produces power in microbial fuel cells. A microbial fuel cell (MFC) utilizes the catalytic action of bacteria to convert the chemical energy of organic or inorganic compounds into electrical energy. MR-1 catalyzed power generation and metal oxide reduction appears to be strongly dependent on how these bacteria are grown, and their ability to produce and employ specialized cytochromes for extra-cellular electrons transfer. These cytochromes are hypothesized to directly pass electrons to substrates via the cell membrane and extra-cellular appendages i.e. nanowires. MR-1’s ability to change the chemistry of its local environment may also play a role in changing the surface characteristics of carbonate and other substrates during attachment. We study interactions between MR-1 and substrates with a multifaceted combination of experimental and theoretical methods. Different MR-1 deletion mutants were generated to explore the role of cytochromes in power production and metal-oxide reduction. The results show that a few key cytochromes play a role in all of the processes explored, but that their degree of participation in each process is very different.

Characterisation of Mo and V interactions with ferrihydrite as an analogue for deep-sea hydrothermal plumes processes

L. BRINZA1, L.G. BENNING1 AND P.J. STATHAM2

1School of Earth and Environment, University of Leeds, LS2 9JT, United Kingdom (l.brinza@earth.leeds.ac.uk, l.benning@earth.leeds.ac.uk)
2National Oceanography Centre, Southampton, SO14 3ZH, United Kingdom (pjs1@noc.soton.ac.uk)

In deep-ocean hydrothermal plumes molybdenum and vanadium are known to be readily scavenged by freshly formed iron oxihydroxides nanoparticles (i.e., ferrihydrite, FH) forming during the oxidation of hydrothermal vent fluids via mixing with seawater. These scavenging processes have important implications for the cycling and budget of Mo and V in the ocean, yet, no quantitative information about the mechanisms that govern the interaction between FH and Mo or V are available.

In order to study the mechanisms involved, poorly ordered ferrihydrite nanoparticles were characterised for their particle size, crystallinity and surface charge (point of zero charge = 7.96). Furthermore, the influences of sorbed inorganic carbon species, of co-precipitated Mo or V, and of ionic strength (0 - 1 M) on the ferrihydrite surface charge were studied.

The comparison between adsorption and co-precipitation for ferrihydrite and Mo or V will be discusses based on differences in the maximum uptake capacities from kinetic and thermodynamic approaches. For the first time, maximum sorption capacities of 1.32mmol Mo/g FH and 1.79 mmol V/g FH were derived, indicating that both metals have a high binding affinity for the FH surface. Interestingly, Mo-edge X-ray absorption spectroscopic measurements of the bonding environment of Mo sorbed on-or co-precipitated with FH showed no difference in Mo speciation between the adsorbed or the co-precipitated system (tetra coordinated Mo with Mo-O first shell bond distances of 1.76 Å in both cases). These results provide evidence that in deep-sea hydrothermal plumes the chemistry of molybdate and vanadate is strongly controlled by the presence of and interactions with neoformed FH nanoparticles.

WOLFGANG BROCK¹ AND BIRGIT HAGENHOFF²

¹Tascon GmbH, Heisenbergstr. 15, 48149 Münster (wolfgang.brock@tascon-gmbh.de)
²Tascon GmbH, Heisenbergstr. 15, 48149 Münster (birgit.hagenhoff@tascon-gmbh.de)

Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) is an analytical tool for surface analysis. Applying ToF-SIMS the impact of primary ions leads, among others, to the desorption of secondary ions that are characteristic for the composition of the sample’s surface. These secondary ions are mass separated and detected by a Time-of-Flight analyzer.

ToF-SIMS offers brilliant imaging options as it is possible to focus the primary ion beam and to raster it over the surface of the sample: The intensity of each detected secondary ion in each rastered pixel can be displayed according to a colorscale. Thus, information on the distribution of elemental as well as organic chemical components can be gained.

Whereas most inorganic components can already be analyzed routinely by this technique ToF-SIMS has developed into a mature technique for the characterization of biomaterials. Nevertheless, imaging applications in this area have been sparse due to the fact that the achievable lateral resolution is not only a function of the primary beam diameter but also of the achievable secondary ion yields (i.e. the number of generated secondary ions per impacting primary ion) of the respective materials. Up to a few years ago typical values for the lateral resolution routinely obtained were in the order of some micrometers using monoatomic primary ion sources. This value can be improved tremendously using recently developed polyatomic primary ions: Just as well as their monoatomic counterparts these projectiles can be focussed down to 50 nm but – more importantly – show a remarkable enhancement of secondary ion yield for molecular secondary ions. Therefore, organic imaging well in the sub-μm range now becomes possible as it could already be shown for a number of samples, e.g. in the field of biochemistry and pharmacetics.

This paper will show the state-of-the-art on ToF-SIMS imaging of biomaterials. Starting with an overview on the general principle of the technique it will focus on the possibilities and limitations regarding the analysis of substances and samples of interest for biogeochemistry.

Petrogenesis and geochronology of jadeitites from the Cycladic blueschist belt, Greece

M. BRÖCKER¹ AND J.J. AGUE²

¹Institut für Mineralogie, ZLG, Universität Münster, 48149 Münster, Germany (brocker@uni-muenster.de)
²Department of Geology and Geophysics, Yale University, New Haven, CT 06520-8109, USA (jay.ague@yale.edu)

Jadeite is a relatively rare rock type which is usually found in association with high-pressure/low temperature rocks and serpentinites in subduction zone settings. The formation of this rock type is yet not fully understood but precipitation from aqueous fluids or fluid-assisted metasomatic alteration of a pre-existing rock represent the most plausible petrogenetic concepts (Harlow & Sorensen, 2005). In the Cycladic blueschist belt jadeitites have been recognized as minor constituents of eclogite- to epidote blueschist-facies mélangé sequences on the islands of Syros, Tinos and Andros. These jadeitites commonly are zircon-bearing and thus are suitable targets for U-Pb geochronological studies. Correct interpretation of zircon ages requires in-depth understanding of the jadeitite-forming process. In order to unravel the origin of these occurrences, we have initiated a study that combines field observations with petrological, geochronological and geochemical aspects, including trace element compositions of zircon.

Preliminary mass balance calculations indicate substantial metasomatic addition of Na to meta-igneous and meta-sedimentary mélangé blocks on Syros. These observations are consistent with experimental results which show that Na concentrations can be considerable in subduction zone fluids (Topper and Manning, 2004). It is possible that these Na-rich fluids were also important for jadeitite formation.

New ionprobe ⁹²⁹⁰⁶Pb/²³⁸⁰⁶U results for two samples from Syros yielded weighted mean averages of 80.6 ± 1.7 Ma and 82.0 ± 2.1 Ma, respectively. Two samples from Tinos provided ⁹²⁹⁰⁶Pb/²³⁸⁰⁶U ages of 82.3 ± 1.7 Ma and 78.4 ± 1.8 Ma. These results further corroborate the geological significance of a previously reported Cretaceous age group for mélangé blocks. Work in progress aims to document unambiguously the jadeitite- and zircon-forming process and to link U-Pb ages to a specific stage in the evolution of this rock type.

Molecular fossils and early life

JOCHEN BROCKS¹ AND JILLIAN BANFIELD²

¹Research School of Earth Sciences, The Australian National University (jochen.brocks@anu.edu.au)
²Department of Earth and Planetary Sciences, UC Berkeley

Life in the Precambrian was dominated by bacteria and archaea, organisms that rarely leave diagnostic cellular remains in the fossil record. However, hydrocarbon biomarkers, the molecular fossils of natural products such as lipids and pigments, can yield a wealth of information about Precambrian ecosystems. Biomarkers often retain the diagnostic carbon skeleton of their biological precursors and may survive in sedimentary rocks for hundreds of millions of years. Many biomarkers are diagnostic for specific microbial groups such as methanogens, methanotrophs or phototrophic bacteria and, thus, may give information about ancient biodiversity. For instance, biomarkers discovered in mudstones that were deposited in a seaway in northern Australia 1,640 Ma ago describe a marine habitat that was Earth history. In this ancient sulfidic marine basin, eukaryotic life responded to massive glaciations in the Neoproterozoic. However, there is a major obstacle that hampers the potential biomarkers produced by microorganisms, even if those 99% of microorganisms that can not yet be cultured may survive in sedimentary rocks for hundreds of millions of years. Many biomarkers are diagnostic for specific microbial groups such as methanogens, methanotrophs or phototrophic bacteria and, thus, may give information about ancient biodiversity. For instance, biomarkers discovered in mudstones that were deposited in a seaway in northern Australia 1,640 Ma ago describe a marine habitat that was fundamentally different from ecosystems observed later in Earth history. This ancient sulfidic marine basin, eukaryotic algae were either insignificant or absent, and primary production was dominated by phototrophic green and purple sulfur bacteria. Generally, biomarkers could answer outstanding questions about Precambrian ecology and evolution, such as how ecosystems responded to the oxygenation of the atmosphere ~2.4 billion years ago or how life responded to massive glaciations in the Neoproterozoic.

However, there is a major obstacle that hampers the application of biomarkers as palaeoenvironmental proxies: the incomplete knowledge of the lipid biosynthetic capacity of living organisms. According to some estimates, less than 1% of microorganisms can be isolated from the environment and grown in pure culture, and the biomarker content of these uncultivated microbes remains almost always unknown. Detecting and describing the lipids and pigments produced by those 99% of microorganisms that can not yet be cultured would boost the value of biomarkers extracted from ancient rocks.

This great challenge might be solved in the coming decade by combining lipid research with environmental genomics and microbial community proteomics. Of particular interest will be studies of communities where it is possible to reconstruct nearly complete genomes, proteomes and lipid profiles of dominant microorganisms taken directly from modern environments without cultivation. These genomes will be screened for genes involved in lipid and pigment biosynthesis and matched with corresponding enzymes and lipids detected in the same sample. In addition to defining the diversity of as yet unknown branches of the tree of life, this will contribute to new understanding of the phylogenetic distribution of potential biomarkers produced by microorganisms, even if they evade isolation. The intricate knowledge of the lipid biosynthetic machinery of present ecosystems will then serve to elucidate new biomarkers and biomarker patterns in ancient sedimentary rocks.

Synthesis, crystal structure and application of compounds with Copiapite- and Voltaite structure

B. BROEMME AND H. POELLMANN

Martin-Luther-University Halle-Wittenberg, Mineralogy/Geochemistry, von-Seekendorff-Platz 3, Germany (beatrix.broemme@geo.uni-halle.de)

Voltaite is a three-dimensional polymerization of complex octahedral-tetrahedral chains with K in located in the interstices [1] with the following composition [2]:

\[ M^{2+}_{2}(OH)(H_2O)_4(SO_4)_3 \cdot 12H_2O \]

M^{2+}: K, Rb, NH₄, Ti, Li
M^{3+}: Mg, Mn, Fe, Co, Zn, Cd
M^{3+}: Fe
M^{2+}: Al, Fe

In the copiapite-group minerals, corner-sharing [M₂(TO₄)₂Ø₂] clusters link through additional tetrahedra to form [M₄(TO₄)₃Ø₂] chains along [101], which are linked together by hydrogen bonds involving unconnected \{Fe²⁺(H₂O)₀\}octahedra and interstitial water groups [1]. The general chemical formula of the copiapite group minerals is [3]:

\[ M^{2+}_{2}(OH)(H_2O)_3(SO_4)_3 \cdot (M^{2+}(H_2O)₀\cdot(H_2O)_6 \]

M^{2+}: Na⁺, K⁺, Cu²⁺, Mn, Mg, Zn, Al, Fe⁴⁺, Fe³⁺, Al³⁺

Synthesis and Results

Voltaite minerals can be synthesized by reaction of metalsulfates and sulphuric acid in an aqueous solution. The crystallisation process takes place at a temperature of 80°C.

Copiapite can be synthesized by the method developed by MAJZLAN [4] and SCHARIZER [5].

The phase identification and characterisation is done by X-ray diffraction, thermogravimetry, scanning electron microscopy and IR-spectroscopy.

Conclusions

The improvement of the synthesis and the investigation of the capacity of reaction under changing conditions of solubility and stability is the intent of the investigation.

The high ability of the exchange of cations indicates a possible use in agriculture, as a water binder or as a short time storage mineral, which will be investigated.

References

Comparisons between fluoride and hydroxide incorporation in nominally anhydrous and fluorine-free mantle minerals.

David W. Bromiley and Simon C. Kohn
Department of Earth Sciences, Wills Memorial Building, University of Bristol, BS8 1RJ, UK

The importance of water to the behaviour of the mantle is now widely recognised. A substantial body of data on the solubility of water in nominally anhydrous minerals has been obtained, and a range of constraints on the distribution of water in the mantle have been proposed. In contrast, the solubility of fluoride in nominally fluorine-free minerals (NFFMs) and the consequences for the global fluoride budget, the effects of fluoride on mantle properties and volatile recycling in subduction zones are all completely unexplored. Very few measurements of the F concentration in NFFMs have been reported (Hervig and Bell, 2005).

In this study, the solubility of fluoride in NFFMs was determined under shallow mantle conditions, by equilibrating forsterite and enstatite with fluorides, fluoro-clinohumite or fluorspar rich silicate melts. Experiments were performed in piston-cylinder apparatus at pressures of 1-2 GPa and 1350-1600°C, and the phases present in the quenched samples were determined using SEM and EPMA. The concentration of F in olivine was measured using EPMA with a beam current of 100-200nA and an accelerating voltage of 15-20 kV.

Extraordinarily high solubilities up to 0.45 wt% F have been observed in olivine in the system Mg₃SiO₄-MgF₂. There is no apparent correlation between F and Mg concentrations in the olivine, implying that the high F concentrations are not simply due to inclusions or lamellae of MgF₂ or clinohumite. The fluoride solubilities observed in the Mg₃SiO₄-CaF₂ and Mg₃SiO₄-NaF systems are lower, for reasons which will be discussed. 19F NMR and TEM studies are underway in order to definitively establish whether the high apparent solubility of F in forsterite is influenced by the incorporation of clinohumite lamellae in the structure, or is entirely associated with point defects such as oxygen vacancies.

The implications of a high solubility of F in NFFMs in the mantle could be wide ranging. For example the low recycling efficiency for F in subduction zones (Straub and Layne, 2003), could be explained by retention of F in NFFMs rather than by incorporation in hydroxyl-bearing minerals such as amphibole and serpentine. The differing partitioning and diffusion behaviour of OH and F imply that measurements of both F and OH concentrations in mantle-derived rocks could help constrain the mantle water cycle.

Hydroxyl defects dissolved in olivine and orthopyroxene dramatically affect the physical, chemical and mechanical properties of the Earth’s upper mantle. Understanding the processes governing the incorporation of these species is also essential before the total hydrogen contents of the Earth can be constrained. Here, we investigate hydroxyl speciation and solubility in both natural and experimentally re-equilibrated single crystals using polarised IR spectroscopy.

Our IR spectra demonstrate that the particular hydroxyl defects dissolved in olivine and orthopyroxene are strongly influenced by sample chemistry and experimental fO₂. As a result, extreme caution must be exercised when developing models for solubility in both these phases in the upper mantle, particularly if models are based on data extrapolated from samples synthesised in chemically simple systems and/or experiments conducted under thermodynamic regimes not relevant to mantle conditions.

Experiments on olivine and orthopyroxene crystals from subduction-related, amphibole-bearing Ichnionemagata xenoliths show that hydroxyl solubility in both phases increase with pressure and temperature. However, if all other variables remain constant (P, T, and aSiO₂), the effect of fO₂ on hydroxyl solubility in olivine contrasts sharply with orthopyroxene. Water contents in olivine crystals re-equilibrated at QFM and QFM -4 decrease from 65 to 50 ppm respectively, whilst the concentration in coexisting orthopyroxene increases from 550 to 640 ppm. Partitioning of hydrogen between these two phases will, therefore, vary as a function of oxidation state in the upper mantle.

Comparing spectra for a whole range of experimentally re-equilibrated samples with those in natural phases from Ichnionemagata demonstrates that hydroxyl defect species and concentrations dissolved in natural crystals of olivine and orthopyroxene were inherited at near water-saturated conditions, similar to those of major element re-equilibration in the upper mantle (1.5 GPa, 950°C, QFM, enstatite buffered aSiO₂). Both the hydroxyl stretching modes and dissolved water contents are reproduced in the experimental samples. Water solubilities are lower than current solubility models would suggest, but do not appear to be the result of low pressure equilibration with the host magma during ascent.
Biologically-mediated weathering of minerals from nanometre scale to environmental systems

The Weathering Science Consortium is a multi-disciplinary project that aims to create a step change in understanding how biota control mineral weathering and soil formation (http://www.wun.ac.uk/wsc). Our hypothesis is that rates of biotic weathering are driven by the energy supply to the organisms, controlling their biomass, surface area of contact with minerals and their capacity to interact chemically with minerals. Symbiotic fungal mycorrhiza of 90% of plant species are empowered with an available carbohydrate supply from plants that is unparalleled amongst soil microbes. They develop extensive mycelial networks that intimately contact minerals, which they weather aggressively. We hypothesise that mycorrhiza play a critical role through their focussing of photosynthate energy from plants into sub-surface weathering environments.

Our work identifies how these fungal cells, and their secretions, interact with mineral surfaces and affect the rates of nutrient transfer from minerals to the organism. Investigating these living systems allows us to create new concepts and mathematical models that can describe biological weathering and be used in computer simulations of soil weathering dynamics. We are studying these biochemical interactions at 3 levels of observation:

1. At the molecular scale to understand interactions between living cells and minerals and to quantify the chemistry that breaks down the mineral structure
2. At the soil grain scale to quantify the activity and spatial distribution of the fungi, roots and other organisms (e.g. bacteria) and their effects on the rates at which minerals are dissolved to release nutrients
3. At soil profile scale to test models for the spatial distribution of active fungi and carbon energy and their seasonal variability and impact on mineral dissolution rates.

A geochemist’s view of environmental science at the molecular level

GORDON E. BROWN, JR.

Surface & Aqueous Geochemistry Group, Department of Geological & Environmental Sciences, Stanford University, Stanford, CA 94305-2115, USA (gordon@pangea.stanford.edu)

Molecular Environmental and Interface Science (MEIS) has evolved over the past two decades in response to the need to understand the speciation and properties of environmental contaminants at the molecular level and the chemical and biological processes at environmental interfaces that control speciation and properties. This highly interdisciplinary field has grown rapidly and is making increasing use of a sophisticated array of instrumentation and major user facilities. Synchrotron radiation sources and the micro-structural, micro-compositional, surface-sensitive, and spectromicroscopy techniques they have enabled are having an increasing impact on our ability to determine the speciation, spatial distribution, and phase association of important heavy metal, metalloid, and xenobiotic organic contaminants in complex environmental samples. In addition, studies of model systems under controlled laboratory conditions are providing fundamental insights about the factors controlling chemical reactivity at environmental interfaces, where much of chemistry of the natural environment occurs. In this talk I will review some of these factors, including defect density, cooperative effects among adsorbate molecules, surface structure, solid variables such as the isoelectric point, solution variables such as pH, and coatings of organic matter and microbial biofilms on mineral surfaces. I will also discuss recent synchrotron-based studies by members of my research group and members of the Stanford Environmental Molecular Science Institute of the structure of bulk water, uranium speciation in the vadose and groundwater zones at Hanford, WA, and the reactivity of nanoparticles of biogenic UO₂(s) and hematite with respect to aqueous Zn(II). Finally, I will offer some thoughts on the future of MEIS following the introduction of hard x-ray free electron lasers.
Speciation of mercury in mining environments

Hg, in its methylated form, is one of the most toxic contaminants in the environment and is also one of the most highly biomagnified contaminants in aquatic ecosystems. Hg in various chemical forms enters the environment from a number of activities, including Hg mining, historic gold mining, and gaseous emissions from coal-fired power plants and crude oil refineries. For example, 90-100 lbs/d of Hg was released into the local environment from individual kilns used for roasting cinnabar ore during operations of the New Almaden and New Idria Hg mines in N. California over a sustained time period, and about 3,000 lbs/y of Hg is released through gaseous emissions into the San Francisco Bay area from five crude oil refineries in the north Bay. Key questions concerning Hg are what are its most common chemical forms, what is the potential bioavailability of Hg in its various forms, and in what chemical forms is it transported from mining environments, where it is typically present as cinnabar (HgS(hex)) or metacinnabar (HgS[cubic]). Over the past few years, we have conducted a number of field- and laboratory-based studies to address these questions. Using a combination of column experiments, XAFS spectroscopy, and TEM, we have found that nanoparticles of cinnabar and metacinnabar are likely forms transported from Hg mines in the California Coast Range. Such nanoparticles are also found in the placer gold deposits in the Sierra Nevada foothills of N. California. We have also found that certain Hg minerals result in higher evaporation of gaseous Hg than others, and that oxidized and reduced forms of S and Fe affect the reactivity of Hg and cause its desorption from goethite. In addition, we have found that a bacterial consortium in the New Idria acid mine drainage can enhance the solubility of HgS by ≈10³⁹. The impact of these processes on the cycling of Hg in mining environments will be discussed.

NEO-sample return mission

J.R. BRUCATO1, A. BARUCCI2 AND NEO-SR TEAM

1INAF-Osservatorio Astronomico di Capodimonte via Moiariello 16 80131 Napoli, Italy (brucato@na.astro.it)
2LESIA – Observatoire de Paris F-92195 Meudon Principal Cedex, France (antonella.barucci@obspm.fr)

Small bodies, as primitive left-over building blocks of the solar system formation process, offer clues to the chemical mixture from which the planets formed some 4.6 billion years ago. Near Earth Objects (NEOs) representative of the population of asteroids and dead comets are thought to be similar in many ways to the ancient planetesimal that accreted to form the planets. NEOs are interesting and highly accessible targets for scientific research. The chemical investigation of NEOs having primitive characters is thus essential in the understanding the planetary formation. They carry records of the solar system’s birth and early phases and the geological evolution of small bodies in the interplanetary regions. Moreover, collisions of NEOs with Earth pose a possible hazard to present life and, additionally, they could have been one of the major deliverers of water and organic molecules on the primitive Earth playing an active role in the origin of life on Earth. For all these reasons the exploration of these objects is particularly interesting. A sample return mission to a NEO and its scientific objectives will be here presented.
Evidence of ancient water on Mars by the APXS onboard the Mars Exploration Rover Opportunity

J. BRÜCKNER\textsuperscript{1}, G. DREIBUS\textsuperscript{1}, R. GELLERT\textsuperscript{2}, J. ZIPFEL\textsuperscript{3} and the ATHENA SCIENCE TEAM\textsuperscript{4}

\textsuperscript{1}Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany, (brueckner@mpeh-mainz.mpg.de)
\textsuperscript{2}Dep. of Physics, Univ. of Guelph, Guelph, On, Canada, (ralf@physics.uoguelph.ca)
\textsuperscript{3}Senckenberg Forschungsinstitut, Senckenberganlage 25, D-60325 Frankfurt, Germany, (jzipfel@senckenberg.de)
\textsuperscript{4}Cornell Univ., Ithaca, NY, USA

In January of 2004, one of the two Mars Exploration Rovers (MER) landed in Meridiani Planum [mission details in Squyres et al., 2006], a site primarily selected for its hematite signature as observed from orbit by TES [Christensen et al., 2000]. As in most terrestrial cases, hematite is formed by aqueous activities and under oxidizing conditions, which makes hematite a tracer for (ancient) water episodes. Lag deposits of iron- and hematite-rich spherules were observed along the rover’s traverse by the Alpha Particle X-ray Spectrometer (APXS) [Brückner et al., 2006] and the Mössbauer Spectrometer (MB) [Morris et al., 2006].

The APXS data are used to determine the chemical composition of soil and rock samples; water (hydrogen) cannot be detected due to the applied method but indirect evidences can be derived. Almost all rocks encountered at Meridiani are sulfur-rich sediments [Rieder et al., 2004] making S with up to 12 wt. % a major element. The formation of these sediments are explained by a two-component mixing model of siliciclastic and sulfur-rich end members. Careful inspection of all data obtained during the last three years of APXS operation revealed unique relationships of major and minor element concentrations with S contents. For Si and Al concentrations, a dilution with increasing S contents is observed indicating that these two elements occur only in the siliciclastic end member. Calcium and Fe show no dilution effects with increasing S; constant concentrations are pointing to an occurrence as sulfates and as rock-forming silicates. Besides other phases, ferric sulfates could be detected by the MB [Morris et al., 2006]. Similar concentration relationships were also found for minor elements, such as Na, P, and K. Magnesium shows two different effects: a positive correlation with S for samples from the first 220 sols, pointing directly to Mg sulfates, and a rather constant concentration afterwards (no dilution by S). Since all the data are observed over a 10-km distance, the sediments formed in an environment that assisted in mixing and distributing the different compounds on large scales. Liquid water was the most probable carrier of such processes, at least for short episodes.

Miocene incorporation of peridotites into the lower crust during opening of the Algerian basin: Insight from U-Pb LA-ICP-MS analyses

O. BRUGUIER\textsuperscript{1}, D. BOSCH\textsuperscript{1}, D. HAMMOR\textsuperscript{2} and R. CABI\textsuperscript{2}

\textsuperscript{1}Géosciences Montpellier, Equipe Manteau-Noyau, 34095 Montpellier cedex 05, France (bosch@gm.univ-montp2.fr)
\textsuperscript{2}Université Badji-Mokhtar, BP12, El-Hadjar, Annaba 23 000, Algeria

Sizeable pieces of deep mantle material croup-out worldwide within orogenic belts involving major continental collisions or within regions with rift-thinned continental margins. From their original mantle position these peridotites have been transferred into the crust by tectonic processes involving subduction, collision or extension and, although minor components of most metamorphic belts, the understanding of how and when they were emplaced within the continental crust and their subsequent exhumation is paramount. A U-Pb age of 17.84±0.12 Ma (2σ) was obtained from monazites separated from a diatexite migmatite collected in close proximity to a small peridotite massif incorporated into the lower crustal sequence of the Edough massif (eastern Algeria), a southern segment of the peri-Mediterranean Alpine Belt. Monazites, extracted from a neighbouring deformed leucogranite, yield a similar age of 17.4±1.3 Ma (2σ) whereas coexisting zircon with magmatic characteristics yield an age of 308±7 Ma (2σ) interpreted as dating the magmatic crystallisation of the leucogranite during the hercynian orogeny. These results emphasize the polycyclic evolution of basement rocks preserved in the crystalline units of the western Mediterranean and indicate that part of their metamorphic features was inherited from older events. Taken together with published Ar-Ar datings, the late Burdigalian age of monazites, indicates a fast cooling rate of \textit{c.} 300°C/Ma and is regarded as closely approximating the emplacement of the peridotites into the hercynian basement. This age is significantly younger than those recorded for orogenic peridotites from the Betic-Rif orocline and for lithospheric extension forming the Alboran sea. It is also younger than rifting and back-arc extension opening the Liguro-Provençal basin. The late Burdigalian age is interpreted as dating the incipient rifting event that opened the Algerian basin. At the scale of the western Mediterranean, opening of the Algerian basin provides a link between the late Oligocene-early Miocene extension in the western part (Alboran basin, Valencia trough and Liguro-Provençal basin) and the upper Miocene extension in the eastern part (Thyrrenian basin) of the western Mediterranean.
Patterns in major and trace element dynamics during long-term decomposition of boreal forest litters

C. B. Brun1, M. E. Åström1, P. Peltola1 and M.B. Johansson2

1School of Pure and Applied Natural Sciences, Kalmar University, Kalmar, Sweden (christian.brun@hik.se; mats.astrom@hik.se; pasi.peltola@hik.se)
2Department of Forest Soils, Swedish University of Agricultural Sciences, Uppsala, Sweden (maj-britt.johansson@sml.slu.se)

Background

The dynamics of a large number of major and trace elements were examined during a series of long-term litter decomposition experiments in Swedish boreal and nemoboreal forests during the 1980s and -90s. Litterbags with leaf litters from Norway spruce (Picea abies), Scots Pine (Pinus sylvestris), Bilberry (Vaccinium myrtillus) and European beech (Fagus sylvatica) were incubated for between 4 and 8 years at sites with a wide geographic distribution in Sweden. In 2004 these samples were reutilized for multielement analysis (ICP-MS).

Multielement dynamics

Principal component analysis and manual scatter plots revealed groups of elements behaving in a similar manner during the decomposition process, although there were some differences between the needle and leaf litters. One group consisted mainly of nutrients, and had a general trend with decreasing amounts during decomposition. Another group contained mostly unessential elements, whose total amounts generally increased during the decay process. An exception from this trend was found for a few elements e.g. Cd and Hg, for which the amounts increased initially followed by a net leaching from the litter. An interesting anomaly in the behaviour of Thallium was discovered, as the total Tl amounts in all needle litters decreased during decomposition, whereas the opposite was seen in the leaf litters. This indicates a difference in the plants uptake or translocation mechanisms, where the deciduous plants are able to protect themselves from the highly toxic Tl.

Conclusions

The results indicate two distinct general trends in element behaviour during litter decomposition. There are however several subgroups or exceptions from these general patterns, e.g. slight differences between the species groups.

The fact that the samples were collected at a time of higher atmospheric metal deposition than at present, provides additional information and usefulness of the results.

Statistical evaluation of anomalous compositions in fluid geochemistry

A. Buccianti, F. Tassi and O. Vaselli

Earth Sciences Dep., Via G. La Pira 4, 50121, University of Florence, Florence (I) (antonella.buccianti@unifi.it; francot@unifi.it; orlando@unifi.it)

Outliers have been defined by Barnett and Lewis (1994) as observations characterised by their extremeness and their discordancy, being unreasonable statistically in terms of some basic model. Thus outliers have be considered in relative terms with respect to a univariate or multivariate random variable assumed as model for the population from which data have been drawn. The problem of detecting outliers in a multivariate matrix is thus equivalent to the problem of determining if all the observations can be considered as representatives of the population under study, characterised by an appropriate distribution function, or if some of them have to be considered atypical or discordant. Identification of anomalous compositions in a database results to be an important item to point out extreme compositions called end-members. Their reconnaissance allows us to evaluate the contributions of the different sources to each of the observation vectors (geochemical samples) of the data set and to understand processes affecting mixtures of fixed source compositions systems. Since geochemical data concerning composition of fumarolic gases are expressed in µmol/mol, to capture the pattern of variability of these datasets it is necessary to use adequate probability distributions (Aitchison, 1986). In this work a discussion about the use of different probability models will be presented by considering samples of fumarolic gas periodically collected at Vulcano Island (Sicily, southern Italy) in the last six years. The implications of the presence of anomalous samples will be discussed on the light of both end-member identification problems to be related to different sources and surveillance problems (monitoring programs of compositional changes). Since many systematic and random processes control the chemistry of gas discharges from active and quiescent volcanic areas, our results indicate that stochastic modelling represents one of the possible way to quantify uncertainty and to assume responsible interpretation of natural phenomena.

2College of Geoinformation Science & Engineering, Shandong University of Science and Technology, Qingdao, 266510, China (lixuping@sdust.edu.cn)

Large volumes of serpentinine are intimately associated with the Zermatt-Saas ophiolite of the Central Alps. The ophiolite represents Tethys ocean floor that formed in the Mesozoic and was destroyed by subduction in the late Cretaceous to early Tertiary. The ophiolite consist of high-P metagabbro, blueschist, eclogite and metasediments.

Antigorite schist is the dominant rock of the serpentinite. The isotopic composition of antigorite is typical of serpentinization by seawater or by “metamorphic water” with δD ranging from -65 to -55 ‰ and δ18O from 2 to 7 ‰.

Assemblages in mafic rocks of the ophiolite suggest that the subduction PT path has reached 27 kbar and 600°C. At this depth (~ 80 km), conditions for serpentinite dehydration are reached. Continued subduction has the consequence that the subduction PT path has reached 27 kbar and 600°C. Once the slab has passed the isograd, rocks may not be returned to the surface by buoyant backflow and high-density peridotite and eclogite will disappear into the deeper mantle.

Dehydration of serpentinite at 90 km depth in the Zermatt-Saas subduction zone released a large amount of water (~100 kg/m³) which has several significant effects. (i) It creates a water excess zone at return point depth. In this area, portions of the overlying mantle wedge was serpentinized so that serpentines formed structurally above mafic rocks of the ophiolite. Thus, many of the Zermatt-Saas serpentinite slices may represent a depleted sub-continental harzburgite protolith rather than ophiolitic mantle. Serpentinite formed in this manner can by scraped off the wedge. Together with serpentinite from the oceanic mantle they enclose lenses of eclogite and other high-P mafic rocks and return them to the surface due to buoyant flow aided by lubrication of dehydration water. (ii) In the water excess zone at return point depth, the mantle part of the oceanic lithosphere is completely serpentinized. Normally, oceanic mantle is serpentinized to variable extent (~20–30%). The ultramafic rocks of the Zermatt-Saas complex have been serpentinized 100%, and most of this serpentinization occurred in the water excess zone at return point in the subduction zone.

Upheaval Dome – Impact approved

E. BUCHNER1 AND T. KENKMANN2
1Institut fuer Geologie, Universitaet Stuttgart, 70174 Stuttgart (elmar.buchner@geologie.uni-stuttgart.de)
2Institut fuer Mineralogie, Humboldt Universitaet Berlin, 10115 Berlin (Thomas.Kenkmann@MUSEUM.HU-Berlin.de)

Upheaval Dome (Utah, USA) has earlier been interpreted, amongst others, as a pinched-off salt diapir [1] or as an impact structure [2]. In previous petrographical studies, no non-ambiguous evidence for shock metamorphism was identified [2]. Nevertheless, most arguments, such as seismic reflection studies, structural features [3], and microstructures in quartz grains [4] agree with an impact origin of Upheaval Dome.

We recently found some single quartz grains in sandstones of Upheaval Dome target rocks suspect to be shocked quartz with multiple sets of planar deformation features. Planar elements in quartz grains of sandstones of the Upper Jurassic Kayenta Formation turned out to be impact-diagnostic planar deformation features provided by both microscopic studies and our TEM investigation.

Shock wave attenuation to magnitudes below the Hugoniot elastic limit of quartz can be deduced for most zones of the target rocks presently exposed at Upheaval Dome [3]. In sandstones of the Kayenta Formation, inhomogeneities in the stress wave induced maximum pressure peaks of ~10 GPa, necessary to generate planar deformation features in quartz grains. Microstructures in quartz grains investigated by the authors have to be explained as distinct features of shock metamorphism and, thus, we interpret this as ultimate evidence for shock metamorphism in the target rocks and for the impact origin of Upheaval Dome.

The thermal state of the Earth: Geochemical solutions to geophysical problems?

BRUCE BUFFETT
University of Chicago, Chicago, USA
(buffett@geosci.uchicago.edu)

Recent geophysical arguments for radioactive elements in the core are motivated by inconsistencies in thermal models for the evolution of the core. Predictions based on typical estimates of heat flow from the core (e.g. 5 to 10 TW) yield a young inner-core age and an implausibly hot temperature at earlier times. Such high heat flows are difficult to avoid because current estimates of the present-day core temperature yield a large temperature drop across D”, and this normally implies a large core heat flow. High heat flow may also be required to supply the power needed to drive the geodynamo, particularly at early times when the inner core was small or absent. However, high heat flow from the core is not easily sustained over the age of the Earth without additional energy sources. Radioactive elements in the core offer one possible explanation if the concentration of elements is sufficiently high.

Other solutions are possible, but none are without their own problems. Arguments for low power consumption by the geodynamo can lower the necessary heat flow and circumvent the problem of high temperatures at early times. However, a low heat flow still needs to be reconciled with estimates of the present-day core temperature. Low heat flow is also permitted by reducing the thermal conductivity of the core, but the same problem applies. Both of these explanations are contingent on some means of lowering heat flow when the core temperature is high. Sequestering radioactive elements in D” is one option, but this imposes another set of demands on the distribution of radioactive elements.

Progress in resolving these questions is likely to rely on many different disciplines. For example, isotopic evidence for an enriched primitive layer at the base of the mantle bolsters arguments for heat sources in D”. Seismic evidence for a phase transition (or transitions) near the base of the mantle would help to constrain the temperature, although the complex dynamics of the region may frustrate any attempt to extrapolate this temperature to the top of the core. It is also possible that the thermal models are incomplete. An important (but neglected) source of gravitational energy is possible if the solubilities of mantle components in liquid iron change as the core cools and the inner core grows. Difficult experiments are needed to quantify core-mantle geochemistry, but the effort may ultimately resolve an important geophysical problem.

A natural analog of "boron-mullite" in granulite-facies metapelites from Mount Stafford, central Australia

I. BUICK¹, E.S. GREW², M.G. YATES², O. MEDENBACH³, G.E. BEBOUT⁴ and G.L. CLARKE⁵

¹Research School of Earth Sciences, Australian National University (ian.buick@anu.edu.au)
²Department of Earth Sciences, University of Maine, USA (esgrew@maine.edu)
³Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität Bochum, Germany (olaf.medebach@rub.de)
⁴Department of Earth & Environmental Sciences, Lehigh University, USA (geb0@lehigh.edu)
⁵School of Geosciences, University of Sydney, Australia (geoffc@mail.usyd.edu.au)

Werner Schreyer and his colleagues gave the name “boron-mullite” to ternary mullite-like phases synthesized in the B₂O₃-Al₂O₃-SiO₂(-H₂O) system. These phases have been synthesized at 1200 °C from mullite + B₂O₃, 1520-1600 °C from BAS melts and at 500-1050 °C, 1 atm-8 kbar from gels (e.g., Figure). A possible natural analog resembles sillimanite; optical properties are in the range for mullite: α = 1.627(1), β = 1.634(1), γ = 1.649(1), 2Vγ = 56(1)°. It is heterogeneous on a very fine scale; compositions range from close to sillimanite to nearly half way to Al borate (B determined by EMPA); FeO and MgO contents rarely exceed 1 wt%. “Boron-mullite” is found in silica-undersaturated, boron-rich metapelites dominated by sekaninaite (Fe-cordierite), hercynite and K-feldspar. “Boron-mullite” typically forms overgrowths mostly <0.1 mm long on the Fe-dominant analog of werdingite, commonly in the vicinity of andalusite or sillimanite, but in one section, it also occurs as prisms up to 0.4 mm long in fringes overgrowing sillimanite bundles. Ominelite (Fe-grandidierite) and biotite are present in most sections; tourmaline is present locally. Granulite-facies conditions reached at least 775-785 °C, at 3.3-4 kbar. “Boron-mullite” appears to be prograde and might have formed from incongruent melting of werdingite in the presence of granite melt, a possibility suggested by the melting of werdingite at 1200 °C, 1 bar under nearly anhydrous conditions in MgO-BAS (Werding & Schreyer 1992), but occurring at lower temperatures and under higher pressures in the more complex natural system.

Earliest evidence of life on Earth

ROGER BUICK

Dept. Earth & Space Science and Astrobiology Program,
University of Washington, Seattle WA 98195-1310, USA
(buick@ess.washington.edu)

A key problem for geochemistry, paleobiology and astrobiology is how to recognize the first traces of life on Earth. Because particularly ancient rocks are scarce and poorly preserved, and because traces of primordial life might differ from the remains of modern organisms, the topic has proved especially contentious. Here I present a personal view of the subject, emphasizing the diversity of approaches that can be used to address it. Nobody else will agree with my conclusions.

Microfossils represent the preserved bodily remains of primordial life, but in the absence of evidence of behaviour, it is often difficult to prove that an organic sphere or filament was once alive. The most ancient such objects clearly showing signs of behaviour are from the ~2.6 Ga Transvaal Supergroup of South Africa. Stromatolites and other macroscopic trace fossils of microbial activities have a considerable Archean history. Molecular fossils of microbial activities have a considerable Archean history. Molecular fossils of microbial activities have a considerable Archean history. Molecular fossils of microbial activities have a considerable Archean history. Molecular fossils of microbial activities have a considerable Archean history. Molecular fossils of microbial activities have a considerable Archean history.

Stromatolites and other macroscopic trace fossils of microbial activities have a considerable Archean history. Molecular fossils of microbial activities have a considerable Archean history.

History of the Rumuruti chondrite asteroid by $^{40}$Ar-$^{39}$Ar dating

A.I. BUICK$^{1,2}$, M. TRIELOFF$^1$, E.V. KOROCHANTSEVA$^{1,2}$
AND J. HOPP$^1$

$^1$Mineralogisches Institut Universität Heidelberg, Heidelberg, Germany (trieloff@min.uni-heidelberg.de)
$^2$Vernadsky Institute of Russian Academy of Sciences, Moscow, Russia

Previous $^{40}$Ar-$^{39}$Ar dating on Rumurutiites yielded complex age spectra, precluding firm conclusions on the early thermal history of Rumuruti and its parent body [1,2]. In an ongoing initiative to constrain the history of meteorite parent bodies [3-6], we applied thermochronological modeling [7,8] to $^{40}$Ar-$^{39}$Ar age spectra of different Rumuruti lithologies (a light type 5/6 clast, a clastic matrix type 3.8 sample, and a type 3 clast). The age spectra show diffusive $^{39}$Ar loss (low temperature extractions), partial plateau segments and age drops at high degassing temperatures due to $^{39}$Ar recoil. The disturbing features correlate with grain size of the main K carrier phase plagioclase (glass). The coarse grained type 5/6 lithology has the best defined age plateau with 4.53±0.01 Ga. Taking into account that K-Ar ages are about 30 Ma too young due to bias in the K decay constants [3,9], a corrected age of 4.56 Ga implies a very short metamorphic history of the asteroid by $^{40}$Ar-$^{39}$Ar dating.

Unravelling the origin of zircon from sheared and altered ultramafic rocks of the Cycladic blueschist belt: A record of fluid infiltration?

F. BULLE AND M. BRÖCKER
Institut für Mineralogie, ZLG, Universität Münster, Corrensstr. 24, 48149 Münster, Germany
(f_bull01@uni-muenster.de; brocker@uni-muenster.de)

The eclogite- to epidote bluechist-facies sequences of the Cycladic blueschist belt in the Aegean Sea include mélanges with meta-igneous blocks and tectonic slabs (< 1 meter to several hundred meters) that are enclosed in an ultramafic or metasedimentary matrix. Due to its lithological variability, high block abundance and eye-catching metasomatic reaction zones at contacts between blocks and an ultramafic matrix, the HP mélangé on the island of Syros has attracted much attention, but less spectacular and less studied block-matrix associations are widespread on a regional scale (e.g. Tinos, Andros, Evvia, Samos). Ultramafic rocks have not been reported from all occurrences and the importance of serpentinite as matrix-forming rock is highly variable, both within and between individual outcrops. Many blocks are only surrounded by a rather thin envelope of serpentinitic material or talc, -chlorite- and actinolite-rich schists which formed by shearing of ultrabasic rocks that locally still are preserved as massive, largely undeformed rock bodies. The focus of our study is on these matrix rocks, which often contain considerable modal amounts of zircon, whereas non- or only weakly deformed ultramafic blocks are zircon free. The presence of zircon in the sheared and altered zones might indicate the incorporation of debris derived from mechanical disintegration of zircon-bearing rocks during deformation. Alternatively, this zircon might represent a newly grown phase that documents Zr release during HP metamorphic mineral reactions or precipitation from syn- or post-HP metamorphic aqueous fluids. In order to test these alternatives, we are studying block-matrix associations on Syros and Tinos. Microtextural criteria and zircon characteristics (morphology, internal structure, trace element patterns, ionprobe U-Pb ages) will be used to constrain the origin and geological significance of zircon occurring in ultramafic high-strain zones.

Methane oxidation, BIF carbonates and glaciation during the earliest Paleoproterozoic

BULUSU SREENIVAS AND SUBRATA DAS SHARMA
National Geophysical Research Institute, Hyderabad 500007, India (bsreenivas@ngri.res.in; dassharma@ngri.res.in)

Diminishing methane levels have been thought to be responsible for the disappearance of mass independent fractionation in S isotopes (S-MIF) and multiple glacial events during the time period between 2.43 and 2.32 Ga (Zhanle et al., 2006). The earliest of the three glacial events is preceded by deposition of largest banded iron formations (BIFs) at a very rapid rate (> 30 m/Ma) (Barley et al., 1997) and a mafic magmatic event as is evident from the Hamersley Group and the Transvaal Supergroup. In other sequences where such large BIF litho-units were absent, the earliest glacial deposits seem to overlie the unconformity represented by quartz pebble conglomerates and paleosols as in the Huronian Supergroup. Thus it appears that the BIF deposition at a very rapid rate has a causal effect on the initiation of the first of global scale multiple glaciation events and also the disappearance of S-MIF. Here we propose that the 13C depleted carbon isotope compositions associated with various BIF lithofacies in both the Hamersley and Transvaal basins have been resulted due to oxidation of methane. The δ13C compositions of carbonate and organic carbon of the various lithofacies of BIFs in both Hamersley and Transvaal basins is given in the following table and also of the source carbon assuming normal organic carbon burial:

<table>
<thead>
<tr>
<th>Lithofacies</th>
<th>δ13C_carb</th>
<th>δ13C_org</th>
<th>δ13C_in</th>
</tr>
</thead>
<tbody>
<tr>
<td>Oxide facies</td>
<td>-12</td>
<td>-18.6</td>
<td>-13.3</td>
</tr>
<tr>
<td>Siderite facies</td>
<td>-7.4</td>
<td>-37.8</td>
<td>-13.5</td>
</tr>
<tr>
<td>Carbonate facies</td>
<td>-1.3</td>
<td>-43</td>
<td>-9.6</td>
</tr>
<tr>
<td>Clastic facies</td>
<td>-3.5</td>
<td>-36.6</td>
<td>-10.1</td>
</tr>
</tbody>
</table>

Considering that highly depleted δ13C values are resulted under normal burial conditions of organic carbon, i.e., 20% total input carbon being stored in organic form, the δ13C of the input carbon during the BIF depositions would range from -13 to -8 ‰. Our calculations suggest that the ambient seawater inorganic carbon pool exchanged with CO2 formed due to oxidation of atmospheric methane (δ13C of -47 ‰) in proportions of ~ 15 to 30 %. This would amount to ~ 1017 moles of atmospheric methane drawdown.

Voltammetry as a tool for detecting metal sulfide particles and nanoparticles in natural waters

E. Bura-Nakic1, D. Krznarić1, G.R. Helz2 and I. Ciglenečki1

1Center for Marine and Environmental Research, Rudjer Bošković Institute, Zagreb, Bijenička 54, 10 000 Zagreb, Croatia (ebnakic@irb.hr; dkrznari@irb.hr; irena@irb.hr)
2Department of Chemistry and Biochemistry and Department of Geology, University of Maryland, College Park, MD 20895, USA [helz@umd.edu]

This paper deals with voltammetric characterization of metal sulfide nanoparticles (PbS, HgS, FeS, CdS, AgS and CuS) at the Hg and the glassy carbon electrodes in 0.55 M NaCl + 0.03 M NaHCO3 electrolyte, pH = 8.5. The aim was to investigate a possibility of using voltammetry in the detection of metal-sulfide nanoparticles in natural waters. The proposed electrochemical approach was applied in the detection of metal sulfide nanoparticles in two stratified lakes: saline Rogoznica Lake on the eastern Adriatic coast and Lake Pavin, a crater lake in the Central Massif, France.

The results of this work demonstrate that Pb, Hg, Fe, Cd, Ag and Cu sulfides, either as suspended powders or as precipitated nanoparticles, yield cathodic peaks between −0.9 and −1.7 V. Different experimental conditions (i.e. ageing of the particles, deposition potential and accumulation time) can affect shapes and positions of these reduction peaks. In anoxic natural samples, reduction peaks similar to those observed in model solutions were detected suggesting that voltammetry is a promising method for determination of metal sulfide nanoparticles. However, reduction peaks in the same potential range have been observed by other authors, who assigned them to the reduction of multimeric FeS(aq) complexes or clusters. The key findings of this work that other analytes: Cu2S, CuS, PbS, HgS, CdS, Ag2S nanoparticles, metal sulfide powders and sulfur powder produce similar reduction peaks. Therefore, here, we propose an experimental procedure to clarify the origin of voltammetric peak around -1.1 V in anoxic natural waters.

Thermodynamic properties and stability of the high-pressure silicate ellenbergerite in natural systems

M. Burchard, C. Chopin and F. Brunet

1Mineralogisches Institut, Universität Heidelberg, INF 236, D-69120 Heidelberg (burchard@min.uni-heidelberg.de)
2Laboratoire de Geologie, Ecole normale superieure - CNRS, 24 rue Lhomond, F-75005 Paris

Ellenbergerite, [(Ti,Zr)2Mg2]Mg18Al18Si24O84(OH)30, was first described by Chopin et al. (1986) as inclusions in pyrope megacrysts from the Dora-Maira UHP-quartzites of Parigi, western Alps, Italy. Three major endmembers are known: two silicate endmembers (titanian and zirconian ellenbergerite) and an isostructural Mg-phosphate endmember (phosphoellenbergerite), along with the isostructural iron-arsenite ekatite. The upper thermal and the lower-pressure stability limits of Ti-ellenbergerite were determined by Chopin et al. (1992) and the limiting lower pressure / lower temperature reaction by Burchard et al. (2001). The upper thermal and lower-pressure stability limits of Zr-ellenbergerite were determined by Burchard & Schreyer (1996). Comodi & Zanazzi (1993 a & b) published compressibility and thermal expansion data.

All these data were used to retrieve the entropy and the enthalpy of formation of Zr- and Ti-ellenbergerite at standard conditions (H° f,298,Ell and S° 298,Ell). The Gibbs free energy of formation of Zr- and Ti-ellenbergerites, calculated according to Berman & Brown (1988) and Holland & Powell (1998), is highly sensitive to water activity and bulk iron content of the rock, which may justify the rarity of ellenbergerite in nature.

ERDA of hydrogen content in hydrous and nominally anhydrous mantle phases

HELENE BUREAU1, CAROLINE RAEPSAET1, HICHAM KHODJA1, ANNA CARRARO2 AND CYRIL AUBAUD3

1Laboratoire Pierre Süe, UMR9956, CEA Saclay, 91191 Gif sur Yvette, France (helene.bureau@cea.fr; caroline.raEPSaet@cea.fr; hicham.khodja@cea.fr)
2Padova University, Dipartimento di Geoscienze Via Giotto, 1 - 35137 Padova Italy (a.carraro@unipd.it)
3LGIS, IPGP, 4, place Jussieu, 75251 Paris, France (aubaud@ipgp.jussieu.fr)

Nuclear methods, more especially ERDA (Elastic Recoil Detection Analysis) are used since a long time to determine the bulk hydrogen content of any kind of matrix material. The advantage of this method is that (1) the analysis is absolute with respect to H with an uncertainty of less than 10% relative, (2) all the H is characterized, not only H bonded with oxygen, (3) the samples are investigated on a micrometric scale. Whereas the method is extremely reliable to quantify hydrous geologic samples (e.g. Bureau et al, 2003), the few attempts made to characterize anhydrous phases were not so successfull because of too high backgrounds usually observed on the ERDA spectra, due to surface’s H (e.g. Sweeney et al., 1997). During the past four years, we have tried to improve the ERDA method in the nuclear microscope of the Pierre Süe laboratory. The setup has been modified, we perform scannings on large sample areas (200x800µm² at maximum) in order to reduce the H loss due to the 3 MeV incident 4He beam (4x16µm² during the ERDA analysis). The maps are processed using a specific software (RISMIN, Daudin et al. 2003). Therefore different areas of a same sample can be selected in order to measure their respective H contents. The detection limit has been measured on dehydrated San Carlos olivine to be 130 ppm wt H₂O (15 ppm wt H). Another advantage is that RBS (Rutherford Back Scattering) and PIXE (Proton Induced X-Rays Emission) are performed simultaneously providing a chemical characterization of the sample with respect to major and some trace elements. In this presentation we will review a few recent results: we have measured the hydrogen content of various kind of geological samples: volcanic glasses and glassy inclusions; synthetic and natural nominally anhydrous minerals (see also Carraro and co-workers, this issue).

Tracking groundwater contribution to rivers by combining hydrogen isotopes and cation concentrations

M. BUREAU1, J. CARIGNAN1, C. FRANCE-LANORD1 AND L. FRANÇOIS2

1Centre de Recherches Pétrographiques et Géochimiques, 15 rue Notre-Dame des Pauvres 54500 Vandoeuvre lès Nancy, France (mbureau@crpg.cnrs-nancy.fr)
2Laboratoire de Physique Atmosphérique et Planétaire, université de Liège, B-4000 Liège, Belgium

While the hydrological response of a basin to various water inputs may be described by models based on hydrographs only, isotopic and chemical analyses are often necessary to understand the mechanism of groundwater flows as well as the interactions between water, soils and rocks. We worked on the upper basin of the Moselle river (France). Samples were collected every 10 days during 18 months and comprised various water compartments such as i) precipitations, ii) groundwater sources, iii) main tributaries and iv) the river itself at 3 different sites. Meteorological and physical parameters were used along with hydrogen isotopes, major and trace elements analyses.

Major groundwater sources in the area yielded homogeneous δD values over the year and very similar to the composition of the weighted average of annual precipitations. This suggests a long residence time of water in the underground reservoirs. Furthermore, the δD values measured for river water during low flow periods are also very comparable to that of groundwater sources, suggesting a major contribution of groundwater to rivers during these periods. During flood periods, the shift in δD values measured in river water implies that only 30-40% of the total water flow may be attributed to precipitation (or snow melt), leaving 60-70% of the water discharge due to an increased contribution from groundwater (piston effect).

Positive relationships are found between dissolved cation (Ca, Mg, K) fluxes and water discharge at a given locality and over the 18 months of sampling. This implies that the increasing water discharge after precipitation events do not lead to a simple dilution of the dissolved species. Rather, an increase of the groundwater input is needed to increase dissolved cation flux. At one site, the relationship is very similar for the three cations, suggesting a simple larger contribution of the groundwater present during the low discharge periods. At other sites, different relationships are found for Ca, Mg or K, suggesting that more than one groundwater mass contributed.
Further constraints on Helium partitioning in mantle minerals

P. BURNARD¹, K. FARLEY² AND M. TOPLIS¹,³

¹CRPG-CNRS, BP20, 54501 Vandoeuvre, France
(peteb@crpg.cnrs-nancy.fr)
²GPS, California Institute of Technology, Pasadena, CA91125
³DTP, Observatoire Midi-Pyrénées F-31400, Toulouse, France

The He isotopic composition of the Earth's mantle varies by at least factor ≈5, with mid-ocean ridges characterized by more radiogenic He than ocean islands. There has clearly been significant, ancient He - U fractionation in the mantle but does less radiogenic He represent less or more processed mantle processed?

Heber et al [1] measured DHe\textsuperscript{mantle-melt} by growing olivine and pyroxene from a He-saturated melt whereas Parman et al [2] 'doped' existing olivine grains with a He atmosphere (without melting the olivine). The presence of inclusions in artificially grown minerals could bias the grown olivine results of [1] (which nevertheless provide a maximum estimate of DHe = 1.7 x10\textsuperscript{-4}) whereas the Parman approach - using gem-quality olivine as a starting material - should not be affected by inclusions therefore should result in DHe ≤ that of grown olivines. Surprisingly, equilibration with a He atmosphere resulted in DHe = 2.5 – 6 x10\textsuperscript{-3} or > 15 times higher that of the grown olivines.

We equilibrated 100µm thick forsterite wafers with 100% \textsuperscript{4}He at 1600°C; the wafers were then irradiated with 220 MeV protons following [3]. Proton irradiation produces \textsuperscript{3}He homogeneously in the olivine matrix [3].

Helium was extracted from doped-irradiated olivines by stepped-heating and measured by mass spectrometry at CIT. \textsuperscript{4}He/\textsuperscript{3}He is highly variable (10 - 1000) in these samples, in contrast to a constant \textsuperscript{4}He/\textsuperscript{3}He which would be the only solution consistent with homogeneous \textsuperscript{4}He dissolution in the olivine matrix. While difficult to interpret, these data imply that a) He is not simply in a single solubility site in the olivine matrix; b) the concentration of He in doped olivines probably overestimate He solubility, and therefore DHe; c) Heber et al's estimate (3 x10\textsuperscript{-5}) remains the best DHe\textsuperscript{ol/melt} upper limit.

Schwertmannite reduction and iron(II)-monosulfide formation in acidified coastal lowlands: Iron-sulfur geochemistry and implications for water quality

EDWARD BURTON, RICHARD BUSH AND LEIGH SULLIVAN

Centre for Acid Sulfate Soil Research, Southern Cross University, Australia (ed.burton@scu.edu.au)

Drainage of formerly waterlogged-sulfidic soils in coastal lowlands has resulted in widespread pyrite oxidation in many areas. This oxidation process liberates acidity, Fe and S; which, in turn, leads to the accumulation of schwertmannite (Fe\textsubscript{8}O\textsubscript{6}(OH)\textsubscript{6}SO\textsubscript{4}). Here we present the results of in-situ studies and laboratory-based experiments examining Fe-S geochemistry and the effects on water quality when schwertmannite accumulations are subjected to reducing conditions. This occurs (1) during diagenesis in the benthic sediments of acidified estuarine waterways; and (2) during prolonged waterlogging of acid sulfate soils as a result of wetland re-establishment.

In acidic (pH 3 – 4) and organic-rich (10% – 25% organic C) soils/sediments, bacterial reduction of schwertmannite-derived Fe(III) occurs readily under anoxic conditions. This produces abundant Fe\textsuperscript{2+}, SO\textsubscript{4} and HCO\textsubscript{3} which thereby drives pH increases to pH 6 – 7 and sequesters some Fe\textsuperscript{2+} via precipitation of siderite (FeCO\textsubscript{3}). As the pH increases above pH 5, adsorption of Fe\textsuperscript{2+} to schwertmannite catalyses the very rapid transformation of schwertmannite to goethite. The combination of near-neutral pH and the effective replacement of schwertmannite by goethite is accompanied by the formation of elemental S and acid-volatile sulfide. Examination by X-ray diffraction, electron microscopy and electron diffraction show that the acid-volatile sulfide mainly comprises nanoparticulate mackinawite (tetragonal FeS). The formation of elemental S and mackinawite reflect significant levels of SO\textsubscript{4}-reduction, even though the soils/sediments contain very large amounts of oxalate-extractable Fe(III). This is curious, as traditional theory (based on overall free energy yields) indicates that SO\textsubscript{4}-reduction should not occur significantly until near-complete reduction of Fe(III). The apparently anomalous co-occurence of Fe(III)- and SO\textsubscript{4}-reduction (as observed in both the field and laboratory) can be explained by an alternative partial equilibrium model of the thermodynamic favourability of Fe(III)- versus SO\textsubscript{4}-reduction. Central to this alternative model is the Fe\textsuperscript{2+}-catalysed transformation of schwertmannite to goethite – a process that facilitates co-occurence of Fe(III)- and SO\textsubscript{4}-reduction, and that promotes the accumulation of nanoparticulate mackinawite. The formation and fate of mackinawite has important water quality implications with regard to acidity fluxes and trace element behaviour.
Stable and radiogenic isotope variations accompanying continental weathering

Many natural isotope systems (both stable and radiogenic) are sensitive to variations in weathering process. The difficulty lies in distinguishing variations that result from weathering process from those caused by differences in rock type. One approach that circumvents this problem is the study of monolithologic catchments, where variations such as catchment age, runoff, physical and chemical weathering, vegetative cover and soil development can be related to riverine chemistry.

This study presents an overview of our recent work on radiogenic and stable isotope in rivers, soils and estuaries from catchments in Greenland, Iceland and Europe. Each case study illustrates the effects of weathering process on the riverine isotope signal, and the estuarine data indicates how this signal is transferred to the oceans. Aside from variations in rock type, the principal controls on isotope variations accompanying weathering are; (i) for many radiogenic isotope systems, preferential (incongruent) weathering of specific primary mineral phases, where those phases possess a markedly different parent/daughter and hence radiogenic isotope composition; (ii) for many stable isotope systems, preferential removal of an isotope into secondary phases formed during weathering, leaving residual waters depleted in that isotope. Recent studies have also shown the importance of biological removal and accompanying fractionation for certain isotope systems.

Taken together, these results clearly demonstrate that weathering processes can exert a significant effect on the isotope composition of natural waters, and for some of those isotopes marine sedimentary archives preserve a record of the changes in such processes with time. For marine records the challenge remains in unravelling the effects of weathering from those caused by variations in rock type, or a simple change in flux or geographical source.

The CO2 sealing efficiency of caprocks

ANDREAS BUSCH1, SASCHA ALLES1, BERNHARD M. KROOSS1, DAVID DEWHURST2 AND HELGE STANJEK3

1Institute of Geology and Geochemistry of Petroleum and Coal, Lochnerstr. 4-20, RWTH Aachen University, 52056 Aachen, Germany (busch@lek.rwth-aachen.de)
2CSIRO Petroleum, Australian Resources Research Centre, Western Australia
3RWTH Petroleum, Australian Resources Research Centre, Western Australia

Shale lithotypes of various compositions occur abundantly in sedimentary basins and act as natural seals for petroleum and natural gas reservoirs over extended geologic periods. Based on their mechanical, petrophysical and chemical/mineralogical properties, shales are becoming increasingly important in the context of geological long-term storage of anthropogenic carbon dioxide in saline aquifers, depleted oil and gas reservoirs and coals.

Due to its chemical reactivity and physico-chemical properties, CO2 is expected to differ substantially from other natural gas components in terms of transport behaviour and interaction with the mineral/water system. An experimental procedure has been developed to measure molecular diffusion of CO2 in water-saturated shales. This non-steady state method provides information on the effective diffusion coefficients and the CO2 storage capacity of the shales. Storage capacities were found to vary significantly but can be as high as 0.14 mmol CO2/g sample. Manometric sorption experiments with CO2 at pressures up to 20 MPa have been performed on dry and moist shale samples to verify the findings noted above. The results of these experiments revealed unexpectedly high storage potentials of the same order of magnitude as those from the diffusion measurements. The CO2 storage capacities do not correlate with organic carbon content. A separate set of experiments with pure clay minerals (Kaolinite, Illite, Montmorillonite....) revealed that some of these materials had high sorptive CO2 storage potential. Comparison of pre- and post-experiment X-ray diffraction patterns showed indications of changes in mineralogy.

These findings provide a new view on the issue of caprock integrity. In addition to their sealing properties, natural shale sequences could represent a significant sink or buffer for carbon dioxide deposited in the subsurface by fixing and immobilising it and hence reduce the risk of leakage to the surface.
Catalytic action of aqueous Fe(II) and S(II) on the transformation of schwertmannite to goethite

RICHARD BUSH, EDWARD BURTON AND LEIGH SULLIVAN
Centre for Acid Sulfate Soil Research, Southern Cross University, Australia (richard.bush@scu.edu.au)

The mineralisation of ferric oxides is of fundamental relevance to the geochemistry of marine and freshwater benthic sediments. In acidic landscapes affected by the oxidation of sulfides, schwertmannite (Fe8O8(OH)6(SO4)2) is a common ferric oxide. Due to its high surface area and intrinsic reactivity, schwertmannite is an important sink for metal contaminants and nutrients. The accumulation of schwertmannite occurs often at the oxic/anoxic boundary of benthic sediments. Under acidic oxygenated conditions the schwertmannite transforms slowly (i.e. 1-2 yrs) to more crystalline iron oxides such as goethite. Near-neutral anoxic conditions are known to enhance the rate that schwertmannite transforms to goethite (i.e. 2-3 months). Here we present the results of controlled laboratory batch experiments that examine the catalytic influence on schwertmannite of two strong and often abundant reductants that occur in the porewaters of benthic sediments, aqueous Fe(II) and S(II).

In the presence of Fe(II) and at a pH > 5.0, the schwertmannite transformed rapidly (i.e. within 15 min) to goethite and lepidocrocite. At pH < 5, Fe(II) had no effect. The increasing tendency for Fe(II) sorption at pH > 5.0 is responsible for the catalysed transformation of schwertmannite to more crystalline phases. Increasing pH and increasing Fe(II) concentration further enhanced this mineralisation reaction. The presence of S(II) caused a similarly rapid transformation of schwertmannite to more crystalline iron oxides. S(II) reacted within minutes with structural Fe(III) in the schwertmannite, producing elemental sulfur and Fe(II), with excess S(II) reacting with Fe(II) to form nano-particleulate mackinawite (FeS).

The catalytic effect of Fe(II) and S(II) can be attributed to electron exchange between the sorbed reductant and structural Fe(III) at the mineral surface, leading to destabilisation of the schwertmannite, its dissolution and transformation to more crystalline iron oxide phases. The catalytic influence of Fe(II) and S(II) on the transformation of schwertmannite to more crystalline iron oxides, and in the case of S(II), formation of elemental sulfur and mackinawite, have important implications for understanding the dynamics of Fe and S cycling, metal contaminant behaviour and water quality in acidic landscapes.

Evidence for nitrogen enrichment during oceanic crust alteration

V. BUSIGNY1, C. LAVERNE2, D. TEAGLE3 AND M. BONIFACIE1,4

1Lab. Géochimie des Isotopes Stables & Lab. Géochimie et Cosmochimie, JFG Paris, France (busigny@ipgp.jussieu.fr)
2Lab. Pétrologie Magmatique, Univ. Paul Cézanne Aix-Marseille III, France (christine.laverne@univ-cezanne.fr)
3National Oceanography Centre, Univ. of Southampton, England (dat@nocsoton.ac.uk)
4GPS, Caltech, USA (bonifaci@gps.caltech.edu)

Because N is present at only low concentration level in the Earth’s mantle, subducting altered oceanic crust may have a significant contribution to the long-term evolution of the N content and isotopic composition of the mantle. To date, whether N is enriched or released during hydrothermal alteration of oceanic crust remains uncertain. Hall [1] measured N content of spilitized basalts from Cornubian massif and suggested that N was enriched during alteration. However, spilitization might not be representative of seawater-oceanic crust interactions. Nitrogen contents of oceanic basalts from several DSDP/ODP Sites support the interpretation of N enrichment but show smaller magnitude than basalts from Cornubian massif [2,3]. The analysis of altered basalts from the ODP Hole 504B contrasts with these results, and indicates a loss of N from rock to fluid [4]. These authors extracted N using a pyrolysis technique, heating samples in molybdenum crucibles. However, N was recently shown to be strongly reactive with molybdenum at high temperature [5]. The low N concentrations measured in altered basalts from Hole 504B may thus result from the incomplete recovery of N rather than a specific type of alteration. To test this hypothesis, we analyzed samples from the Hole 504B using a sealed tube combustion technique, with samples embedded in platinum foils. The results show significant N enrichment (up to 12 ppm) relative to fresh degassed MORB (~1 ppm). This confirms that oceanic crust alteration acts as a sink for N from surface reservoirs and must be considered in subduction zone budget to evaluate the efficiency of N recycling to the mantle.

Mineral weathering rates coupled to bedrock fracturing and saprolite formation

HEATHER L. BUSS1, SAMUEL M. WEBB2, PETER B. SAK3, AND SUSAN L. BRANTLEY4

1U.S. Geological Survey, Menlo Park, CA, USA (hlbuss@usgs.gov)
2Stanford Synchrotron Radiation Laboratory, Stanford Linear Accelerator Center, Menlo Park, CA, USA (samwebb@slac.stanford.edu)
3Department of Geology, Dickinson College, Carlisle, PA, USA (sakp@dickinson.edu)
4Earth and Environmental Systems Institute, Penn State University, University Park, PA, USA (brantley@eesi.psu.edu)

Spheroidal weathering is a common mechanism by which bedrock corestones disaggregate to form saprolite. In the Rio Icacos watershed in the Puerto Rican rainforest, quartz diorite bedrock weathers spheroidally, producing a 0.2-2 m thick zone of concentric, partially weathered rock layers (~2.5 cm each) called rindlets. Spheroidal fracturing has been modeled to occur when a weathering reaction with a positive $\Delta V$ of reaction builds up elastic strain energy (Fletcher et al., 2006). The rates of spheroidal fracturing and saprolite formation are therefore controlled by the rate of the weathering reaction.

Based on petrographic evidence and thermodynamic calculations, we have identified biotite oxidation as the most likely fracture-inducing reaction. Oxidation of Fe(II) within the biotite lattice occurs with a concomitant loss of interlayer K+ to maintain charge balance. Adsorption of water to the interlayer could produce a positive $\Delta V$ of reaction sufficient to initiate fracturing if it occurs before other weathering reactions increase porosity enough to relieve the stress generated. Thus, detection of incipient weathering reactions is crucial for identifying the rate-controlling reaction.

Evidence for progressive biotite oxidation across the rindlet zone was inferred from the decreasing K content of the biotites and by decreasing Fe(II) content in bulk samples of the rindlets. Using a 1-D linear model (White, 2002) of the gradient in Fe(II), we calculated a biotite oxidation reaction rate of 7.2x10^{-14} mol m^{-2}s^{-1}. Evidence for incipient biotite oxidation was documented within the bedrock corestone by hard X-ray microprobe mapping and XANES, both performed at Beamline 2-3 at the Stanford Synchrotron Radiation Laboratory. Maps of Fe(II) and Fe(III) at 2 µm resolution revealed oxidized zones within individual biotite crystals. This ability to map oxidation states within individual crystals holds promise for identifying incipient weathering reactions within “pristine” bedrock, which in turn will allow quantification of rate limiting reactions in coupled processes such as spheroidal weathering.

Paradox of the plankton: Why is Proterozoic export production dominated by cyanobacteria?

NICHOLAS J. BUTTERFIELD
Department of Earth Sciences, University of Cambridge, Cambridge, UK CB2 3EQ

Eukaryotic organisms are well documented in the fossil record from at least the Mesoproterozoic, but the distribution of 2-methylhopanoid biomarker molecules suggests that cyanobacteria continued to dominate marine productivity until the Phanerozoic (Summons, R. E., et al. 1999. Nature 400:554–557). Although poorly resolved, the switchover to modern-style, eukaryote dominated export production can be broadly linked to the early Cambrian (Tommotian) “explosion” of animals, trace fossils and small ornamented acritarchs, the latter reasonably interpreted as the cysts of eukaryotic phytoplankton. The coincidence of these various signatures points to a fundamental shift in marine ecology.

The subdued expression of pre-Cambrian algae has been attributed to nitrogen limitation associated with a sulphidic deep ocean, but this is not supported by recent experimental results (Zerkle et al. 2006. Geobiology 4:285–297). Nor can the switch be simply attributed to appearance of eumetazoans, which precede the Cambrian explosion by some hundred million years and appear to have been exclusively benthic. The first real opportunity for eukaryotic phytoplankton came as metazoans moved into the water column to graze directly on primary productivity. In the absence of predation, unicellular phytoplankton are expected to evolve to minute size, without morphological elaboration, playing strongly to the strengths of cyanobacteria. The key to eukaryotic success, however, lies in their capacity for morphological differentiation, in this case the diverse ornamentation of early Cambrian acritarchs serving to frustrate grazing mesozooplankton. By selectively removing the long-standing cyanobacterial incumbents – and providing the trophic link between unicellular phytoplankton and macrozoaons – mesozooplankton can be held responsible for uniquely eukaryotic expression of the Phanerozoic biosphere.

Evidence for cross formation hot brine flow from integrated $^{87}$Sr/$^{86}$Sr and REE data in Central Tarim

CHUNFANG CAI, HONGTAO LI AND LI KAIKAI

Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, P. R. China

In Central Tarim, commercially oil and gas has been produced from fluorite reservoirs in the Ordovician carbonates. The fluorite occurs as replacement of carbonate wallrock and fracture fillings. Associated minerals with the fluorite include barite, anhydrite, calcite, quartz and pyrite. Calcite veins show wide ranges of fluid inclusion homogenization temperatures (HTs) and $^{87}$Sr/$^{86}$Sr ratios (0.70797 to 0.70977) and have $\delta^{13}$C values close to the ambient limestone. Anhydrite and fluorite veins have lower HTs and show much higher $^{87}$Sr/$^{86}$Sr ratios (0.70912 to 0.71036) than barite (~0.7090) and bulk limestone (0.7064 to 0.7094), but closer to the present brines (0.71026 to 0.71109), suggesting mixing of relatively hot Ba-rich and $^{87}$Sr-depleted fluid with relatively cool $^{87}$Sr-rich fluid. The cooler $^{87}$Sr-rich fluid has been proposed to have been derived from the west to the Central Tarim (Cai et al., 2001a). The hotter fluid was most likely derived from pre-Cambrian clastic rocks or/and from the basement. This proposal is supported by REE data. REE data of calcite, anhydrite and fluorite veins are characterized by a similar pattern with a positive Eu anomaly and LREE enrichment relative to HREE. The positive Eu anomaly indicates a reducing, hot fluid (>200 °C) during migration. The positive correlative relationships of Eu to Ba, Sr and Zn suggest that the hotter fluid was enriched in Eu$^{2+}$, Ba$^{2+}$, Sr$^{2+}$ and Zn$^{2+}$. When the hotter fluid mixed with the cooler fluid, barite and calcite precipitated at ~145 °C. Moreover, there was still diffraction peak corresponded to Ca-minerals including calcite, anhydrite and fluorite, resulting in the Ca-minerals having more radiogenic Sr than structure water of clay. This work is financially supported by China’s 973 projects (2006CB202304 and 2003CB214605) and NSFC 40573034.

Significance of the variation characteristics of interlayer water in smectite of source rocks

JINGONG CAI1, LONGFEI LU1, YUJIN BAO2, CONGXIAN LI1, JINLI XU2 AND XINGXIN WANG2

1State Key Laboratory of Marine Geology, Tongji University, Shanghai 20092, China (sediment@online.sh.cn)
2Institute of Earth Science, Shengli Oil Componary, Shandong 257015, China

The characteristics of interlayer water bonded to organic matter in interlayer of smectite were determined by thermo-XRD, DTA, TG and PY-GC for organo-clay complexes extracted from source rocks, and it plays an important role in explaining formation and migration of hydrocarbon in source rocks. As revealed by XRD curves, the $\delta^{34}$S reflected peak decreases under temperature of 250°C-500°C and not reaches 1.00‰ until 550°C, which is obviously different from smectite that keeps on 1.00‰ from 250°C to 500°C. Similarly, DTA curves show some exothermic peaks in the same temperature range. These observations clearly indicate that there is organic matter in smectite interlayers. PY-GC results show that the number of expelled organic matter is large under temperature of 250°C -500°C and in turn the temperature range is the just expulsive temperature span for interlayer organic matter. These pyrolysis products have a bimodal distribution dominated by short-chained C5 and long-chained C25 hydrocarbon, suggesting the interlayer organic matter correlate to oil components.

There are two vales, interlayer water and textural water endotherm vales, near 100°C and 600°C respectively, in DTA curves, which are similar to smectite completely, while a new endotherm vales appears at 500°C, which is characteristic of organo-clay complexes. PY-GC results also provide evidences supporting the existence of endotherm vale at 500°C. Moreover, there was still diffraction peak corresponded to smectite at 500°C XRD curve, implying smectite structure kept intact and the expelled water is interlayer water rather than structure water of clay.

Taken together, we find interlayer organic matter expelled at 500°C, followed by expulsion of interlayer water, suggesting the water may be water bridge between organic matter and smectite, which has a great influence on the hydrogenation on hydrocarbon generation. Curve fitting of the DTA and TG show that the expelled water at 500°C accounts for 4-6%, which may provide dynamic force and be a good medium for petroleum migration.

In situ natural radionuclides transport and retardation in coastal groundwater of the southern China

MINGGANG CAI, YIPU HUANG, MIN CHEN AND GUANGSHAN LIU

Department of Oceanography, University of Xiamen, Xiamen, 361005, China, (minggang.cai@chem.umu.se)

238U and 232Th decay-series disequilibria in groundwater naturally occur as a result of water-rock interactions. The studies connected with them provide site-specific, natural analog information which improve the understanding of migratory behavior of radionuclides in groundwater. In these studies, a mass balance model was used to relate the distributions of decay-series radionuclides among solution, sorbed and solid pools in an coastal aquifer system to processes of water transport, sorption-desorption, radioactive ingrowth-decay and α-recoil. Isotopes of Ra (226Ra, 228Ra, 224Ra) and Rn (222Rn) were measured in coastal groundwater from Xiamen, China, where both seawater intrusion and submarine groundwater discharge are found which make the rock-water interaction probably more remarkable there.

The results show that α-recoil supply rates of 222Rn (Pr,Ra) and 224Ra (Pr,Ra224) decrease seaward from 206 to 5.4 atoms L⁻¹ min⁻¹ and from 295 to 7.8 atoms L⁻¹ min⁻¹, respectively, which give good explanations for their spatial distributions. Pr,Ra224 is larger than Pr,Ra in each station, suggesting solids in studied aquifer may contain more thorium than uranium. Pr,Ra224/Pr,Ra increases seaward from 0.3 to 0.9 along the path with an average value of 0.6, suggesting the primary source of groundwater 222Rn is α-recoil of 226Ra decay in solid pool, and it is also seen that the ratio increases along the path. 226Ra decay in the sorbed pool (Rs,Ra226/Ar,a226) attributes about 40% of total source of coastal groundwater. 222Rn. Pr,Ra224/Ar,a224 ranges from 14.0 to 333.0, with an average value of 177.8, almost two orders higher than that of Pr,Ra/Ar,a, while α-recoil supply rate (Pr) from the aquifer rocks of both nuclides are within the same order. This shows that retardation of different nuclides by groundwater are differ greatly: α-recoil supply rate of 224Ra by aquifers rock is much faster than other radionuclides in Xiamen coastal groundwater, revealing aquifers rock have strong retardation on radium isotopes, while the immigration scale of 222Rn is longer than radium isotopes in groundwater.

The retardation factor of radium isotopes (Rf,Ra) in groundwater decrease seaward from 2.19×10⁷ to 0.94×10⁷, with average value 0.8×10⁷, while its liveliness extent increase gradually, which result in the decreasing of 222Rn of groundwater in a certain degree.

Calculation by the mass balance model also suggest that observed 224Ra/226Ra)a.r. of groundwater are mainly controlled together by α-recoil in aquifer solid pool and retardation by rocks. Both of effects decline gradually from land to sea, and make 224Ra/226Ra)a.r. increase gradually seaward the cooperatively.

Phanerozoic ocean chemistry and anthropogenic ocean acidification

KEN CALDEIRA

Carnegie Institution Department of Global Ecology, 260 Panama Street, Stanford CA 94305 USA; (kcaldeira@globalecology.stanford.edu)

Phanerozoic ocean carbonate chemistry

Phanerozoic ocean carbonate chemistry can be estimated using estimates of surface ocean carbonate mineral saturation states, calcium concentrations, temperature, and atmospheric carbon dioxide content. Any Phanerozoic carbonate chemistry reconstruction must be interpreted at best as indicating likely trends and magnitudes of past variation and not as a quantitatively accurate record.

Figure 1: Ocean pH computed assuming constant surface-ocean carbonate mineral saturation

Phanerozoic carbonate mineral saturation

There is no direct record of surface ocean carbonate mineral saturation states, but some idea can be gained by looking at the latitudinal extent of carbonate reefs, taking into consideration factors such as paleo-temperature and the dominant lithology of reef builders at any given time. It is likely that organisms have become more efficient at building carbonate skeletons due to the selective advantage bestowed upon organisms able to calcify in less saturated waters.

Variations in saturation states also follow geologic CO2 degassing rates. High CO2 degassing means high atmospheric pCO2 means high silicate weathering means high cation flux to the oceans. Ocean carbonate-ion concentrations must increase in response until the carbonate mineral saturation increases enough to induce carbonate burial that balances riverine inputs. Thus, on multi-million year time scales surface ocean carbonate saturation state tend to parallel atmospheric CO2 concentration.

Future carbonate mineral saturation

This situation contrasts markedly with what may occur over the next decades and centuries. Because of the rapidity of our CO2 emissions, over the next decades and centuries carbonate mineral saturation states will be approximately inversely proportional to atmospheric CO2 concentrations. Unabated anthropogenic CO2 emissions could produce surface ocean saturation conditions that are lower than any since the Cretaceous-Tertiary boundary extinction event.
Evidence of mantle metasomatism beneath São Tomé Island (Cameroon Volcanic Line)

R. CALDEIRA\(^1\) AND J.M. MUNHÁ\(^2\)

\(^{1}\)INETI -Departamento de Geologia, Alfragide, Portugal (rita.caldeira@ineti.pt)
\(^{2}\)Departamento e Centro de Geologia, Universidade de Lisboa, Portugal (jmunha@fc.ul.pt)

The occurrence of CO\(_2\) rich and carbonatitic metasomatic fluids as fertilizing agents of sub-continental mantle sources of the Cameroon Volcanic Line has been frequently referred. This report provides evidence for metasomatic processes in the mantle beneath São Tomé Island (oceanic sector of the CVL) based on mineralogical and geochemical data from primitive lavas and ultramafic xenoliths.

São Tomé primitive basalts (Mg\# > 57; Ni > 170 ppm) geochemistry reveals a non-p rimordial, heterogeneous, oxidized, amphibole bearing source, characteristic of metasomatic activity in the magma sources. Incompatible trace element patterns show an overall enrichment (e.g., Ce/La = 0.55 ± 0.02) implying a non-primordial character of their mantle sources. Observed variations on trace element contents and ratios (e.g. \(\Delta\log(\text{Ce/La})\)) suggest mantle heterogeneities sampled by low, but variable, partial melting degrees (< 17%), whereas K negative anomalies and D\(_{\text{K}_2}\text{O}\) > D\(_{\text{Rb}}\) and D\(_{\text{Sr}}\) > D\(_{\text{Ba}}\) indicate amphibole as the predominant K-rich residual phase. High \(\Delta\log(\text{Ni})\) values estimated for São Tomé primitive magmas reflect the oxidized nature of their asthenospheric magma sources. These features, together with sub-chondritic Ti/Eu ratios (5669 ± 706), uncorrelated with Mg\# and negatively correlated with Zr/Hf, La/Sm, and Th contents, suggest that mantle metasomatism was induced by interaction with carbonatitic melts.

Lack of correlation between silicate mineral Mg\# values and modal compositions in spinel peridotite xenoliths enclosed by São Tomé basaltic lavas indicate that these xenoliths are not simple residues, suggesting the occurrence of metasomatic activity within the regional lithospheric mantle. Abundant carbonate and CO\(_2\) rich fluid inclusions (Tm = -56.6°C), development of low-Al\(_2\)O\(_3\) secondary clinopyroxene, and high \(f_O_2\) [\(\Delta\log(\text{Ni})\) ~ 1] in peridotitic xenoliths are consistent with the inferences on geochemical processes operating at their host magma sources, providing further support for carbonate (fluid/melt) related metasomatism in the mantle beneath São Tomé Island.

Nickel stable isotopes as biogeochemical tracers

V. CAMERON\(^1\), D. VANCE\(^2\), C. ARCHER\(^2\) AND C.H. HOUSE\(^1\)

\(^{1}\)Department of Geosciences & Penn State Astrobiology Research Center, The Pennsylvania State University, University Park, PA. 16802 USA (cvyllinn@geosc.psu.edu; chouse@geosc.psu.edu)
\(^{2}\)Department of Earth Sciences, University of Bristol, Wills Memorial Building, Bristol. BS8 1RJ, UK (D.Vance@bristol.ac.uk)

Nickel (Ni), a bioessential trace metal, is functionally important to predominantly prokaryotic microorganisms (Archaea & Bacteria) in which, for example, Ni-containing enzymes act as catalysts in very specific metabolisms such as methanogenesis. Only one known enzyme, urease, in higher-order organisms (e.g. fungi & plants) requires Ni. Thus, from a biological point of view, it seems that the importance of Ni is relegated to more primitive and probably, ancient metabolisms that existed before the appearance of oxygen (Frausto da Silva and Williams, 2001).

We undertook an exploratory study of the Ni stable isotope system in an effort to determine natural variability for geochemical and particularly, biological applications. With the exception of extraterrestrial materials, Ni isotope studies have not previously been carried out. Additionally, as an astrobiological tool, Ni stable isotopes may potentially be utilized as biosignatures in characterizing and understanding microbial metabolisms and trace metal acquisition. A proven Ni isotope biomarker could be a useful tracer for microbial processes in which the geologic record of Ni isotopic composition might be employed in evaluating the evolutionary history of certain metabolisms, such as methanogenesis. Similarly, Ni isotopic compositions may be useful for assessing the metabolic characteristics of modern microbial ecosystems.

Method development and isotopic measurements were carried out at the University of Bristol. Initial experiments were of a biological nature and results will be presented.

Reconciling potentiometric titration and Second Harmonic Generation measured diffuse layer potential of an aqueous silica suspension

R. KRAMER CAMPEN1, ALLISON PYMER2, SATOSHI NIHONYANAGI3 AND ERIC BORGUET2

1Department of Geosciences, Pennsylvania State University, University Park, PA, USA (campen@geosc.psu.edu)
2Department of Chemistry, Temple University, Philadelphia, PA, USA (a.k.pymer@temple.edu; eborguet@temple.edu)
3Molecular Spectroscopy Lab, RIKEN: The Institute of Chemical and Physical Research, Wako, Saitama, Japan (nsatoshi@riken.jp)

The mineral surface potential plays a significant role in the quantitative understanding of mineral dissolution, contaminant transport and mineral colloid stability yet generally is not directly accessible experimentally. In particular, for most mineral surfaces of interest there are thought to be (at least) two relevant surface potentials: that of the mineral surface ($\phi_{\beta}$ and/or $\phi_0$) and, some distance into the aqueous phase, a diffuse layer potential ($\phi_d$). Surface potential is generally determined using electrokinetic techniques. However, these methods require hydrodynamic perturbation of the system and necessitate employing a model with difficult to constrain parameters to calculate $\phi_0/\phi_{\beta}/\phi_d$.

Second Harmonic Generation (SHG) is a second order nonlinear optical process, driven by an intense laser source, which is sensitive to interfacial electrical fields. For this reason the variation in the intensity of measured SHG ($I_{SHG}$) with changes in pH (for systems where H$^+$ is the sole potential determining ion) and salt concentration has previously been used to describe the surface potential of a variety of noncrystalline organic materials in water, as well as to determine the $pH_{bic}$ of several mineral/water systems. Here we measure the $I_{SHG}$ for the colloid silica/water system as a function of salt concentration at a variety of pH and use the results, in tandem with potentiometric titration, to quantify the mineral surface potential as a function of solution chemistry.

Origin and application of GOI data of oil inclusions in structurally complex Junggar Basin (NW China)

J. CAO1, Z.J. JIN2, W.X. Hu1, L. Xie1 AND S.P. YAO1

1Department of Earth Sciences, State Key Laboratory for Mineral Deposit Research, Nanjing University, Nanjing 210093, China (jcao@nju.edu.cn)
2Exploration and Production Research Institute, SINOPEC, Beijing 100083, China

GOI (grains containing/with oil inclusions) data are commonly used to identify paleo-oil columns and to map original oil-water contacts in hydrocarbon reservoirs. However, in superimposed China’s basins, oil-water contacts mostly have changed for variable times due to complex tectonic evolution. Thus, those threshold lines suggested in previous literatures, such as 1% for water zone and 5% for oil zone, can still be used effectively?

The Junggar Basin is one of the typical tectonically complex but most prolific oil provinces in China. In this study, five typical wells with different oil and gas shows were selected for GOI analyses in the Mosuowan area, central Junggar Basin. Discussion on analytical results from 48 reservoir samples indicates that the GOI data were mostly decided by intensity of reservoir hydrocarbon charging. However, due to the complex petroleum charge histories in superimposed basins, it is suggested that we should not simply use the GOI data to define petroleum migration according to previous threshold lines (e.g., 1%, 5%). It is more probable that based on geologic background, firstly to discuss the origin of GOI composition and then to have an application in reservoir characterization.

The case study in the Mosuowan area of the central Junggar Basin infers three specific points. Firstly, a GOI value of less than 1% was not always indicative of water zone or only migration of oil, but possible of gas reservoir or dysmigration of hydrocarbons. Secondly, the GOI values below 5% were still likely to indicate expose to high oil saturation when considering the difficulty in capture of oil inclusions in places. Thirdly and lastly, the threshold line of 6% GOI was likely the criterion for migration of industrial hydrocarbon reserves in the study area.

In a word, GOI method is still effective in quantitative evaluation of petroleum migration in structurally complex basins, but should be used comprehensively in combination with geologic background.

Treatment of high metal concentration AMD using Dispersed Alkaline Substrate (DAS), a novel passive treatment system

MANUEL A. CARABALLO¹, TOBIAS S. RÖTTING², JOSÉ MIGUEL NIETO¹ AND CARLOS AYORA²

¹Dpt. of Geology, Univ. of Huelva. Avda Fuerzas Armadas s/n 21071 Huelva, Spain. (manuel.caraballo@dgeo.uhu.es)
²Institute of Earth Sciences “Jaume Almera” CSIC, Lluis Solé y Sabari s/n. 08028 Barcelona, Spain. (Tobias.Roetting@newcastle.ac.uk)

In spite of the existence of many Passive Treatment Systems used for remediation of Acid Mine Drainage (AMD), with moderate metal concentrations and acidity, all of these systems shown severe problems when exposed to high metal concentrations such as those present in AMD from sulfide mining districts. To overcome this problem we have developed a novel Dispersed Alkaline Substrate (DAS), consisting in a mixture of a fine-grained alkaline reactive (limestone sand in T1 and T2 and MgO dust in T3; Fig. 1) and a coarse inert matrix (wood chips). AMD at Monte Romero (Iberian Pyrite Belt, SW Spain) has a pH of 3-3.5, net acidity of 1400-1650 mg/L as CaCO₃, 320 mg/L Fe (95% Fe²⁺), 310 mg/L Zn, 75 mg/L Al, 0.1-1 mg/L Cu, As, Pb, Co, Ni and Cd. The pilot-scaled field experiment (Fig. 1) presents encouraging results. T1+D1+D2 remove 100% of Al, As, Pb and Cu, 50% of Fe, 15% of Cd and 5% of Zn from the inflow water. T2+D3+D4 remove almost 100% of Fe and T3 is designed to remove the remaining Zn and Cd, although results for T3 are not available yet.

Figure 1: Localization and schematic representation of the DAS pilot treatment plant developed at Monte Romero Field Site (SW Spain).

(Mg,Fe,Al)(Si,Al)O₃ post-perovskite and the D” layer

RAZVAN CARACAS
Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany, razvan.caracas@uni-bayreuth.de

We perform first-principles calculations based on density-functional theory to investigate the effects of Fe-Mg and MgSi-AlAl substitutions on the properties of MgSiO₃ perovskite (pv) and post-perovskite (ppv).

Our results show that Fe²⁺ partitions preferentially in ppv and significantly reduces the pv-ppv transition pressure. Fe²⁺ is in high-spin state; it decreases the seismic wave velocities and slightly decreases the seismic anisotropy of MgSiO₃. Al partitions preferentially in pv and increases the pv-ppv transition pressure. It decreases the seismic wave velocities and considerably increases the seismic anisotropy of post-perovskite. Consequently the D” layer can be explained by the pv to ppv transition in pyrolite, suggesting that D” is not only a repository of sunken slabs:

The variation of the physical properties of pv and ppv with chemistry also suggest that the regions where the D” layer is thicker should be rich in iron. They should have lower seismic wave velocities than the Fe-poor regions and comparable shear wave splitting. The ultra-low velocity zones, situated at the base of the D” layer may thus be even iron richer. The regions where the D” layer is thinner should be poor in iron and richer in alumina. These regions will have lower seismic wave velocities and will show larger shear wave splitting. In a hot mantle regime the transition is narrower as the variation of the element partitioning is reduced compared to a cold mantle regime where the transition is broadened.

We can also correlate seismic anisotropy with the crystal orientation and the chemical composition of pv and ppv.
Isotope tracing of atmospheric metals (Pb, Zn, Cd, Hg)
J. CARIGNAN
CRPG-CNRS, 15, Rue Notre-Dame des Pauvres, B. P. 20, 54501, Vandoeuvre-lès-Nancy Cedex, France (carignan@crpg.cnrs-nancy.fr)

Among other heavy metals, Cu, Zn, Cd and Pb concentrations are often well correlated in aerosols, precipitation or lichen samples, suggesting common sources of atmospheric emissions. However, quantifying the relative proportions of anthropogenic and natural metals and identifying different pollution sources is not straightforward unless sampling is done in the area of a known specific emitter (smelters, waste incinerators, ...). On the other hand, the isotopic composition of atmospheric Pb was revealed to be a powerful tool to discriminate anthropogenic from natural sources and between pollution sources having different isotopic compositions.

Relationships between Pb isotopes and metal concentrations (Pb, Zn, Cd, ...) may be looked at in order to document any coherence between sources and metal compositions in both space and time. Concentration relationships sometimes suggest that metal sources are decoupled and/or that metals have different reactivity during transport, leading to different atmospheric residence time. Zn concentrations in aerosols and precipitation samples are often found in excess relative the other metal concentrations, suggesting a significant source for Zn in atmospheric fallout that is not well constrain, either natural or anthropogenic. For example, a systematic difference in chemical and isotopic compositions (Pb-Zn) is observed between wet and wet+dry atmospheric depositions in NE North America. The data suggests that dissolved and particulate matter are not in isotopic equilibrium and that the different phases do not originate from the same sources. As an other example, Hg concentrations are also often decoupled from those of other heavy metals. In some coastal areas, Hg concentration is rather related to that of halogen elements, suggesting either a source relationship or atmospheric chemical reactions. Isotope fractionation of the $^{202/198}$Hg may be expected between gaseous metal Hg and an oxidised form such as HgCl$_2$ or HgBr$_2$ so that Hg oxidation by halogen elements should be isotopically traceable. In addition, volatile metals like Cd and Hg might be isotopically fractionated by industrial processes (volatilisation and condensation) and be traced in the environment. Combined to Pb isotopes, new isotopic systems such as Zn, Cd, Hg should provide further useful information about surface cycles of heavy metals.

Delta zero reference materials for stable isotope analysis and applications to in situ measurements
J. CARIGNAN, C. ROLLION-BARD AND M. CHAMPENOIS
CRPG-CNRS, 15, Rue Notre-Dame des Pauvres, B. P. 20, 54501, Vandoeuvre Cédex, France (carignan@crpg.cnrs-nancy.fr; rollion@crpg.cnrs-nancy.fr)

For the last 3 to 5 years, measurement of the isotopic composition of various elements, which were classified as "non-traditional", exploded with the development of multi-collector ICP-MS. The data production was faster than consensual agreements on the expression and the notation of all these isotopic systems. In the mean time, simple conventions, such as primary and secondary reference materials (RM) and isotopes of normalisation, were adopted by many laboratories worldwide. Most primary "delta zero" RM were selected out of existing materials, namely from NIST or IRMM. According to the available certificate of analysis, some RM would not be sufficiently homogeneous in isotopic composition to fit the high measurement precision and accuracy now achieved in various laboratories. Except for the NIST SRM 981 Mg, which was effectively inhomogeneous at ±1% for the $^{25/24}$Mg ratio, Ca, Li, and Fe selected primary RM (respectively NIST SRM 915a, CAL-S, IRMM-14) revealed isotopic composition that was much more homogeneous than the reported uncertainties. This made the materials suitable for being delta zero RM. However, these are delivered as a powder or a liquid form, not suitable for in situ analysis techniques such as LA-MC-ICP-MS and SIMS.

Moreover, as bulk material is introduced in the mass spectrometer for in situ measurements, the instrumental mass bias is very dependent on the sample matrix analysed and a similar matrix is needed for reference materials. Thus, SIMS laboratories usually develop their own internal reference materials (IRM). These IRM are tested for their chemical and isotopic homogeneity at the microscale and are analysed by bulk methods relative to the appropriate delta zero RM. For each isotope system and sample matrix, two IRM are needed, one for normalisation and the other for checking on the signal linearity and accuracy. In order to distinguish true isotopic variations from "cryptic" matrix effects, we measured $^{44/40}$Ca in synthetic samples having different Mg/(Mg+Ca) ratios.

The measurement of O isotopes in garnet required 3 garnet IRM being Ca, Fe and Mg rich respectively. An integrated correction of mass bias using these IRM was used for samples of known chemical compositions (Vielzeuf et al., 2005).

Chondrite Barium, Neodymium and Samarium isotopic heterogeneity and early Earth differentiation

RICHARD CARLSON¹, MAUD BOYET¹,² AND MARY HORAN¹

¹Carnegie Institution of Washington, Washington, DC, USA (rcarlson@ciw.edu, horan@dtm.ciw.edu)
²Université Jean Monnet, St. Etienne, France (maud.boyet@univ-st-etienne.fr)

Understanding the early earth differentiation requires using a cosmochemical reference that represents the bulk composition of the planet. The difference of ~20 ppm measured between chondritic and terrestrial $^{142}\text{Nd}/^{144}\text{Nd}$ have been interpreted to reflect an early silicate differentiation of the Earth [1], $^{142}\text{Nd}$ being formed through time by the radiogenic decay of $^{146}\text{Sm}$ (half-life = 103 Myr). A critical requirement in this application is demonstration that the small isotopic variations do not simply reflect isotopic heterogeneity in the Solar nebula caused by imperfect mixing of the various stellar contributions [2].

New determinations of Ba, Nd, and Sm isotopic composition in 12 chondrites from different groups show that carbonaceous chondrites contain well-resolved $s$- and $p$-process deficiencies in these elements relative to ordinary and enstatite chondrites. Using $^{146}\text{Nd}/^{144}\text{Nd}$ to correct for the observed $s$-process deficiency produces a chondrite $^{146}\text{Sm}$-$^{144}\text{Nd}$ isochron that is consistent with previous estimates of the initial Solar System abundance of $^{146}\text{Sm}$ and a $^{142}\text{Nd}/^{144}\text{Nd}$ at average chondrite Sm/Nd ratio that is 21 ± 3 ppm lower than measured in terrestrial rocks [2, 3]. This result strengthens the conclusion that the deficiency in $^{142}\text{Nd}$ in chondrites compared to terrestrial rocks reflects $^{146}\text{Sm}$ decay.

Despite showing large variation in Lu/Hf, both refractory and lithophile elements like the REE, chondrites from different groups show little variation in their Sm/Nd ratios. No chondrites measured so far have $^{147}\text{Sm}/^{144}\text{Nd}$ high enough to explain the terrestrial $^{142}\text{Nd}/^{144}\text{Nd}$. The $p$-process deficits in $^{146}\text{Sm}$ measured in carbonaceous chondrites suggest that ordinary and enstatite chondrites are better analogs for the bulk composition of the earth. Only superchondritic $^{142}\text{Nd}/^{144}\text{Nd}$ have been measured in terrestrial rocks. These results suggest that a major volume of Earth’s mantle was depleted in incompatible elements as a result of magma ocean crystallization. We are pursuing evidence for the presence of the complementary enriched reservoir, which should be preserved in the deep mantle despite 4.5 Gyr of mantle convection.

Ensuring accuracy in high-precision isotope ratio measurements

RICHARD CARLSON¹, MAUD BOYET² AND MARIA SCHÖNBÄCHLER³

¹Carnegie Institution of Washington, Washington, DC, USA (rcarlson@ciw.edu)
²Université Jean Monnet, St. Etienne, France (maud.boyet@univ-st-etienne.fr)
³Department of Earth Science and Engineering, Imperial College, London, UK (marias@imperial.ac.uk)

Recent improvements in isotope ratio measurement precision are most clearly associated with physical improvements in the instruments used to make these measurements. Factors such as faraday cup efficiency, detector linearity and dynamic range, and consistent ion focussing clearly were critical in pushing precisions below the 10 ppm level. A number of other factors enter into the precision, and particularly the accuracy of isotope ratio measurements at this level. Common to both TIMS and ICP-MS are the question of the correct form of the instrumental mass fractionation correction, and the difficulty of detecting, and correcting for, isobaric interferences that may be a million times smaller than the signal analysed. ICP sources and the desire to measure stable isotope fractionation add another suite of issues that include: a richer and more complex atomic and molecular interference spectrum; the need to correct for sample mass fractionation that may occur during sample volatilization (in laser ablation), chemical separation, introduction into the plasma (particularly when using desolvating nebulizers), evaporation and ionization in the plasma, ion-electron separation, and ion extraction and focussing. Simple mass-only dependency of fractionation in the ICP was revealed as a myth as precisions moved from the hundreds to tens of ppm range. Many of these issues add to our dependency on high quality standards to ensure interlaboratory comparison. For TIMS Nd, for example, all available standards have more Ce and Sm than rock samples separated using modern procedures. For ICP-MS, standard comparison often cannot be done with relatively easily prepared single-element solutions, but requires standards with matrices similar to the samples being analysed to show that chemical separation and sample introduction effect standard and sample in similar ways. With care, these issues can be dealt with well enough to obtain isotope ratio precisions within a factor of 2 to 4 of counting statistics. Therefore, future precision improvements are likely to come from instruments that produce nanoamp beams from micrograms of sample instead of picoamps from nanograms, and have faraday detectors that can maintain perfect collection efficiency at this increased level of abuse. Improving precision of small sample analysis likely will depend primarily on improved sample utilization (delivery, ionization and transport) efficiency and on the development of electron multipliers that provide better linearity, dynamic range and longevity.
Saturation state of seawater with respect to the otavite-calcite solid solution

J. CARNEIRO, M. PRIETO AND H. STOLL
Departamento de Geologia, Universidad de Oviedo, C/ Jesús Arias de Velasco, s/n, 33005 Oviedo, Spain (joana@geol.uniovi.es; mprieto@geol.uniovi.es; hstoll@geol.uniovi.es)

In the oceans, the vertical distribution of dissolved cadmium (Cd) generally exhibits a nutrient-type profile. For this reason, it has been admitted that its depletion in the surface waters is regulated by biogeochemical processes. On the other hand, experiments on the sorption of Cd$^{2+}$ to calcite and/or aragonite surfaces have shown the effectiveness of these minerals – especially aragonite – in removing Cd from freshwater solutions (e.g. Prieto et al., 2003).

Our aim in this study has been to thermodynamically evaluate the possible occurrence of an inorganic removal of Cd from seawater, by sorption/coprecipitation onto/calcite, to form otavite-calcite solid solutions. This research has resorted to chemical modelling, previous to experimental observations.

Using the geochemical computer code PHREEQC (Parkhurst and Appelo, 2003), and JGOFs data collected from the equatorial Pacific (lat=0º, long=−140º) at depths from 20 to 175 meters, we have calculated the saturation state of this seawater with respect to the pure endmembers of the (Cd,Ca)CO$_3$ solid solution. We observe that seawater is supersaturated with respect to pure calcite and subsaturated for pure otavite. Furthermore, by computing the “stoichiometric supersaturation function” (Prieto et al., 1993) for the whole solid solution compositional range, we observe that the maximum supersaturation of seawater deviates slightly from the pure calcite composition, i.e. the solid phase most likely to precipitate from the aqueous solution is a Cd-bearing solid. Also, an increase in the dissolved Cd in the aqueous solution leads to a higher equilibrium distribution coefficient, which in turn results in a higher mole fraction of Cd in the precipitating solid phase.

These findings may suggest that an uptake of Cd from seawater on an inorganic basis might have some influence in the Cd depletion of the surface oceans. This inorganic removal would, however, depend on the availability of inorganic calcitic and/or aragonitic particles in the surface waters, among other factors.

Earthworms and mineral weathering

DANIEL CARPENTER$^1$, MARK E. HODSON$^1$, PAUL EGGLETON$^2$ AND CAROLINE KIRK$^3$

The role of organisms in mineral weathering has been investigated by several authors. Studies have shown that bacteria, fungi, lichen and plants all have a role in mineral weathering. The role of annelid worms in mineral weathering has been little studied. Mineral weathering has been demonstrated in marine annelids (McIlroy et al. 2003) and there is some indication that earthworms may also play a role in mineral weathering (Suzuki et al. 2003). Earthworms interact intimately with the mineral soil and have a major influence on the physical structure and chemistry of soils. They increase the porosity and the water holding capacity of soils. Their casts have more available plant nutrients than the bulk soil. They transport material from the lower horizons to the soil surface and they are responsible for the incorporation of organic matter into the lower horizons. A series of experiments were run to investigate the effect of an epigeic earthworm (*Dendrobaena attemsi*) on soil minerals weathering. The minerals anorthite, biotite, olivine, kaolinite and smectite were mixed with a sterilized manure substrate. Four treatments were used to investigate the effect of the earthworms on the minerals; earthworms and minerals, and no earthworms and minerals. The earthworms were left to process the substrates for 1, 2, 4 and 6 months. Four sacrificial replicates were used. Changes in mineralogy were investigated by several authors. 3Laboratoire des Géomatériaux, Université de Marne la Vallée, France (yves.fuchs@univ-mlv.fr)

Hydrogen contents were quantified in olivine (ol) and clinopyroxene (cpx) grains using the nuclear microprobe. The analysed minerals form spinel peridotite xenoliths with protogranular to porphyroclastic texture, hosted in alkaline basalts from two localities of the Eastern Veneto Volcanic Province (NE Italy). Mineral compositions indicated good re-equilibration at T-P upper mantle conditions (T = 850-950°C and P = 1.7±0.04 GPa). A combination of ERDA (Elastic recoil Detection Analysis) and RBS (Rutherford Back Scattering) methods were used for H measurements (Laboratoire Pierre Süe, France). The following analytical conditions were applied: 4He+ energy = 3.0 MeV, beam spot size = 4x4 µm2, 4x16 µm2 for ERDA, scanned on large sample areas, scattering angle = 170°, recoil angle = 30° (see also Bureau and co-workers, this issue). 22 samples were prepared following a specific protocol in order to decrease the effect of H absorbed at the surface of the polished samples. The same grains were analysed with electron microprobe, in order to check possible chemical heterogeneities in the areas investigated by ERDA. Chemically homogeneous ERDA maps were selected using Daudin et al. (2003): results reported below are referred to H depleted zones:

All cpx grains show H contents in the ranges reported from the literature for mantle analogue phases, obtained by commonly used IR spectroscopy, whereas ol grains have H concentrations close to or higher than maximum values reported for mantle ol (Ingrin & Skogby, 2000). Cpx samples systematically show H contents higher than those found for olivine: this is confirmed by recent IR data (Demouchy et al., 2006) and probably due to the fact that H diffusion at mantle temperatures is faster in olivine than in pyroxene.

In situ cosmogenic nuclides in river bedload. Implications for catchment-scale erosion rate and surface exposure dating

SEBASTIEN CARRETIER, VINCENT REGARD AND CAROLE SOUAL1

LMTG - Observatoire Midi-Pyrénées - UMR 5563 UR 154 CNRS / IRD / University of Toulouse – 14 av. E. Belin – 31400 Toulouse – France (carretie@lmtg.obs-mip.fr, regard@lmtg.obs-mip.fr)

Terrestrial Cosmogenic nuclides (TCN) have been widely used to date the exposure of alluvial surfaces and to estimate catchment scale erosion rates. However, dispersion in TCN concentrations in distinct samples of the same locality remains to be explained.

We develop a numerical model to calculate the TCN concentration at a clast center on hillslope and along a main river path. The hillslope model is an analogue to freeze-thaw and rock fall. In river, transport velocity of clasts depends: 1- on a probability to be buried in a mixing sediment layer, which depends on clasts size, or within adjacent terrace, 2- on clast size, which decreases downstream by abrasion. Below a specified size, clasts go in the washload. We run the path of numerous clasts of variable size and we analyse statistically their TCN concentration at river outlet.

Clast abrasion tends to increase the mean and variance of concentrations of the small clasts fraction because this class incorporates initially big clasts which traveled a long distance and initially small clasts launched near outlet. However, the final size-concentration relationship depends on the initial size distribution. This suggests that minimizing inheritance in surface exposure dating requires the analysis of clast size distribution and lithology. Moreover, this size-concentration relationships suggests that the largest hillslope inheritance is not necessarily in fine sand but may be in coarser fractions. The distribution of concentrations does not evolve any more from a certain river length corresponding to a no-deposition critical travel length. This suggests that bedload might integrate only material from the bottom of large catchments, which might bias TCN-derived catchment-scale erosion rates. The proposed theory can be tested from measurements in bedload sediments of differing sizes. In addition, we provide approximate analytical solutions which could permit to constrain the mean transport velocity law for a clast.
Benthic foraminifera as a novel substrate for deep-water Nd isotopes

P. CARTER, D. VANCE AND D.N. SCHMIDT

Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK.
(paul.carter@bristol.ac.uk)

The neodymium (Nd) isotopic composition of Fe-Mn crusts, fish teeth and leachates of Fe-Mn oxides from bulk sediment have all been used to reconstruct deep ocean circulation. However, each has its limitations, including low temporal resolution or terrigenous contamination. Here we present species specific Nd isotope records, coupled with multiple element/calcium ratios, from a highly available substrate, benthic foraminifera. Comparisons are made with a seawater Nd isotope profile to assess their ability to accurately represent modern ocean composition.

Holocene depth profiles from two sites, and core-top scrapings from 4 sites, all in the NE Atlantic, were hand picked for monospecific samples of Cibicidoides wuellerstorfi, Planulina ariminensis, Melonis barleaneum, and Uvigerina peregrina. Nd concentrations are found to be three times higher in epifaunal species than in infaunal (1.5ppm compared to 0.5ppm). The epifaunal εNd profile reveals a constant down-core (0-10cm) value of -12, whilst the infaunal profiles are identical for all but the upper 2cm. Nd concentrations in benthic foraminifera are also found to co-vary with Cd/Ca ratios, a widely used palaeoceanographic water mass proxy, providing confidence in the use of Nd isotopes from benthic foraminifera.

The foraminifera Nd isotope data are compared with both a new nearby seawater profile and with Fe-Mn oxide leachate data. Though the εNd of bottom water, foraminifera and leachates all agree, elevated Nd concentrations in bottom water samples suggest an addition of Nd to bottom water from sediment and/or pore water. Benthic foraminifera are therefore thought to reliably record bottom water Nd isotopic composition. Bottom water at this ocean margin site is influenced by interaction with sediments as recently proposed for many ocean margin settings [1].

Mantle-derived carbonados: Insights from Dachine diamonds (French Guiana)

PIERRE CARTIGNY

Laboratoire de Géochimie des Isotopes Stables de l'IPG-Paris, France. (cartigny@ipgp.jussieu.fr)

Carbonados are black/greyish almost graphitic in appearance non gemmy polycrystalline diamonds, up to 3100 carats in size, made of sintered irregular diamond grains in the nano- to micrometer range. Carbonado sensu-stricto seem geographically restricted to Brazil and Central Africa. Understanding the formation of carbonado is one of the most enigmatic problems in diamond geology. It has been suggested that carbonado may either be formed during impact metamorphism, by irradiation of carbonaceous-rich material or even formed in exploding super-novae. A mantle-derived origin is generally rejected based on the observation that carbonados do not occur within either lamproite and kimberlite which bring deep mantle-related diamonds to the surface and because carbonados have a series of features clearly distinct from any other type of diamond: among them their carbon isotope signatures centered at ~-28‰ (e.g. [1]) and their poorly advanced nitrogen aggregation state [2] which require that the sample spent virtually no time in the Earth’s mantle.

We studied 160 diamonds from the Dachine area (French Guiana). These diamonds are the only samples recovered so far from a volcaniclastic komatiite [3]. The samples are monocrystalline (i.e. non polycrystalline) macrodiamonds (>500 microns) mostly (>95%) irregular in shape with resorbed octahedron and cubes being occasionally recognised. No syngenetic inclusion has been identified yet. Most (>90%) samples are nitrogen free (Type II) and the few samples containing nitrogen (Type I) are characterised by low aggregation states. Their carbon isotope compositions range from -31.9 to +0.15‰ with an average of -24.4‰.

The observed general 13C-depletion among diamonds from Dachine including both octahedron and cuboids (and their respective resorbed forms), among both Type II and Type I diamonds demonstrates that an entire diamond population with 13C-depletion can originate from the mantle. Thus the long-standing statement that carbonados could not derive from the mantle based on distinct carbon isotope composition and N-speciation is now contradicted by our new data and the possibility of carbonados being formed in the mante deserves closer examination. A mantle-related formation of carbonados would succeed in explaining first order observations in particular their large size.

Compositional gradient of Cpx produced by fluid assisted eclogitization

F. O. CASARIN1, H. AUSTRHEIM1,2 AND A. PUTNIS1

1Institut für Mineralogie, 48149 Münster, Germany (fcasa_01@uni-muenster.de; putnis@uni-muenster.de)
2PGP, Universitetet i Oslo, 0316 Oslo, Norway (h.o.austrheim@geo.uio.no)

The Precambrian granulite facies assemblages (P ≤ 10 kbar, 800°C) of the anorthositic rocks of the Bergen Arcs, Western Norway was overprinted by eclogite facies assemblages (P=15-20 kbar, 650-700°C) along shear zones and fluid pathways associated with the Caledonian orogenic cycle (Jamtveit et al. 1990).

The aim of this study is to investigate the mechanism of fluid-mineral interaction that take place as the granulite facies clinopyroxene is altered to omphacite using microscopy and micro-analytical techniques (SEM, EMP and TEM).

The investigated sample comes from the margin of a shear zone and contains relicts of garnet and clinopyroxene while the former plagioclase domains are reacted to kyanite, omphacite, amphibole, clinozoisite and white micas (paragonite and phengite). Relict clinopyroxene in contact with plagioclase domains is replaced by the following sequence of reaction zones: 1) a core of Al-rich diopside (granulite facies), locally with domains of intergrown garnet and diopside. 2) An inner zone consisting of coarsely intergrown pyroxene (Jd 24) and amphibole (symplectite A). 3) An intermediate zone of porous pyroxene (Jd 43) with inclusions of dolomite. 4) An outer zone consisting of grains of omphacite (Jd 59) surrounded by symplectites of amphibole and plagioclase (symplectite B).

The reaction zones that developed around the granulite facies pyroxene core have a total width of ca 500 µm and formed during reaction between the infiltrating fluid and the original pyroxene.

4Dept. of Earth and Atmospheric Sciences, Purdue University, West Lafayette, IN 47907, USA (filley@purdue.edu)

Vegetation change is controlled primarily by the influences of temperature, hydrology, and atmospheric [CO₂]. In tropical Africa, hydrological variations appear to be more important than either temperature or [CO₂]. Furthermore, hydrological variability in tropical Africa has a much more profound impact on human welfare than temperature or [CO₂]. Thus, reconstructing the timing of past wet and arid phases in this region is critical to understand the role and response of the tropics to global climate change. Here, we present a molecular isotopic record of vegetation and climate change from a well-dated sediment core from Lake Malawi spanning the period from the Last Glacial Maximum (LGM) to the present.

Our data show that the region surrounding Lake Malawi was cooler and drier during the LGM and the Younger Dryas (YD) than through the Holocene. This change of hydrology directly influenced the vegetation in the surrounding watershed, with a greater proportion of C4 plants such as grasses (which compete well in dry conditions) during these times. Conversely, the wetter and warmer Holocene is characterized by an increase in the proportion of C3 plants (such as trees) that require greater amounts of moisture to be successful. Finally, we note that at 11 cal ka there is a shift in the coherence between the Lake Malawi aridity record and high latitude ice core methane records (records of global tropical wetness); these records are in phase prior to 11 cal ka, and antiphased after this time. We attribute this to a shift in the dominant mechanisms controlling aridity associated with a shift in the mean latitudinal position of the Intertropical Convergence Zone.

The origin of high ³He/⁴He values in oceanic lavas: Arguments against a heterogeneous upper mantle source

P.R. CASTILLO, D. HAHM AND D.R. HILTON
Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093, U.S.A. (pcastillo@ucsd.edu; dhahm@ucsd.edu; drhilton@ucsd.edu)

One of the contentious issues fueling the debate on the origin of intraplate magmatism is the source of high ³He/⁴He ratios in oceanic lavas. The contemporary hotspot hypothesis posits that the high ³He/⁴He signature is coming from a distinct source reservoir that lies relatively deep in the mantle whereas others argue that there is no such a reservoir. For example, the SUMA (Statistical Upper Mantle Assemblage - Meibom & Anderson, EPSL 17, 2003) hypothesis argues that the compositional variability of oceanic lavas results from sampling upon melting of the heterogeneous upper mantle. It claims that extreme isotopic signals, such as high ³He/⁴He ratios, of some oceanic lavas are due to small degrees of partial melting that preferentially sample dispersed, anomalous mantle components. In contrast, large degrees of partial melting sample a larger volume, and hence many components of the heterogeneous mantle; these also promote more effective mixing of the resulting melts, producing a relatively homogeneous composition typified by that of N-type MORB.

To constrain the source of high ³He/⁴He lavas, we analyzed a dozen representative samples from the axis and near-ridge seamounts in the 11°45’N to 15°00’N segment of the EPR. Axial lavas are N- to T-type MORB that came from a heterogeneous mantle source (Castillo et al., G3 1, 2000). Seamount lavas extend the compositional variability of axial lavas to both higher and lower Sr, Nd and Pb isotope values, suggesting that seamount lavas indeed result from smaller degrees of partial melting of the heterogeneous mantle beneath the region. Our preliminary results, however, also show that the majority of both axial and near-ridge seamount lavas have indistinguishable, MORB-like ³He/⁴He values, at 8 +/- 1 RA, over a range of He concentrations. The remainder have ³He/⁴He < 8 RA. Thus we conclude that the heterogeneous Pacific upper mantle cannot provide the high ³He/⁴He signature in oceanic lavas.
Metamorphic history of the pre-3750 Ma Nuvvuagittuq Supracrustal Belt, Québec (Canada)

N.L. CATES AND S.J. MOJZIS
Department of Geological Sciences, University of Colorado, Boulder, Colorado USA (cates@colorado.edu)

The ca. 3750 Ma Nuvvuagittuq Supracrustal Belt (NSB) in northwestern Québec is among the oldest volcano-sedimentary sequences thus far discovered; it overlaps in age with the Eoarchean Isua Supracrustal Belt and the Akilia association supracrustal enclaves in West Greenland [1]. Mapped NSB sequences are dominated by amphibolites (± Gt), ultramafic rocks, granitoid gneisses and leucogranite intrusions, but also comprise both chemical and detrital metasediments such as finely laminated banded iron-formations and quartzite. Like other pre-3600 Ma terranes, the NSB has been thermally metamorphosed and multiply deformed. Our preliminary garnet-biotite and plagioclase-amphibole geothermometry coupled with U-Pb zircon geochronology suggests that the belt last reached the mid- to upper amphibolite facies (550-600°C) consistent with growth in a metamorphic fluid. The core age yields an age 2736±25 Ma with very low Th/U (0.009) consistent with growth in a metamorphic fluid. The core age of 3743±26 Ma was reached at a depth of 4.6 km thick overgrowth on the R.H. axis. Shaded regions have implausible O₂ fluxes. After the advent of oxygenic photosynthesis, photochemically-stable anoxic oroxic atmospheres can exist (Fig. 1). A ~3% increase in the ratio of O₂:CH₄ fluxes to the atmosphere causes a transition to the anoxic state. In an anoxic environment, O₂ and CH₄ flux to the atmosphere in a 2:1 redox neutral ratio, according to CO₂ + 2H₂O = 2O₂ + CH₄, the net reaction of photosynthesis + methanogenesis. This ratio increases if sufficient sulfate allows microbial anerobic oxidation to change the reduced partner of O₂ to CH₄. Alternatively, with increasing sulphate, the reduced partner of O₂ may change from CH₄ to biogenic sulphur gases. These gases, unlike CH₄, are kinetically more stable than O₂ and may have left a signal in S-MIF. References

Archean methane, oxygen and sulfur

D.C. CATLING¹, M.W. CLAIRE² AND K.J. ZAHNLE³

Mass-independent fractionation (S-MIF) of S isotopes marks the 2.4 Ga division of Earth’s anoxic and oxic atmospheres. We emphasize that S-MIF also indicates abundant Archean atmospheric CH₄. In addition, the magnitude of S-MIF reflects the size of S gas fluxes to the atmosphere. Thus, high amplitude S-MIF in the late Archean may indicate the advent of significant biogenic S gases. Relatively inert CH₄ leaves little geochemical trace. For many years, the only evidence that Archean CH₄ was abundant came from a global distribution of 2.5-2.8 Ga ²³C-enriched kerogens attributed to methanogenic CH₄ incorporated into methanotrophs. S-MIF now provides independent evidence. S-MIF occurs when S exits the atmosphere in soluble sulfate and insoluble polymerized sulfur (S₈) [1]. Our models [2] show that O₂ <1 ppmv and a high abundance of CH₄ are required for significant rainout of S₈. Sufficient CH₄ enables the reduction of S-bearing gases to sulfur (S₈). Plentiful H₂ is an alternative but is implausible because H₂ is biologically converted to CH₄.

Fig. 1: Fluxes in a 100 ppmv CH₄ atmosphere. Plus symbols (+) indicate the ratio of O₂ (φO₂) to CH₄ (φCH₄) bio-fluxes, on the R.H. axis. Shaded regions have implausible O₂ fluxes. After the advent of oxygenic photosynthesis, photochemically-stable anoxic oroxic atmospheres can exist (Fig. 1). A ~3% increase in the ratio of O₂:CH₄ fluxes to the atmosphere causes a transition to the anoxic state. In an anoxic environment, O₂ and CH₄ flux to the atmosphere in a 2:1 redox neutral ratio, according to CO₂ + 2H₂O = 2O₂ + CH₄, the net reaction of photosynthesis + methanogenesis. This ratio increases if sufficient sulfate allows microbial anerobic oxidation to change the reduced partner of O₂ from gaseous CH₄ to solid sulphide. Alternatively, with increasing sulphate, the reduced partner of O₂ may change from CH₄ to biogenic sulphur gases. These gases, unlike CH₄, are kinetically more unstable than O₂ and may have left a signal in S-MIF. References

Source depletion versus extent of melting in the Tongan Sub-arc mantle

J.T. CAULFIELD, S. TURNER, A. DOSSETO and N.J. PEARSON

GEMOC, Macquarie University, Sydney, Australia
(jcaulfield@els.mq.edu.au, sturner@els.mq.edu.au, adosseto@els.mq.edu.au, npearson@els.mq.edu.au)

The currently active Tonga arc produces some of the most depleted compositions found in oceanic arcs. This signature is observed most strongly in their depletion in High Field Strength Elements (HFSE) relative to Depleted MORB Mantle (DMM) and Light Rare Earth Elements (LREE) compared to Heavy Rare Earth Elements (HREE). Previous work on low HFSE concentrations (DMM) and Light Rare Earth Elements (LREE) compared to Heavy Rare Earth Elements (HREE) observed most strongly in their depletion in High Field Strength Elements (HFSE) relative to Depleted MORB Mantle (DMM) and Light Rare Earth Elements (LREE).

Here we present new Nb-Ta data for Tongan volcanics in order to try to differentiate between arc magma production (i) prior melt extraction in the back-arc that depletes the source of arc magmas in the most incompatible elements [1]; or (ii) higher degrees of partial melting during melting in the Tongan Sub-arc mantle has produced two fundamentally different models; (i) prior melt extraction in the back-arc that depletes the source of arc magmas in the most incompatible elements [1]; or (ii) higher degrees of partial melting during arc magma production [2]. Here we present new Nb-Ta data for Tongan volcanics in order to try to differentiate between these models by developing a model for melt generation in the mantle underlying the Tonga arc/Lau Basin back-arc system.

Nb/Ta ranges from 18-3.5, with Nb between 0.2-0.4ppm. Data were acquired by LA-ICPMS of non-fluxed sample glasses produced using a molybdenum strip fusion technique. Significantly, the lowest Nb/Ta values are found in the north of the arc where both subduction and attendant back-arc spreading rates are greatest. These findings are in agreement with a model whereby greater degrees of mantle melt extraction in the back-arc produces more depleted source compositions beneath the arc [3].

Large degree batch melts (up to 35%) of DMM fail to reproduce the sub-chondritic Nb/Ta values (<17) of the arc. Alternatively, melting of source compositions having undergone 0.1-7% prior melt extraction produce melting curves that bracket the dominant arc trend.

Nb normalised plots of fluid immobile elements (e.g. Yb vs. Sm) produce a linear array that plot parallel to mixing lines for 20-35% remelting of 0.1 and 7% depleted DMM sources. Simple calculations show that the average sub-arc Tongan source melts at between 1-1.25% depletion. In the case of the Lau Basin spreading centre, this corresponds to the incorporation of the lower 4-5km of the melt column in to the sub-arc melting regime. This is in excellent agreement with current models for melting regimes at active spreading centres whereby only the lower most portion of the melt column has flow paths within the convecting asthenospheric mantle [4].

Elemental speciation (i.e., oxidation state, nature of aqueous complex) in hydrothermal fluids is crucial for modelling fluid-fluid and fluid-rock interactions. Elemental speciation in hydrothermal fluids preserved as fluid inclusions can be studied by heating the host mineral while performing X-ray absorption spectroscopy. This technique was applied to fluid inclusions from gold mineralisations at the arsenic K-edge. As and Au are closely associated in many Au deposits, but the cause of this association remains controversial. We aim to better understand As transport in Au-bearing fluids by comparing speciation in natural fluids with recent experimental results on synthetic systems.

XRF mapping of single fluid inclusions showed heterogeneous elemental distributions at room temperature (Fig. 1), thus stressing the need of performing spectroscopic analyses at homogenisation temperature.

Figure 1: left: optical view of a CO2 rich fluid inclusion. Middle: As distribution in the same inclusion. Right: XANES spectrum at the As-K edge at room temperature in an inclusion of the same generation.

XANES experiments were performed using a Linkam THMSG-600 heating-stage on the new microfocus end-station installed on the ESRF FAME beamline. XANES spectra (Fig. 1) were measured from 25 to 350°C to record evolution in arsenic speciation in those fluid inclusions.

This work details arsenic speciation changes upon heating and stresses the high interest of fluid inclusion studies based on experiments performed in situ.
Geological storage as a carbon mitigation option

The most promising approach to solve the carbon problem involves widespread implementation of zero-emission power plants. These are likely to be fossil fuel-based plants with carbon capture and storage (CCS) technology. Low-emission electricity has the secondary advantage of allowing for electrification of the transportation sector, and as such can lead to very large reductions in CO\textsubscript{2} emissions if implemented at the global scale. While a variety of storage options are being studied, geological storage appears to be most viable. Injection of captured CO\textsubscript{2} into deep geological formations leads to a fairly complex flow system involving multiple fluid phases, a range of potential geochemical reactions, and mass transfer across phase interfaces. General models of this system are computationally demanding, with the problem made more difficult by the large range of spatial scales involved, and the importance of local features for both fluid flow and geochemical reactions. An especially important local feature involves leakage pathways, with one example being abandoned wells associated with the century-long legacy of oil and gas exploration and production. Such pathways also have large uncertainties associated with their properties. Therefore, inclusion of leakage in the storage analysis requires resolution of multiple scales, and incorporation of large uncertainties. Taken together, these render standard numerical simulators ineffective due to their excessive computational demands. In this lecture, I will present a series of simplifications to the governing equations that can ultimately render the system solvable by analytical or semi-analytical methods. These solutions, while restrictive in their assumptions, allow for large-scale analysis of leakage in a probabilistic framework.

Palaeohydrology of the Mulhouse Basin: Are fluid inclusions in halite tracers of past seawater composition?

Brine reactions processes were the most important factors controlling the major-ion evolution in the Oligocene, Mulhouse Basin (France) evaporite basin. The combined analysis of fluid inclusions in primary textures in halite by Cryo-SEM-EDS with sulfate-δ\textsuperscript{34}S, δ\textsuperscript{18}O and \textsuperscript{87}Sr/\textsuperscript{86}Sr isotope ratios reveals hydrothermal inputs and recycling of Permian evaporites, particularly during advanced stages of evaporation in the Salt IV member which ended with sylvite formation. The lower part of the Salt IV evolved from an originally marine input. Sulfate-δ\textsuperscript{34}S shows Oligocene marine-like signatures at the base of the member (Fig.1). However, enriched sulfate-δ\textsuperscript{18}O reveals the importance of re-oxidation processes. As evaporation progressed other non-marine or marine-modified inputs from neighbouring basins became more important. This is demonstrated by an increase in K concentrations in brine inclusions, Br in halite and variations in sulfate isotopes trends and \textsuperscript{87}Sr/\textsuperscript{86}Sr ratios. The recycling of previously precipitated evaporites was increasingly important with evaporation. Therefore, regardless of the apparent marine sequence (gypsum, halite, potassic salts), the existence of diverse inputs and the consequent chemical changes to the brine preclude the use of trapped brine inclusions in direct reconstruction of Oligocene seawater chemistry.

**Figure 1:** SO\textsubscript{4}-δ\textsuperscript{34}S, δ\textsuperscript{18}O and \textsuperscript{87}Sr/\textsuperscript{86}Sr isotope trends.
Origin of calcium isotope fractionation in river waters: Evidence from the Strengbach catchment, France

B. CENKI-TOK*, F. CHABAUX, D. LEMARCHAND, P. STILLE, M.-L. BAGARD AND M.-C. PIERRET
Centre de Géochimie de la Surface, UMR 7517, Ecole et Observatoire des Sciences de la Terre 1, rue Blessig, 67084 Strasbourg Cedex, France
*Present address: Universität Bern, Institut für Geologie, Baltzerstrasse 1+3, 3012 Bern, Switzerland (cenkitok@geo.unibe.ch)

Understanding calcium isotope systematics in river and surface waters plays a key role in unravelling the calcium oceanic cycle as well as characterizing chemical weathering processes in continental systems. However, only few studies have focussed on deciphering the factors controlling calcium isotope fractionation in continental river waters. In order to shed light on the origin of calcium fractionation in river waters, we investigated the different reservoirs for calcium isotopes and their interactions in a forested first order scale catchment (Strengbach, France).

Variations of $\delta^{44/40}$Ca within springs, brooks and river waters are small (0.17-0.87‰) and display typical values for continental rivers, reflecting the control of lithology on calcium isotopic composition of water on a global scale. Compared to these values, soil solutions are significantly depleted in light calcium ($\delta^{44/40}$Ca: 1.00 to 1.47‰) whereas vegetation is enriched in light calcium ($\delta^{44/40}$Ca: -0.98 to +0.19‰). At the small watershed scale, our results suggest that vegetation controls the calcium isotopic composition of waters: (i) the origin of depletion in light calcium in soil solutions is directly linked to calcium recycling and fractionation within plants, (ii) the calcium isotopic composition of the water at the outlet of the watershed shows a yearly cycling directly related to the activity of vegetation.

In summary, surface waters are influenced by vegetation whereas deep waters preserve the calcium isotopic signature inherited from the parent rock. Therefore, calcium isotope analysis clearly helps to evaluate the role of vegetation and to unravel the hydrologic cycle at the watershed scale.

Durability and degradation of oil well cement exposed to a source of H$_2$S and CO$_2$ gases

J. CENTENO$^1$, A. RAMÍREZ$^2$, A. BLANCO$^1$ AND A BALZA$^1$

$^1$PDVSA Intevep, Los Teques, Venezuela.
$^2$Instituto de Ciencias de la Tierra, UCV, Venezuela.
(centenojs@pdvsa.com; blancoa@pdvsa.com; balzaau@pdvsa.com)

Introduction

Usually, the oil industry gives relevance to failures in metallic structures produced by the corrosion caused by H$_2$S and CO$_2$ and its implication in the well life. The search of new reservoirs in deep environment conditions, in which concentrations of H$_2$S and CO$_2$ are noteworthy, requires the study of the sour gas effect on nonmetallic structures, such as oil well cement.

Methods

Recent studies have demonstrated the effect of degradation in the chemical and mechanical properties of oil well cement exposed, in the short term, to aggressive atmospheres, thus, endangering the well life (Centeno et al., 2005). This study shows the influence of H$_2$S and CO$_2$ gases and their mixtures, in different H$_2$S/CO$_2$ ratios (0.1; 0.2 and 0.4), on the chemical and mechanical properties of cement samples (class G and H) exposed to high pressure and temperature in well bore real conditions, using a exposure time of 20, 40 and 80 days. Test tubes were exposed to the action of a mixture of CO$_2$/H$_2$S, dissolved in water, in a Parr reactor for HPHT. The test solution was analyzed by Inductive Coupled Plasma -ICP- (elements) and Ionic Chromatography (anions). Solid phase mineralogy was determinate by SEM and X-ray analysis.

Results and Conclusions

The H$_2$S and CO$_2$ mixtures have an effect on cementing material causing a mass profit corresponding to CaCO$_3$ formation, that is maximum when the H$_2$S/CO$_2$ relation approaches to 0.2. This CaCO$_3$ mass profit was detected with test tube weight comparison, before and after acid attack, and mineralogy analysis. For H$_2$S/CO$_2$ ratios > 0.2 a mass loss was observed, which causes degradation of cementing material verified by compressive strength decrease.

The results allow to model the effect of oil well cement dissolution with time, for H$_2$S/CO$_2$ ratios < 0.2 using second degree polynomials, in which the dependent variable is a chemical species such as: Ca$^{2+}$, Na$^+$, K$^+$ or SO$_4^{2-}$, or a physical measure such as the compressive strength.

Cerium is the most abundant lanthanide and generally the only one to undergo redox reactions at the Earth’s surface. Because their unique electron transferring properties, Ce-minerals have been proposed as optimal material for nanotechnological applications. Yet, to date, little mechanistic information is available on the stability of Ce-bearing nanoparticles in the presence of biological material and their toxicity.

Here, we study molecular interactions between small-sized CeO2 and biomolecules (e.g., DNA, RNA, proteins) using carbon and cerium spectroscopy. As determined by aggregation kinetics by Dynamic Light Scattering (DSL) and UV, the aggregation behavior of nanoCeO2 is susceptible to pH variations imposed by the presence of biological moieties. The aggregation kinetics of aggregation is of zero-order with respect to solid concentration. Results show progressive transformation of biological material (as % carbon) with decreasing CeO2 particle diameter (13 < d < 84 Å), which substantiates an intimate relation between CeO2 unit cell expansion and reactivity towards organics susceptible to undergo redox transformations. As evidenced by C and Ce spectroscopy, organic polymers that form because of oxidation are distributed next to the mineral surface and its occurrence is coupled to Ce reduction-oxidation. Analyses by nephelometry of acidophiles and fungi cultures incubated with nanoCeO2 at pH 2 show variations in the population density and growth rate values, which reveal bonding site specificity and in agreement with non-enzymatic results.

Experimental determination of equilibrium solubility quotients of the natural colemanite in NaCl solutions up to 2.0 m

ZIYA CETINER1, YONGLIANG XIONG2 AND SAFAK OZKAN3

1Canakkale 18 Mart University, Department of Geological Engineering, 17010, Canakkale, TURKIYE (ziyac@comu.edu.tr)
2Sandia National Laboratories, 4100 National Parks Highway, Carlsbad, NM 88220, USA (yxiong@sandia.gov)
3Istanbul University, Engineering Faculty, Mining Engineering Department, 34320, Istanbul, TURKIYE (sgozkan@istanbul.edu.tr)

Colemanite (CaB3O4(OH)3:H2O) is an important evaporite borate mineral. Experimental studies on the solubility constants of colemanite in a wide range of ionic stengths are few. In this study, we experimentally determined the equilibrium solubility quotients of the natural colemanite from the Kestelek, Turkey, in NaCl solutions ranging from 0.1 m to 2.0 m at 20 °C. The solubility constant of the natural colemanite at infinite dilution at 20 °C from this study regarding the following reaction,

$$\text{CaB}_3\text{O}_4(\text{OH})_3\cdot\text{H}_2\text{O} + 4\text{H}_2\text{O} = \text{Ca}^{2+} + 3\text{B(OH)}_4^- + \text{H}^+$$

is $-17.5\pm0.1$ (2σ) based on the Specific Interaction Theory (SIT) model for extrapolation to infinite dilution according to the weighted linear regression. The derived ∆ε is 0.027. By using $\varepsilon(\text{Ca}^{2+}, \text{Cl}^-)$ and $\varepsilon(\text{H}^+, \text{Cl}^-)$ from Xiong (2006), the $\varepsilon(\text{Na}^+, \text{B(OH})_4^-)$ derived from this study is $-0.09\pm0.02$. This value is in excellent agreement with the literature value of $-0.07\pm0.05$ evaluated by Ciavatta (1980).

The above solubility constant is significantly different from the one calculated regarding the above reaction from the Gibbs free energy of formation of colemanite predicted by Li et al. (2000) in combination with the auxiliary data from Wagman et al. (1983), which is $-13.41$ in logarithmic unit at 25 °C, or $-13.57$ at 20 °C according to the enthalpy of the reaction to extrapolate to that temperature. This means that colemanite is more stable than previously predicted.

Geochemical and geophysical insights into a large magmatic system in Central Java, Indonesia

J. P. CHADWICK1, D. WAGNER2, V. R. TROLL1, I. KOULAKOV3 AND B.-G. LUEHR3

1The Dept. of Geology, Trinity College Dublin, Ireland (chadwij@tcd.ie)
2Institute for Geosciences, Christian-Albrechts-Universität zu Kiel, Otto-Hahn Platz 1, Kiel, Germany
3GeoForschungsZentrum Potsdam, Telegraphenberg, Potsdam, Germany.

Ascent and stalling of primary arc magmas in the crust promotes modification by numerous processes including crystallisation, magma mixing and crustal interaction. We have studied a suite of recent lavas, crystals, enclaves, plutonic inclusions, and crustal xenoliths to evaluate the role of these processes in magmatic evolution at Merapi volcano and the nature of the magmatic system feeding volcanism.

Crystalline components in recent Merapi lavas and hosted inclusions provide us with two complimentary sets of data:

1. Petrochemical and geobarometric analysis of igneous inclusions combined with geophysical techniques yields information on the structure of the Merapi plumbing system. Our results indicate that Merapi overlies a network of numerous magma bodies reaching down to the upper mantle. This is a far more extensive supply system than previously considered, with recycling of igneous material and the potential for increased interaction with the crust beneath Merapi.

2. Skarn-type meta-sedimentary xenoliths highlight the influence of the carbonate country rock on Merapi magma. Crystals from Merapi lavas show clear signs of interaction with this crust and their correlation with crystals in meta-sedimentary xenoliths may indicate integration of xenocrystic material. This interaction is not preserved in whole rock isotope analyses. Whole rock compositions may be buffered given the scale of the system feeding Merapi and potential recycling of igneous material.

Combined petrochemical and geophysical data indicate the development of a large and complex magmatic system in the crust of Central Java. These findings require a re-evaluation of how Merapi and potentially other similar systems are considered.

Murmanite lujavrites: A neglected member of the peralkaline intrusive sequence at Lovozero (Kola, Russia)

A. CHAKHMOURADIAN1 AND R. H. MITCHELL2

1Dept. of Geological Sciences, University of Manitoba, Winnipeg, Canada (chakhmou@cc.umanitoba.ca)
2Dept. of Geology, Lakehead University, Thunder Bay, Canada (rmitchel@lakeheadu.ca)

Although murmanite lujavrites (ML) were distinguished at Lovozero (Kola, NW Russia) some 40 years ago, they are completely neglected in the recently published literature. These rocks occur as a discrete intrusive suite in the Lovozero composite pluton; they are emplaced into the earlier-formed Differentiated and Eudialyte-Lujavrite Units as small plugs and dike(let)s lacking chilled margins. The name ML alludes to a characteristic trachytoid texture of these rocks and the presence in them of abundant oikocrysts of exotic minerals (e.g., murmanite, lamprophyllite and lorenzenite). Clinopyroxene (Cpx), amphiboles (Amp) and eudialyte occur both as euhedral groundmass crystals and as oikocrysts. The groundmass also comprises alkali feldspars, nepheline (Ne), sodalite and accessory REE, Sr, Ti-Nb, U and Th minerals.

Cpx has the compositional range $\text{Ae}_{69-94}\text{Di}_{7-17}\text{Hd}_{0-20}$; Amp is zoned from (fluor-)magnesio-arfvedsonite to (potassic-)arfvedsonite; Ne typically has higher Ks and lower SiO$_2$ contents (mol.%) in the rim (overall range Ne $69-82$Ks$15-22$Qtz$1-14$). The ML are peralkaline rocks ($K_{\text{peralk}} \geq 1.4$) enriched in silica, Na, K, Rb, Mn, Sr, REE, Zr, Hf, U, Ta and W, but depleted in Mg, Ca, Fe$^{2+}$, Sc, V, Ti and P relative to the bulk Lovozero composition. This petrographic suite is characterized by its consistently superchondritic Zr/Hf (40-55) and subchondritic Nb/Ta signature (7-15). The ML are isotopically indistinguishable from the major intrusive units: ($^{87}\text{Sr}/^{86}\text{Sr}$)$_i = 0.7037-0.7043$; $\varepsilon$Nd) = 3.4-3.8. We interpret the ML suite to have crystallized from a highly evolved phonolitic melt similar to the one that produced the Eudialyte-Lujavrite unit (EL melt), but containing higher normative Na$_2$SiO$_3$ and lower CaMgSi$_2$O$_6$. The ML parental magma could be derived from the EL melt by fractionation of Cpx, eudialyte, loparite and apatite.
Geospeedometry as a tool for identifying different lithotectonic packages in Higher Himalayan Crystallines, Sikkim, India

SUMIT CHAKRABORTY¹ AND SOMNATH DASGUPTA²

¹Institut für Geologie, Mineralogie und Geophysik, Ruhr Universität Bochum. D-44780 Bochum, Germany
²Department of Geological Sciences, Jadavpur University, Kolkata 700032, India

The Higher Himalayan Crystallines (HHC) in Sikkim, India is made up of an interlayered sequence of pelitic migmatites (Qtz-Kfs-Pl-Silik-Bt-Grt-Ilm-Rut-Crd-Spl, with Kfs > Pl), quartzofeldspathic gneisses (Qtz-Pl-Kfs-Grt-Ilm-Bt) and minor metabasites and calc-silicates. Unlike in the adjacent sections in Eastern Nepal (e.g. Goscombe et al., 2006), there is no obvious lithological contrast within the section of HHC studied by us in Sikkim. Thermobarometry indicates metamorphic pressures and temperatures of ~ 8 Kbar, 700 - 850 °C. Textural relations indicate an early decompressional path (documented by breakdown of garnet to cordierite, plagioclase or plagioclase + spinel), followed by cooling. This is similar to the path deduced by Ganguly et al. (2000) for other rocks from nearby regions. There is evidence of melts produced during the decompression (e.g. Harris et al., 2004), which presumably reacted with garnet during cooling to produce various symplectitic textures. While all of these features are found spread across the entire HHC sequence between the Main Central Thrust (MCT) and the South Tibetan Detachment System (STDS), compositional zoning in garnets are clearly different in different parts. We have modeled these compositional gradients using a code that allows multistage thermal histories with different boundary conditions to be handled. In the northernmost part of the HHC, just south of the STDS, compositional zoning indicates very rapid cooling (e.g. from 800 - 600 °C within 100000 years). In contrast, in the southern part of the HHC just north of the MCT, there appear to be two groups of rocks: (i) initial rapid cooling for about 50000 years followed by slower decompositional cooling over the next 2 myrs., and (ii) single stage, relatively slow cooling between 800 - 600 °C over 0.5 myrs. These results show that it is possible to use geospeedometry to distinguish lithotectonic packages evolving with different P-T-t histories, even when petrographic criteria fail to reveal obvious distinctions. This may prove to be an easily applicable but useful tool for mapping in high grade terrains.

Stable isotopic studies of intermontane basins in the Rocky Mountains, Basin and Range and Sierra Nevada record the isotopic fingerprint of an evolving landscape during the Cenozoic. During the early Eocene the western edge of this orogen consisted of high proto-Sierra Nevada and to the east lay a broad plateau of the Sevier hinterland bordered on its east by intraforeland basins with local basement uplifts. Mean elevation was spatially and temporally transient with increased peak elevations and elevated relief migrating from north to south. This occurred at 50-47 Ma in SW Montana, at 40-35 Ma in N. Nevada, and by ~22 Ma in S. Nevada, as evidenced by large negative shifts in O isotopes that are diachronous in the Basin and Range. During this time the drainage basins in the Sevier foreland were reorganized which resulted in river capture events that caused rapid (<200 ka) and large O isotope shifts in these lakes. Sr isotopic studies of lacustrine rocks in the intraforeland basins and paleosols in the hinterland suggest that the drainage networks of these basins evolved from local networks draining adjacent basement uplifts to large catchments that extended deep into the Sevier hinterland. This drainage reorganization is diachronous first occurring in the north and sweeping south with time, as evidenced by the temporal variation in O isotope profiles in the intraforeland basins. North to south migration of a high rugged landscape is contemporaneous with the timing of core complex formation and volcanism. As such, our work is consistent with tectonic models calling for north to south removal of the Farallon slab or delamination of the mantle lithosphere, both of which would have caused a rise in surface elevations and triggered dissection of a pre-Cenozoic continental plateau.
Steady state chemical weathering in an eroding landscape

C.P. CHAMBERLAIN¹, G.E. HILLEY¹, M.T. HREN¹, S. PORDER² AND A.D. JACOBSON³

We developed a steady-state chemical weathering model that describes the advection of fresh rock into the weathering zone and the dissolution of minerals during weathering (Waldbauer and Chamberlain, 2005, Ecol. Studies 177). This model has been modified to account for the growth of secondary minerals during weathering (Chamberlain et al., 2005, EPSL) and to examine the competing affects of reaction kinetics and rock advection (Hilley et al., in review, GCA). To first-order the model predicts chemical weathering rates at spatial scales from global to orogens to individual catchments (Hren et al., in press, AJS). Two overarching results come from this analysis. 1) The supply of fresh rock to the weathering zone is the dominant control on weathering rates except under extremes in uplift rates, temperature and precipitation. 2) Landscapes can be quantified as reaction- and supply-limited with much of the Earth’s surface between these two extremes. The results of this body of work have implications to CO₂ uptake in both ancient and modern environments. The ability of forest ecosystems to uptake carbon dioxide depends, in part, on the supply of rock-derived nutrients. Of these, phosphorus is particularly important, and we have combined models with field data to predict the P supply to landscapes in different tectonic settings (Porder et al., 2007, Ecosystems). Unlike forests on stable cratons, those on tectonically active areas are less likely to be P limited and may have a greater ability to increase productivity as a result of increases in CO₂. On longer timescales, we show that areas of high uplift will have the highest silicate weathering rates contributing to the long-term drawdown of CO₂.

Formation of biomineralized stalks by a marine iron-oxidizing bacterium

⁴University of Southern California, Department of Biological Sciences, Los Angeles, CA 90089 (kje@usc.edu)

Aerobic, neutrophilic iron-oxidizing bacteria (FeOB) are abundant at Fe(II)-dominated hydrothermal vent systems. They grow by O₂-dependent oxidation of ferrous iron to highly insoluble ferric iron. A distinctive feature of many FeOB is the formation of extracellular structures covered in iron oxyhydroxides. Beyond their distinctive appearance, little is known about the composition or function of these structures. One hypothesis is that these polymers control the precipitation of iron and move it away from the cell, thereby preventing mineral encrustation of the cells. 

Mariprofundus ferrooxydans PV-1 is a marine FeOB isolated from iron microbial mats at hydrothermal vents at the Loihi Seamount, Hawaii. M. ferrooxydans produces mineralized ribbon-like stalks that are prominent constituents of these microbial mats. Because this morphology is often used as a signature of FeOB activity in both modern and ancient (i.e. fossilized) environments, we need to determine what role it plays in the metabolic process, in order to be able to interpret the meaning of this potential signature and positively link it to the FeOB metabolism.

To this end, we have analyzed the ultrastructure, chemistry, and formation process of the Mariprofundus ferrooxydans PV-1 stalk. We developed a microslide culture method for PV-1 and coupled this with in situ light microscopy and time lapse imaging, allowing us to observe cell growth and determine rates of stalk formation. Stalk ultrastructure, mineralogy and cell-stalk-mineral spatial relationships were observed using transmission electron microscopy (TEM). This work showed that the stalks consist of a discrete number of fibrils (25-200 nm wide) mineralized initially by poorly crystalline FeOOH, and later coated with lepidocrocite. The juxtaposition of the poorly crystalline FeOOH within the stalk fibrils, and more crystalline lepidocrocite on the surface implies that organics in the fibrils retard mineral growth. Synchrotron-based scanning transmission x-ray microscopy (STXSM) was used to map the spatial distribution of iron, carbon, and nitrogen, and characterize the organic functional group chemistry of the stalk. The element maps show that iron is localized on the stalk, whereas the cell is relatively free of iron. Together these approaches show that the stalks do indeed play an important role by binding ferric iron and transporting it away from the cell in a manner that prevents entombment of the cell in iron oxyhydroxides.
Geochemistry and tectonic significance of peridotites from the Kiogar ophiolite, SW Tibet

Gavin H.-N. Chan¹, Mike Searle¹, Jonathan Aitchison² and George S.-K. Ma²

¹Department of Earth Sciences, Oxford University, UK
²Department of Earth Sciences, University of Hong Kong, Hong Kong

The Kiogar ophiolite in southwest Tibet forms part of the Indus-Yarlung Zangbo suture zone that marks the collision between the Indian continent and the Lhasa Block of Eurasia (Ganseer 1964; Aitchison et al. 2003). The ophiolite is dominated by a mantle sequence of clinopyroxene-bearing harzburgite, dunite, olivine orthopyroxenite and chromitite with trace amount of gabbro-norite. The dunite pods and dykes cut the cpx-bearing harzburgite and are characterized by U-shaped REE patterns, low incompatible element abundances and high Cr # (0.74-0.80). This is in contrast to the cpx-bearing harzburgites that display upward spoon-shaped REE patterns with low incompatible element abundances and low Cr # (0.37-0.55). Trace element modelling shows that the cpx-bearing harzburgites represent the residues of 15-20% partial melting. The compositions of cpx compare well with those of abyssal peridotites. Using field, textural and geochemical evidence, we suggest the Kiogar ophiolite formed in a two-stage process. The cpx-bearing harzburgites originated from melting of a MORB-source at a ridge, which were subsequently modified to dunites by interaction with boninitic melts in a supra-subduction environment. The modified lithosphere was emplaced onto the deformed Mesozoic continental margin sequence of the north Indian plate prior to the closure of Neo-Tethys in the Paleocene.

Geochemical analyses using a benchtop polarized beam XRF spectrometer

B.W. Chappell¹ and J. Heckel²

¹University of Wollongong, Wollongong, NSW 2522, Australia (brucec@uow.edu.au)
²Spectro Analytical Instruments, Boschstr, 10, 47533 Kleve, Germany (JHeckel@spectro.com)

Principle of polarized-beam XRF spectrometry

X-rays scattered through an angle of close to 90° are strongly plane polarized. Most of the background in XRF spectrometry results from the scatter of the “continuous spectrum” (Bremsstrahlung) produced in the X-ray tube. The fluorescent X-rays used for analysis, of course, originate in the sample. Polarization of the primary X-rays in a plane at a right-angle to the sample largely eliminates the background. The analytical precision and detection limits are thereby enhanced.

Measurement of X-ray photon intensities

Si(Li) detectors have been used in polarized beam spectrometers since the first commercial instruments were developed. Silicon drift detectors (SDD) are a modification of the Si(Li) that show some dramatic improvements in performance. The SDD require only moderate cooling (~–30ºC) that can be achieved electrically. They can measure much higher intensities, up to 10⁶ cps, and there are significantly fewer detector artefacts, particularly in the newer versions. Their disadvantage is that they are very thin and therefore relatively inefficient for elements such as Sn, Ba and the REE in the K spectrum.

An SDD polarized beam XRF spectrometer

The XEPOS instrument incorporates a recently developed SDD in a benchtop XRF spectrometer. A 50 W X-ray tube produces radiation from a very small area (1 mm x 1 mm). For the lightest elements a divergent beam of Pd Lα radiation from that “point source” can be focussed onto a sample using curved graphite that diffracts the beam at close to 90º, so that the beam incident on the sample is strongly plane polarized. We will report data obtained with this instrument; some Na and Rb contents for reference materials are listed here, measured on fused glasses and powder pellets, respectively.

Infracrustal and supracrustal granites – The Nanjing separation

B.W. CHAPPELL1 AND A.J.R. WHITE2

1University of Wollongong, Wollongong, NSW 2522, Australia (brucec@uow.edu.au)
2University of Melbourne, Melbourne, Vic, Australia

In 1974 we proposed that granites are derived from two contrasting sources, igneous and sedimentary, giving the I- and S-type granites. At the 1982 Nanjing Symposium on Granites and their Metallogenic Relations we suggested that the terms “infracrustal” and “supracrustal” describe the two types in a more fundamental way. This Nanjing separation has not been widely taken into account by later workers and, for example, it is hard to reconcile with suggestions that I- and S types are transitional, parts of a spectrum of granites.

Since our initial studies of eastern Australian granites in the 1960’s, we have realized that the I-type granites were derived from rather homogeneous sources, which cannot have been supracrustal or volcanic rocks. This understanding predated our recognition of the S-type granites. Such a conclusion is required by the extremely strong correlations between elements, typical of the low-temperature I-type granite suites.

Inter-element correlations are relatively poor among granites of S-type suites and isotopic compositions can be quite variable. For example, ten initial Sr isotopic values for the Jillamatong Granodiorite, exposed over an area of 101 km² and formed from a single batch of S-type magma, range from 0.7111 to 0.7153. Also, the more mafic S-type granites contain supracrustal enclaves carried from depth, whereas mafic enclaves that were derived from igneous rocks are rare.

We provide examples of these contrasting patterns of geochemical behaviour. The origin of the source rocks of the supracrustal granites is clear, with debate about the proportions of introduced mantle components.

The infracrustal granites, generally developed by partial melting of crust, must have had a major and often dominant ultimately mantle-derived source combined in some way with a crustal component, shown by isotopic compositions (Sr_i = 0.704-0.710; εNd = +4 to -9; δ¹⁸O = +6 to +11 in the Lachlan Fold Belt for granite suites in which the more mafic rocks contain hornblende). Chemical and isotopic relationships show that such variations cannot have been a result of large-scale magma mixing/mingling, or of assimilation during evolution of the magmas. The evidence strongly indicates that the observed isotopic compositions and specific chemical features of granite suites were also characteristics of rather homogeneous source rocks before partial melting. The precise way in which those features were acquired remains a problem. The possibility that many I-type granite source rocks resulted from prior mixing between mantle-derived melts and melted crust should be considered.

Surface analytical studies of feldspar surface reaction with U(VI)

Feldspar minerals are thermodynamically unstable in the near-surface environment and their surfaces are well known to react readily with aqueous solutions, leading to incongruent dissolution at low pH values, but congruent dissolution at neutral and high pH values. Interactions with mineral surfaces are an important control on the environmental transport of trace elements and detrital feldspars are abundant in soils and sediments.

The interaction of U(VI) ions with the feldspar surface has been studied. Sorption experiments with uranyl ion (UO₂⁺) at pH 2, 6 and 10 were carried out and measurable uptake, generally through surface complex formation, was only found at pH 6 and 10. Reacted surfaces were analysed by X-ray photoelectron spectroscopy and secondary ion mass spectrometry. At pH 6 and at an initial U(VI) concentration above 21.0 µM, precipitation of a surface phase was observed by atomic force and scanning electron microscopies, and this was identified as becquerelite (Ca[UO₂(OH)₂]·2.8H₂O) by grazing incidence X-ray diffraction. Secondary ion mass spectrometry showed diffusion of uranium into the altered surface layer.
A new approach to precise Pb dating of CAI’s by thermal extraction and thermal ionization in silica melt

CHRISTOPHER R.J. CHARLES AND DONALD W. DAVIS
Jack Satterly Geochronology Laboratory, Department of Geology, University of Toronto, 22 Russell Street, Toronto, ON, M5S3B1 (christopher.charles@utoronto.ca, dond@geology.utoronto.ca)

Calcium-aluminum-rich inclusions (CAIs) from carbonaceous chondrites are known to contain primary Pb that is highly radiogenic but at very low concentrations (0.3 – 0.01 ppm). The challenge to precise dating of these refractory phases by 207Pb/206Pb chronometry is an efficient removal of terrestrial contaminant Pb. Presently, this is done through leaching, dissolution and chromatographic separation in clean-lab environments (Amelin et al. 2002). A novel method is described here that embeds whole CAIs in silica glass on a Re filament for thermal Pb-isotope extraction and efficient ionization in a mass spectrometer (TE-TIMS). CAI fragments were obtained from Allende (Royal Ontario Museum, specimen #M29173 and Dr. O. Bogdanovski) by freeze-thaw disaggregation. After washing in clean H2O and acetone, whole-chips were mixed directly with clean concentrated silicic acid + H3PO4 on rhenium filaments. The mix was slowly fused to a glass under vacuum, taking care to fully embed the CAI fragments inside the glass. Pb/Pb-ratios were measured on a VG354 thermal ionization mass spectrometer (TIMS) in ion-counting mode using a Daly detector.

Initial results on two ca. 0.1 mg samples yielded mostly thorogenic Pb (208Pb/204Pb = 160 and 260). 208Pb emission began to increase at 1580C and attained between 16 – 30 kcps over about about 40 min. Thus, the presence of a whole CAI in the melt does not appear to have significantly reduced the ionization efficiency of the Pb and precise ratios can be measured if sufficient sample can be embedded on the filament. The low concentration of uranogenic Pb combined with significant common-Pb (206Pb/204Pb = 16) precludes precise dating of these samples. BSE imaging and EDS analysis of the embedded sample after melting showed extremely high concentration of Re in the CAI. Dissolved Re from the filament may have been efficiently partitioned into a molten Fe phase. No detectable Re could be found in the glass or unheated CAIs.

Aside from initial washing of the specimen, no clean chemical separation is required. In addition, thermal pre-treatment may prove useful for differential evaporation of contaminant Pb from meteoritic materials, as shown with zircon (Kober 1987 and Davis, this volume).

Early saturation of ilmenite and plagioclase buoyancy in Fe-Ti deposits associated with Proterozoic anorthosites

B. CHARLIER AND J. VANDER AUWERA
Department of Geology, University of Liege, Belgium (b.charlier@ulg.ac.be)

The igneous origin of Fe-Ti deposits associated with Proterozoic massif-type anorthosite anorthosites is unanimously accepted but magmatic processes responsible for these oxides concentrations are still debated. New data on the trace element content of ilmenite from various Fe-Ti ores are modelled by a fractional crystallization process of a Fe-Ti-rich ferrodioritic melt. The sequence of crystallization has ilmenite as an early liquidus phase after plagioclase and before ferromagnesian silicates. Cotectic proportions of ilmenite calculated from linear trends in log-log diagrams are in the range 15-20 wt.%, which is commonly lower than the modal proportions of ilmenite observed in Fe-Ti deposits. The mechanism responsible for the ilmenite enrichment is removal of plagioclase through segregation by flotation. Indeed, the plagioclase has a lower density (2.61-2.65 g.cm-3 for An60-40) than ferrodioritic melts from which it crystallizes (ca. 2.75 g.cm-3). Direct evidences for plagioclase buoyancy are found in the Tellnes (SW Norway) and Lac Tio (Quebec) deposits where anorthositic rocks outcrop close to Fe-Ti deposits and commonly at a higher stratigraphic level. These grey anorthosites significantly differ from their host pink massif-type anorthosite and represent the complementary liquidus phases to the non-cotectic cumulates of the ore bodies. Flotation of plagioclase is also described in the Grader layered intrusion (Quebec) where the saturation of apatite is reached after that of plagioclase and ilmenite. Ilmenite-apatite rocks (nelsonites) thus occur in plagioclase-free layers. This thus implies that nelsonites actually represent cumulates rather than Fe-Ti-P-rich immiscible melts. The cumulate origin is thus largely documented for different types of Fe-Ti ores in anorthosites and related rocks. It is accompanied by plagioclase floatation which is responsible for the relative enrichment of Fe-Ti oxides and may be a major controlling factor in the genesis of Fe-Ti deposits.
Diverse sources for Oruanui rhyolite (NZ): Evidence from feldspar and zircon
B.L.A. CHARLIER1 AND C.J.N. WILSON2
1Dept. Earth Sciences, The Open University, Milton Keynes, MK7 6AA, UK (b.l.a.charlier@open.ac.uk)
2SGGES, University of Auckland, Private Bag 92019, Auckland, New Zealand (cjn.wilson@auckland.ac.nz)

In many arcs, the erupted products reflect the integrated effects of differentiation mechanisms, which modify primary magma(s) as they ascend from their source region(s). Radiogenic isotope systematics can aid discrimination among various differentiation processes if the different end-members have contrasting isotopic signatures. Use of crystal isotope microstratigraphy, which employs microanalysis for Sr isotopes, shows that intra-crystalline isotopic and compositional heterogeneities exist within many volcanic rocks.

The 26.5 ka Oruanui eruption (530 km³, magma) from Taupo volcano in New Zealand is the world’s youngest supereruption. Oruanui rhyolite is mildly zoned (mostly 73-76% SiO₂) but was tapped non-systematically. Within some pumices, 1-5% of the plagioclase feldspars have grey cores mantled by clear rims. High resolution EMP traverses and Normarski imaging show a growth history punctuated by magmatic events that are seen as unconformities and inclusion rich zones within the crystals.

The grey cores have 87Sr/86Sr of 0.70540, and the clear rims are 0.70562, the latter being compatible with Oruanui rhyolite whole-pumice values. Intermediate zones sometimes have large excursions to very radiogenic 87Sr/86Sr values (max. ~0.7076). Accompanying these variations are changes from ~An₃₀ at the rim (in equilibrium with the host pumice) to ~An₆₅ in the core. Associated timescales of these variations in the grey-cored crystals are obtained from SIMS 238U-230Th model ages of zircons included within some of the growth zones. These ages can be compared with the age spectrum of zircons present as free crystals in the host pumice to show that incorporation of both xenocrystic and antecrystic material occurred during assembly of the Oruanui magma body.

Bacterial surfaces inhibit the oxidation of Fe(II)
XAVIER CHÂTEILLIER¹, MOHAMAD FAKIH¹, MÉLANIE DAVRANCHE¹, ALINE DIA¹ AND CHRIS DAUGHEY²
1Géosciences Rennes, UMR 6118, CNRS, Université de Rennes 1, Campus de Beaulieu, bâtiment 15, Avenue du Général Leclerc, 35042 Rennes Cedex, France.
2Geological and Nuclear Institute, Lower Hutt, New Zealand.

Bacteria are known to affect the fate of metals through sorption reactions. Secondary minerals, such as iron-oxides, are another important phase scavenging metals in the environment. It has often been suggested that bacterial surfaces favor the precipitation of iron-oxide phases. In this study, we demonstrate that this is not the case. We have mimicked the processes occurring at an oxic interface, which lead to the formation of iron oxides, by introducing progressively a fixed total amount of Fe²⁺ ions at a fixed pH of 6.5 in an aerobic reactor in the absence and in the presence of increasing concentrations of Bacillus subtilis bacterial cells. Alternatively, increasing amounts of Fe²⁺ ions were added to a fixed concentration of Anoxybacillus flavithermus bacterial cells. The kinetics of the reaction were monitored by measuring the rate of addition of the base needed to maintain the pH constant. In another set of experiments, we added Fe²⁺ ions at once in anaerobic conditions and oxygenated the suspension afterwards. The rate of oxidation of the Fe(II) was then measured directly using the ferrozine colorimetric method. In both types of experiments, it was clearly observed that the kinetics of oxidation of the Fe(II) are dramatically reduced by the presence of the bacterial cells. This is an important result, as the oxidation state and the speciation of the sorbed Fe impact the immobilization by the bacterial-iron composite suspensions of other metals. For instance, we have observed that a given amount of Fe reduces the Cd sorption ability of the cells, and it does this more effectively when it occurs as a sorbed Fe(II) species as when it is precipitated as adhering iron oxide nanoparticles.
Elemental distributions in zircons from diamondiferous UHPM rocks from the Greek Rhodope: A TOF-SIMS study

E. CHATZITHEODORIDIS1, D. KOSTOPOULOS1, I. LYON2, T. HENKEL2, N. CORNELIUS2, E. BALTATZIS1 and T. REISCHMANN3

2The University of Manchester, School of Earth, Atmospheric & Environmental Sciences, Manchester, U.K. (ian.lyon@manchester.ac.uk)
3Institut für Geowissenschaften, Johannes-Gutenberg Universität, Mainz, Germany (corneliu@uni-mainz.de)

The Rhodope Massif in N. Greece is a newly established ultrahigh-pressure metamorphic (UHPM) province in the world (Mposkos & Kostopoulos, 2001). Microscopic observations on zircons separated from a garnet gneiss revealed a simple zoned structure consisting of a somewhat rounded detrital core and a metamorphic overgrowth rim. This is ascribed to zircon growth in the presence of garnet under UHP conditions. By contrast, Li shows the reverse distribution pattern being negligible in the rim domain. This suggests a significant input of Li at subduction depths well in excess of 100 km. It is well established that phengite can host significant amounts of Li and that it is an important phase stable during subduction of crustal material to pressures up to 10 GPa. Since the peak PT conditions of the Rhodope UHP rocks have been estimated at 7 GPa / 1000°C, we favour the interpretation of phengite breakdown along its dehydration solidus during diamond formation. Sulphur, Cl and H distribution maps display high concentrations of these elements in the vicinity of diamonds strongly implying diamond precipitation from supercritical C-O-H-S-Cl fluids.

Recycled oceanic crust and sediments control the Hf-Nd mantle array

C. CHAUVEL, E. LEWIN, M. CARPENTIER and J.-C. MARINI

LGCA, Grenoble University, Grenoble, France (catherine.chauvel@ujf-grenoble.fr)

Hafnium and neodymium isotopes measured on ocean island basalts and mid-ocean ridges define a linear array, the “Mantle array” that passes above the Bulk Silicate Earth value (BSE). No convincing explanation of the origin of the discrepancy has yet been suggested. Patchett et al (EPSL, 2004) argue that with a slightly more radiogenic Hf isotopic composition for a similar Nd isotopic composition, the BSE value would lie in the OIB array. Alternatively, the mantle array could lie above BSE, suggesting that plume sources are different from primitive mantle: either lower mantle is not primitive or plumes do not sample lower mantle. In both cases, a reservoir with a low Hf isotopic ratio is required to balance the OIB-MORB mantle source. Continental crust, as compiled by Vervoort et al (EPSL, 1999), is not a good candidate for this low Hf reservoir. As an alternative, kimberlites or a deep-mantle reservoir have been suggested, with important implications for mantle structure and dynamics. Here, we propose that the reservoir could be created by sedimentary processes.

We determined the average Hf isotopic composition of a representative section of old, altered Pacific oceanic crust and overlying oceanic sediments sampled during ODP Leg 185. The average basaltic crust composition is similar to that of present-day MORB while the average sediment composition falls in the field of Fe-Mn crusts and nodules with an elevated $\varepsilon_{Nd}$ relative to $\varepsilon_{Hf}$. We use these $\varepsilon_{Hf}$ values combined with the average composition given by Su (2002) for average MORB, and Plank & Langmuir (Chem. Geol. 1998) for global subducted sediment (GLOSS) to evaluate the effect of recycling in the past of similar materials into the convecting mantle and its influence on the composition of the mantle. Over Earth history, such recycling had a marked effect on the mantle and would have shifted its composition towards higher Hf isotopic ratios. This process could explain the position of the mantle array above BSE. Using a Monte Carlo simulation of reasonable mixtures of sediment and basalt with surrounding mantle, we can reproduce the compositions of OIB and MORB and their position above BSE.

The high $\varepsilon_{Hf}$ relative to $\varepsilon_{Nd}$ typical of deep-sea sediments could have its complement in another sedimentary reservoir. We suggest it might be sand rich in heavy minerals which are present in large quantities along continental margins. Given that the “crustal array” of Vervoort is mainly based on fine grained sediments it might not be representative of the continental crust as a whole. The continental crust could contain a higher proportion of the coarser grained sediments with low $\varepsilon_{Hf}$ than previously thought. The “crustal array” could therefore lie below the “mantle array” in $\varepsilon_{Hf}$ versus $\varepsilon_{Nd}$, and a deep-seated mantle reservoir would not be necessary.
Fate of CO2 leaked from seabed
B. CHEN1, M. NISHIO1, Y. SONG1,2 AND M. AKAI1
1National Institute of Advanced Industrial Science and Technology (AIST), Japan (b.chen@aist.go.jp)
2Dalian University of Technology, China (power@dlut.edu.cn)

Models and Case Runs
We estimated the fate of CO2 droplets leaked from seabed and the physiochemical impacts produced on seawater column by means of numerical simulations. The model (Chen et al., 2003) used in this study is a full two-phase small-scale turbulent ocean model, of which the submodels had been calibrated by both lab. experiments and field observations. Predicted distances drops could move to from variant leakage depths (deeper than 800m) and initial drop sizes (Do mm) is shown in Fig.1. The water column impacts indicated by pH change are given in Fig.2 for cases of variant leakage rate (M, kg/s), Do, and current speed (Uc m/s) at leakage time of one hour. The background ocean is Okinawa.

Discussion of Results
The drop rising distances are almost linearly proportion to Do with a rate of 38m/mm and independent to the leakage depth if Do<15 and a rate increased from 10.3 to 24.7 as deeper leaked for large deformed drops. The maximum pH change can be reduced from 1.6 of Case B(M=0.6, Uc=2.5, Do=8) to 1.2 by reducing M=0.1 (Case A) and 1.1 by a larger Uc=25, (Case C). Smaller Do=5 produces a larger pH change, of which is balanced by a smaller M=0.3 (Case D).

Conclusions and Suggestions
At leakage depth larger than 800, no pure CO2 is found to be able to reach to the ocean surface even at size as large as 40mm. Physiochemical impacts of leaked CO2 on seawater can be reasonably estimated by using models developed with monitoring data of droplet plume height, from which the Do can be determined, and local leakage rate. For monitoring CO2 drops leaked, acoustic sonar technology is a suggested method. For CO2 leaked from shallow seabed, more lab. data are expected for calibrating the models, such as bubble drag and shrinking rate.

Zircon Lu-Hf isotope and its significance to ultra-high pressure metamorphic rocks from Dabie Terrain, Eastern China
DAOGONG CHEN1, ETIENNE DELOULE2, BINXIAN LI1 AND TAO NI1
1School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026 China (dgchen@ustc.edu.cn)
2CRPG-CNRS, Nancy 54501 France (deloule@crpg.cnrs-nancy.fr)

Zircon intragrain Lu-Hf and U-Pb isotope analyses were carried out for ultra-high pressure eclogite, jadeite quartzite and granitic gneiss from Shuanghe, Huangzhen and Xindian, Southern Dabie Terrane, Eastern Central China by using LA-MC-ICP-MS and SIMS (CAMECA) technique, respectively. The results show that zircon Hf isotope distributions are mainly controlled by the formation age of metamorphic precursor. Metamorphic zircon succeeded basically Hf isotopes of their protolith. The results also show systematic change among 206Pb/238U age, initial Hf isotopic compositions, Th/U and Lu/Hf ratios in zircons from different genetic domains. Metamorphic growth domains are characterized by low Th/U(<0.1), low Lu/Hf(<0.0005) and low 206Pb/238U ages, but high 176Hf/177Hf ratio relative to igneous core and mantle with partial recrystallization of pre-metamorphic ages. The low Lu/Hf and Th/U ratios of metamorphic growth zircon were caused by the decreasing of Lu and Th, and increasing of Hf, the high 176Hf/177Hf ratio relative to igneous core and mantle with partial recrystallization of pre-metamorphic ages. The low Lu/Hf and Th/U ratios of metamorphic growth zircon may represent the Hf isotope composition of the whole rock at the same time. In some cases Hf isotope compositions of metamorphic and inherited zircons are undistinguishable within same range.

The trace of initial Hf isotope composition of Hf and the Hf model age of depleted mantle TDM and U-Pb age for inherited zircon core indicates that their age and origin are different for metamorphic precursor. Eclogite from Shuanghe show the source mixture of depleted mantle of 2.5Ga with at least 2.7Ga late Archean crust. The material for eclogite precursor from Huangzhen and Xindian was formed mainly by melting of juvenile crust, with few old crust contamination. The material of gneiss precursor from both localities show same formation age and were derived from mixing of weak depleted mantle and crust. Whereas gneiss from Huangzhen shares the common source with eclogite. The zircon Lu-Hf isotope of UHP metamorphic rocks from Dabie orogen reflects new crust growth during 0.7-0.8 Ga and 1.8-1.9 Ga, which was consistent with wide magmatism and tectonic setting of north margin of Yantze Craton.

This research is financial supported by NSFC grant No. 40573008 and SFRDP grant No. 20040358050.
Tectonic implication of detrital muscovite from Carboniferous sedimentary rocks in the Northern Dabie Mountains, China: Evidence from single grain Rb-Sr dating

FUKUN CHEN1,2, QIULI LI3, XIANGHUI LI2 AND RENWEI LI1

1State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China (fukun-chen@mail.igcas.ac.cn)
2Laboratory for Radiogenic Isotope Geochemistry, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China

The Dabie ultrahigh-pressure orogenic belt represents the eastern part of the Qinling-Dabie orogenic belt in China, which was formed by collision of the North and South China Blocks during Early Mesozoic. Time of this collision has been constrained at ca. 230-220 Ma by numerous radiometric studies [1-2]. The Dabie belt is geologically made up of four tectonically juxtaposed zones, from south to north, the Susong HP zone, South Dabie UHP zone, North Dabie gneiss zone, and Beihuayang low-grade zone. UHP metamorphic mineral inclusions are found in garnet and zircon, indicating subduction of continental crust during the collision.

Low-grade metamorphic Paleozoic sedimentary rocks are exposed along northern margin of the Qiling-Dabie orogenic belt. Provenance and tectonic setting of these low-grade rocks are constrained at ca. 230-220 Ma by numerous radiometric studies [1-2]. The Dabie belt is geologically made up of four tectonically juxtaposed zones, from south to north, the Susong HP zone, South Dabie UHP zone, North Dabie gneiss zone, and Beihuayang low-grade zone. UHP metamorphic mineral inclusions are found in garnet and zircon, indicating subduction of continental crust during the collision.

This study presents results of detrital biotite and muscovite minerals of Carboniferous sedimentary rocks exposed in the northern margin of the Dabie Mountains. About 15% of detrital muscovite grains are phengitic in composition indicated in high Si/Al ratios of >3.3. Single grain Rb-Sr isotopic analyses show that either phengite or muscovite give about 400 Ma isochron age, while detrital biotite grains are scattered in two groups of Rb-Sr isotopic composition, likely suggesting different sedimentary sources of old crustal and juvenile material probably of magmatic rocks related to Paleozoic convergence along southern margin of the North China block. Whole-rock Nd isotopic composition of the sedimentary rocks also demonstrates a mixture of sedimentary sources of different ages, similar to the conclusions proposed previously [3]. Paleozoic detrital phengite can be originated from the North Qinling terrain where Paleozoic subduction and subsequent collision have been proposed [4].

This study is supported by the NSFC (No. 40525007).

Zn isotope measurements in freshwater and its use as a probe of anthropogenic contamination in the Seine River

JIUBIN CHEN, JÉRÔME GAILLARDET AND PASCALE LOUVAT
Equipe Géochimie et Cosmochimie, IPGP, 4 place Jussieu, 75005, Paris, France (chen@ipgp.jussieu.fr)

The recent development of MC-ICP-MS allows a precise and accurate determination of Zn isotopic compositions (1,2), and a total variation of about 2‰ for δ66Zn has been determined among terrestrial materials. Despite its potential pollution impact on aquatic environments, only few studies exist on Zn isotopic ratios in natural waters and none for rivers. In this context, it is worth studying its behaviour and isotopic composition in the Seine river basin, a basin with significant anthropogenic input (250 persons/km²). The human impact has been demonstrated by the continuous increase in Zn concentration from headwater to estuary both in the dissolved phase (17 times) and in the particulate phase (4 times).

We have developed a new two-column protocol for the direct ion-exchange separation of Zn from freshwater samples with very small dissolved Zn concentrations. This avoids the evaporation of large quantities of sample (~200 ml). The protocol is proven to be reproducible by tests on standard-doped distilled water and column-purified Seine river water, with an average yield of 100% and no isotopic fractionation (mean δ66Zn for all purification tests is 0.005‰).

For Zn isotope measurements, the instrumental mass discriminations are corrected statically for each measurement session using a method of internal reference element doped sample-standard bracketing (Zn for Cu; Cu for Zn isotopic measurement) (3). Repeated measurements of Zn and Cu AAS standards during 15 months yielded a precision of 0.04‰ (2σ) for δ66Zn in water samples of the Seine river basin, and a total variation of about 2‰ for δ66Zn in water samples of the Seine river basin, and a total variation of about 2‰ for δ66Zn in water samples of the Seine river basin, and a total variation of about 2‰ for δ66Zn in water samples of the Seine river basin.

Isotopic characterization of Zn in various phases (dissolved, suspended, colloidal) provide clues about both the source of metal pollution and the geochemical and biochemical processes in river water system.

~2.5Ga Sanukitoids from Guyang greenstone belt, North China

LIANG CHEN1,2*, JINGHUI GUO2, FU LIU3 AND YONG SUN1

1Key Laboratory of Continental Dynamics, Ministry of Education; Department of Geology, Northwest University, Xi’an 710069, China
2Institute of Geology and Geophysics, Chinese Academy of Sciences (IGGCAS), Beijing 100029, China (*turik@163.com)

The late Archean Guyang greenstone belt, the largest greenstone belt in the Western block of North China Craton (NCC), locates in the central Inner Mongolia, North China. It consists of three tectonically contacted low-grade volcanic-sedimentary assemblages, and the main emplacement age is around 2.5 Ga (Li et al., 1987; Wang, 1993).

The sanukitoid suite occurs in middle part of the lower assemblage. The suite is predominately andesitic (SiO2 = 58-65%) and is characterized by high Mg number (0.52-0.57), as well as high K2O contents (2.5-4.4%), high K2O/Na2O ratios (0.7-2.1) and low FeO/MgO ratios (1.6-2). The high K2O/Na2O and low FeO/MgO ratios are consistent with calc-alkaline serie trend. The high Ba (349-1062 ppm) and Sr (0.7-2.1) and low FeO T/MgO ratios (1.6-2) of the suite are significantly higher than comparable to modern adakites. However, Cr (114-350 ppm) and Ni (60-118 ppm) of the suite are significantly higher than adakites, indicating a high-extent hybridization with mantle peridotites (Smithies and Champion, 2000). The sanukitoids also have high Zr/Y ratios ranging from 8.6 to 30.7. In the primitive mantle normalized spider diagram, depletion of Nb and Ti relative to neighboring REE is significant (Nb*=0.07-0.47, Ti*=0.33-0.67), while Zr and Hf anomalies are less evident, comparable to average compositions of sanukitoids in Martin et al. (2005).

In Guyang greenstone belt, the sanukitoids occur in association with Nb-enriched basalts (NEB) (Chen, in preparation, 2007). The association has widely been proved to be the magmatic products of interaction between slab derived melts and overlying mantle wedge, hence is indicative of a modern-style subduction setting developed around 2.5Ga in the western block of NCC.

Are peridotite xenoliths in Mesozoic plutons inherited from Paleozoic kimberlites?

LI-HUI CHEN, SHAO-YONG JIANG, ALBRECHT W. HOFMANN, ZORAN JOVANOVIC, LIE-WEN XIE AND XIN-HUA ZHOU

1State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, China

3State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

Mantle xenoliths-fragments of the Earth’s mantle, are transported to the surface via volcanic/subvolcanic exclusively [1]. As direct mantle samples, these peridotite-dominated xenoliths provide principal approach to investigate the nature of the Earth’s mantle. Recently, peridotite xenoliths are exceptionally found in some Mesozoic diorite-gabbro plutons of North China Craton (NCC), and their genesis is still controversial [2-5]. Here we use zircons from a composite dunitie-phlogopite orthopyroxenite xenolith from Tietonggou pluton in Laiwu, one of Mesozoic plutons in the NCC, to trace the nature of these xenoliths. This sample is composed mainly of phlogopite-rich orthopyroxenite and subordinate pebble-like dunites [6]. Two stages (130 Ma and 450 Ma) of zoned zircons are found in this sample, the ages of which are concordant with those of the host pluton and of the Paleozoic kimberlites of the NCC, respectively. The similarities of Hf isotopes and rare earth element patterns, as well as the clear correlations between T(Ti) and Th/U ratio and T(Ti) v.s. Hf content for both the zoned Cretaceous zircons and the diorite zircons, demonstrate that these zircons were crystallised in the same magma chamber. In contrast, similarities in the compositional signature of phlogopite and the Nd-Hf isotopic compositions suggest that this composite xenolith was originally Paleozoic kimberlite with dunitie xenoliths before incorporation by the host pluton. We therefore suggest that peridotite xenoliths found in the Mesozoic plutons are inherited from the destroyed Paleozoic kimberlites.

Mineral H isotopes and water contents in UHP eclogite-gneiss contact from CCSD core samples

R.-X. CHEN, Y.-F. ZHENG AND B. GONG
School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China
(chenrx@mail.ustc.edu.cn)

By taking advantage of having depth profiles between contrasting lithologies from core samples of the Chinese Continental Scientific Drilling (CCSD) project, a combined study was accomplished by means of TC/EA-MS and FTIR methods to examine changes in mineral H isotope, total water and hydroxyl contents in garnet and omphacite across the contacts between ultra-high-pressure (UHP) eclogite and gneiss in the Sulu orogen, east-central China. The results are used to decipher both origin and availability of metamorphic fluid during exhumation of deeply subducted continental crust. The samples of interest were from two continuous core segments from the CCSD main hole at depths of 734.21 to 737.16 m and 929.67 to 932.86 m, respectively. The results show δD values of −116 to −64‰ for garnet and −104 to −82‰ for omphacite, consistent with incorporation of meteoric water into protoliths of UHP metamorphic rocks by high-T alteration. Both equilibrium and disequilibrium H isotope fractionations were observed between garnet and omphacite, suggesting fluid-assisted H isotope exchange at local scales during amphibolite-facies retrogression.

While bulk water analysis gave total H2O concentrations of 522 to 1584 ppm for garnet and 1170 to 20745 ppm for omphacite, structural hydroxyl analysis yielded H2O contents of 80 to 413 ppm for garnet and 228 to 412 ppm for omphacite. It appears that significant amounts of molecular H2O are present in the minerals, pointing to enhanced capacity of water storage in the UHP eclogite minerals. Hydrogen isotope variations in the transition between eclogite and gneiss show correlations with variations in their water content. Petrographically, the degree of retrograde metamorphism generally increases with decreasing distance from the eclogite-gneiss boundary. Thus, retrograde metamorphism results in mineral reactions and H isotope variation. Because hydroxyl solubility in nominally anhydrous minerals decreases with dropping pressure, significant amounts of water are expected to be released from the minerals during decompression exhumation. Decompression exsolution of structural hydroxyl from 1 m3 volume of eclogite composed of only garnet and omphacite results in release of a quantitative estimate of 3.07 to 3.44 kg water that can form 140 to 156 kg amphibole during exhumation. Therefore, it is concluded that fluid for retrogression of the eclogites away from the eclogite-gneiss boundary was derived from the decompression exsolution of structural hydroxyl and molecular H2O in nominally anhydrous minerals. For the eclogites adjacent to gneiss, in contrast, the retrograde metamorphism was principally caused by aqueous fluid from the gneiss which is relatively rich in water.

New achievements in the study of the excess argon in HP-UHP metamorphic minerals

W. CHEN, Y. ZHANG, X.Y. LIU AND Q.L. WANG
Laboratory of Isotope Geology, Institute of Geology, Chinese Academy of Geological Science, Beijing, 100037 China (chenwenf@vip.sina.com)

Based on the study of the genesis, diffuse and transference of excess argon in the High and Ultrahigh-pressure metamorphic minerals using classical Ar-Ar and laser microprobe Ar-Ar dating method, the following conclusions can be drawn:

1. In the eclogites of different time (from the Caledonian to Indo-Sinian epoch) and different area in China, not only the phengites contain large amounts of excess argon, but the other trace potassium minerals, such as olivine, garnet and pyroxene, also contain excess argon and even the biotites in some eclogites also contain excess argon.

2. Four phengites for Ar-Ar dating are concentrated from the eclogites range from the margin to the center of the eclogite body on the top of the Qinglong Mountain in eastern China. The excess argon content of the four samples from the outer to the inner part of the rock body within 60 cm is 73%, 74%, 76% and 78% respectively, which indicates that the excess argon in the phengites of the eclogites is distributed unevenly and show a little positive gradient. Therefore, the excess argon is basically believed to be inherited from its parent rock and not from its outside.

3. The phengites in the eclogite of Yuka area in the northern margin of the Qaidam Basin in western China, whose country rock is marble, do not contain excess argon, which indicates that the lithology of the country rock is a key factor to control the occurrence of the excess argon in eclogite.

4. The content of the excess argon in the phengites is found to be positively correlated with the ratio of its Na/(Na+K) and the correlation formula is:

\[ y = -112.14 + 10710x - 251844x^2 + 3 \times 10^6x^3 - 1 \times 10^7x^4 \]  
\( (R^2=0.997) \)

In which y is the content of the excess argon (%) and the x is the ratio of Na/(Na+K).

C- and S-isotope study on depositional environment of late Cryogenian Mn carbonate, Datangpo Fm., South China  

XI CHEN, DA LI AND HONG-FEI LING  

State Key Laboratory for Mineral Deposit Research,  
Department of Earth Sciences, Nanjing University,  
Nanjing 210093, PR China  

The Datangpo manganese carbonate deposit overlies diamictite of Tiesi’ao Formation (equivalent to Sturtian) and occurs at base of Datangpo Formation which underlies diamictite of Nantuo Formation (equivalent to Marinoan). Considerable $^{13}$C-depleted Mn carbonate and highly $^{34}$S-enriched pyrite from the base of the Datangpo Formation document unique oceanic chemical environment before the final oxygenation of the Earth’s surface.  

The observation of most $\delta^{18}$O~10 and no linear correlation between $\delta^{13}$C and $\delta^{18}$O suggests that C-isotope compositions of the Mn-carbonate are unaltered by late diagenesis. The $\delta^{13}$C values (meanly -7.2‰) below the mantle or crust values (-5~6‰) are consistent with the early diagenetic model for stratiform Mn carbonate deposit, which argues participation of carbon derived from bacterial remineralization of organic matter during Mn-carbonate precipitation. However, the relatively small standard deviation (0.81‰) of $\delta^{13}$C values indicates carbonate precipitation occurs near the water-sediment interface rather than in the oxic pore water, thus the $\delta^{13}$C values were inherited from the bottom water. The best-fitting line ($r^2=0.69$) of $\delta^{13}$C vs. fractionation ($\Delta$) between carbonate and organic carbon yields a slope=0.78 and an intercept of -26.94, which cannot be readily explained by steady-state model of carbon cycle. Therefore, we suggest that negative $\delta^{13}$C excursion was resulted from oxidation of part of a large dissolved (including suspended) organic carbon reservoir. In addition, large $\Delta$ values (meanly 25.3‰) imply high CO$_2$ concentration in the atmosphere.  

High $\delta^{34}$S values of pyrites within the Mn-carbonate indicate extremely $^{34}$S-enriched sulphate in a restricted basin. The pyrites probably precipitate in the relatively oxic pore water beneath sea water with low sulfate concentration, which is consistent with the observation of large and scattered pyrite framboids that are symbolic of diagenetic formation beneath dysoxic bottom waters.  

In conclusion, the Mn-carbonate deposit at the base of Datangpo Formation records abundant paleoenvironmental information, such as high CO$_2$ concentration in the atmosphere and low sulphate concentration in the ocean after the Sturtian ice age, considerable O$_2$ concentration in the atmosphere which caused the ocean chemocline moving to the water-sediment interface in the outer shelf, large dissolved organic carbon reservoir which was partly oxidized by Mn oxides and SO$_4^{2-}$ enzymatically near and below the chemocline. (This study is supported by NSFC grant 40572017.)

Authigenic carbonates in the Chinese loess-paleosol sequence: Morphologic and isotopic study  

YANG CHEN, XUEFEN SHENG, JUN CHEN AND JUNFENG JI  

State Key Laboratory of Mineral Deposit Research, Institute of Surficial Geochemistry, Department of Earth Sciences, Nanjing University, Nanjing, China (chenyang@nju.edu.cn)  

Carbonate is a common component in the eolian loess-paleosol sequences, north China. Usually carbonate content is about 10 wt% in loess while lower (e.g. 0.3 wt %) in paleosol due to pedogenic leaching (Liu, 1985). Carbonate is easily leached out and accumulated in the loess profile. In this study we found at least six types of authigenic calcium carbonate accumulation in the Luochuan loess-paleosol sequence: coatings, rhizoconcretions, fossil snail shells, pseudomyseliums, nodules and nano-scale rods. Various carbonates have different morphologic features and isotopic compositions (Table 1), showing different forming conditions. Among them, carbonate nodules were precipitated under multi–alternations of heavy rainfall and intense evaporation without biological processes. Other authigenic carbonates may form from biological-controlled or biological-induced interactions. Detailed study on these authigenic carbonate can provide a reasonable way to trace the biogeochemical process in the loess sequence.

Can rutile thermometry link to rutile U-Pb age?
ZHENYU CHEN 1 AND QIULI LI 2
1Institute of Mineral Resources, Chinese Acadeny of Geological Science (czy7803@126.com )
2Institute of Geology and Geophysics, Chinese Academy of Geological Science (qiul8@263.net)

T-t information of metamorphic rocks is basic and critical content in petrogenesis study. Rutile U-Pb dating are often used to constrain cooling age of metamorphism. Zr-in-rutile thermometry is a newly developed single mineral thermometry. According to the experimental data, diffusion parameter of Pb and Zr are similar in rutile. So can we link rutile thermometer to its’ U-Pb dating?

Jinheqiao 99JHQ-1 eclogite is the only one which has got precise rutile U-Pb age in China up to now11. It is tectonically located in the South Dabie UHPM zone. Peak conditions estimated in Jinheqiao area were 680–940°C and 3.2–4.3Gpa. Here we present Zr content of rutiles analyzed by electron probe in 99JHQ-1 eclogite and discuss the link between rutile temperature and its’ U-Pb dating.

Fourty-two rutiles were analyzed and gave Zr content between 37–118ppm, average in 67ppm. Rutiles as garnet inclusion have a little higher Zr (75ppm) than rutiles in matrix (64ppm), but they share the similar variation range. Temperatures calculated by Watson2 and Zack3 were 519–563°C and 507–600°C respectively. Zr-in-rutile thermometry are often used to calculate peak temperature of high grade metamorphic rocks. However, rutile Zr temperature in 99JHQ-1 eclogite is obviously lower than the peak temperature calculated by garnet-quartz O isotope thermometry of 695°C, but is significantly higher than Tc of about 460°C for U-Pb system in rutile and rutile-quartz O isotope thermometry of 460±15°C estimated in this eclogite.

Petrographical observation show that 99JHQ-1 eclogite had experienced strong retrograde metamorphism. Omphacite were almost transformed into simplectite, garnets were always surrounded by a wide rim of hornblende, and many rutiles were partly transformed into ilmenite or titanite. These phenomena show that the retrograde fluid were intensive during the exhumation of this eclogite. Rutiles were re-crystallized or retrogress to various extent. Large variation of Zr content in rutile indicate that Zr in rutile had also been reset to various extent, i.e. Zr in rutile were not equilibrate with retrograde zircon and quartz.

In summary, Zr-in-rutile thermometry may bear any geologic meaning in highly retrograde eclogite. Despite the experimentally similar diffusion parameter of Zr and Pb, O in rutile, Tc of Zr may be higher than those of Pb and O in actual geological condition, and one should be careful in linking the rutile thermometry to its’ U-Pb dating.

Rates of eclogitic metamorphism of subducted continental slab
H. CHENG1, R.L. KING2, E. NAKAMURA3 AND J.D. VERVOORT2
1State Key Laboratory of Marine Geology, Tongji University, 200092, Shanghai, P.R.China
(chenghao@mail.tongji.edu.cn)
2School of Earth & Environmental Sciences, Washington State University, Pullman, Washington 99164, USA

3The Pheasant Memorial Laboratory for Geochemistry and Cosmochemistry, Institute for Study of the Earth’s Interior, Okayama University, 682-0193, Misasa, Japan
(eizonak@misasa.okayama-u.ac.jp)

Knowledge of the duration of concurrent processes affecting the rocks such as heating, recrystallization and deformation is fundamental to an understanding of metamorphism. Various approaches such as thermal modeling, radioisotopic dating, chemical and textural analysis can be utilized to envisage these durations. Combined textural analysis (CSDs), chemical analysis with Lu-Hf and Sm-Nd geochronology study on the Dabie HP/UHP eclogites can thus provide a comprehensive understanding regarding garnet growth histories so as to the subduction and exhumation processes of its host rocks. Garnet compositional profiles show well-preserved growth zoning with a decrease in Mn, Ca and heavy rare earth elements (HREEs) and an increase in Mg towards rims. Textural quantification analysis for the garnets reveal apparent pseudo-lognormal CSDs, which alone can be interpreted by several plausible nucleation growth mechanisms; however, the mineralogy of inclusions in garnets and the compositional zoning patterns reveal a three-episodic nucleation and growth process. The Rayleigh-type HREE zoning and near-constant MREE zoning in the garnets indicate that the obtained ~5 Ma time span, defined by the decoupling between 224.2±1.9 Ma Lu-Hf and 217.8±4.2 Ma Sm-Nd ages, represents timing of the last garnet growth episode deviating from the nucleation process. Based on the absence of significant diffusional reequilibration as indicated by the compositional zoning, the textural analysis and the mineralogy of inclusions in garnets, we interpret the initiation of garnet growth during prograde metamorphism must have predated the 224.2±1.9 Ma Lu-Hf age and the 217.8±4.2 Ma Sm-Nd age is an estimation for the closure of garnet growth corresponding to the amphibol-facies overprint along exhumation path; therefore, the time elapsed at eclogitic condition should be extremely short.

High-precision MC-ICP-MS lead isotope analysis using Tl-normalization: Calibration and applications to lead isotope study of ore deposits

I.V. CHERNYSHEV, A.V. CHUGAEV AND K.N. SHATAGIN
IGEM RAS, Moscow, Russia (cher@igem.ru)

The demands for radical improvement (compared to conventional TIMS method) of lead isotope ratios measurements precision exist in isotope geochemistry for last 30 years. It becomes practicable owing to multicollector-ICP-mass-spectrometry which makes possible to correct lead isotopes mass-discrimination with $^{205}$Tl/$^{203}$Tl ratio. This method was elaborated and adapted to different MC-ICP-MS instruments in wide number of works (for example, [1-5]).

Developing this method [5] we use 9-collector-ICP-MS NEPTUNE. The $^{205}$Tl/$^{203}$Tl value in TlNO$_3$ reference sample instruments in wide number of works (for example, [1-5]).

The $^{205}$Tl/$^{203}$Tl ratio in two mixtures Tl+-Pb (SRM 982) and Tl+-Pb (SRM 981) in 10 parallel analyses for each one respectively are: 2.3898±12 and 2.3888±20. Analyses of both mixtures yield $^{205}$Tl/$^{203}$Tl ratio in excellent agreement between them, when a total mean value 2.3889±1 coincides in error limits with recent data 2.3887±7 [3] and 2.3889 [4].

Isobar interference of $^{204}$Hg$^+$ contribution to total peak 204 m/e intensity was controlled and corrected by $^{202}$Hg$. Its contribution didn’t exceed 4×10$^{-17}$A or <0.001% in terms of $^{204}$Pb$^+$ peak. Background signals in analyses were less than 1.5×10$^{-15}$A, whereas $^{204}$Pb$^+$ peak intensity during analyses ranges from 2.5×10$^{-11}$ to 8×10$^{-11}$A.

Precision of the method involved has been evaluated from long-term (1.5 years) reproducibility of 90 parallel analyses of common lead standard SRM 982 and galena samples (±2SD): $^{206}$Pb/$^{204}$Pb = ±0.016%; $^{207}$Pb/$^{204}$Pb = ±0.016%; $^{208}$Pb/$^{204}$Pb = ±0.018%; $^{207}$Pb/$^{206}$Pb = ±0.005%; $^{208}$Pb/$^{206}$Pb = ±0.009%.

The method described was applied to detailed lead isotope study of same well known ore deposits. Systematic study of 12 massive sulphide and base metal deposits of Ural, Russia was performed. Another object was Banska Stiavnica Au-Ag deposit (West Carpathian, Slovakia), which demonstrated perfect homogeneity of lead isotope composition.

Stable nitrogen isotopic composition of amino acids: Implications for aquatic food web studies

Y. CHIKARAISHI, Y. KASHIYAMA, N.O. OGAWA, H. KITAZATO AND N. OHKOUCHI
Japan Agency for Marine-Earth Science and Technology (ychikaraishi@jamstec.go.jp)

Compound-specific stable nitrogen isotope analysis of amino acids is a potential tool for elucidating trophic position of organisms in the food web (McClelland and Montoya, 2002). Large $^{15}$N-enrichment (~7‰) in glutamic acid along the trophic level provides a greater scope for defining trophic position than the small change (~3‰) in bulk material, and little change in $^{15}$N of phenylalanine along the trophic level provides information of nitrogen sources at the base of the food web. However, it is still uncertain whether or not the $^{15}$N relationship observed in McClelland and Montoya (2002) is generally applicable to other sets of ecosystems.

We investigated the nitrogen isotopic composition of individual amino acids from macroalgae and gastropods in a natural marine coastal environment, to further evaluate them as a tool for ecological studies and to understand the factor(s) controlling the isotopic compositions in terms of biosynthetic and metabolic processes (Chikaraishi et al., 2007). The isotopic compositions of 12 amino acids range from -3.3 to +12.9‰ for marine algae, and from -0.6 to +16.6‰ for gastropods (Fig. 1). The isotopic distribution between algae and gastropods are consistent with those in the previous report, suggesting them to be quite useful for studying the food web structure. The nitrogen isotopic variation between amino acids would strongly reflects their biosynthetic and metabolic processes. We suggest that the metabolic fate is an important factor to produce the distinct trophic relationship in the nitrogen isotopic compositions between amino acids.

Figure 1: Nitrogen isotopic composition of individual amino acids in marine macroalgae and gastropods.

Removal of Hg(II) by natural zeolite

ANAAD CHIMEDTSOGZOL¹, KURT FRIESE² AND HERBERT POELLMANN³

¹National University of Mongolia, Ulaanbaatar, Mongolia
²Centre for Environmental Research, Magdeburg, Germany
³Martin Luther University, Halle (Saale), Germany

Natural zeolite will be more widely considered for roles in environmental clean-up processes—especially those involving radioisotopes and heavy metals (Dyer, 1995). The limited data are also available for mercury ion exchange with the clinoptilolite in terms of equilibrium isotherms and kinetics using radiochemical analysis with 203Hg and 22Na as a radiotracer. (Misaelides et al., 1994).

Modified natural zeolite with sodium produced a cation exchangeable material which has been tested for the ability to remove Hg(II) from aqueous solution with nitric acid using a flow injection mercury system (FIMS 400). The amounts of adsorption depend mostly on contact time, acid concentration of aqueous solution and initial mercury concentration, mixed cation of mercury and its subgroup elements. The study of the kinetics of mercury uptake revealed that all sorbents exhibit a fast rate of sorption. The highest sorption capacities were observed for the sodium forms (TSA-Na, TEC-Na, TUS-Na) and were up to 5 times higher than for the natural zeolite (TSA, TEC, TUS).

The maximum sorption capacity toward mercury is determined as 0.09286 µg/g at an initial concentration of 10µg/L for TSA-Na. The sorption of Hg (II) has an ion-exchange nature and consists of three stages, i.e., the adsorption on the surface of microcrystals, the inversion stage, and the ion exchange in the interior of the microcrystal. Sorption capacity decreases with the increase of mercury concentration. The presence of other metal ions such as Cd(II), Cu(II), Ni(II) and Zn(II) increases Hg(II) uptake capacity. Finally, sorption for Hg(II) was investigated in batch systems and were up to 5 times higher than for the natural zeolite (TSA, TEC, TUS).

The experimental observations suggest a mechanism based on the protonation of FeS surface (Chirita and Descostes, 2006) followed by oxidation of FeS by dissolved oxygen to produce Fe²⁺, S²⁻ and SO₄²⁻. Fe²⁺ is unstable in oxidative conditions (Descostes et al., 2002) and transforms into Fe(OH)₃ and goethite after approximately 30 h of reaction.

Pyrrhotite oxidation in weakly acidic solutions

P. CHIRITĂ¹, M. DESCOSTES² AND M.L. SCHLEGEL³

¹Chemistry, University of Craiova, Calea București 1071, Craiova 200440, Romania (paul@chimie.ucv.ro)

³CEA, DEN/DANS/DPD/SCP/Laboratory for the Reactivity of Surfaces and Interfaces, F-91191 Gif-sur-Yvette, France (michel.schlegel@cea.fr)

The kinetics and mechanism of pyrrhotite (for simplicity noted FeS) oxidation by dissolved oxygen was investigated in weakly acidic solutions as a function of pH (2.75 to 3.45) and temperature (25 to 45°C). The changes in Eh, pH and total dissolved iron were monitored to quantify the reaction progress. Additionally, Fourier transform infrared spectroscopy (FTIR) was used to characterize the oxidation products of FeS.

The experimental results demonstrate the importance of temperature and initial pH for the FeS oxidative dissolution. The amounts of dissolved iron (nFe) and removed H⁺ (nH) increase with temperature and initial [H⁺]. The activation energy of FeS oxidative dissolution is 41.6±10.7 kJ mol⁻¹ at initial pH=3.00 suggesting that the kinetic regime is controlled by a mix of diffusion and surface reaction (De Guidici et al., 2005). It was found that the reaction order of oxidative dissolution of FeS is 1.03±0.02 (25°C) with respect to initial [H⁺].

FTIR spectroscopy indicated the presence of several sulfur species (S⁰, S²⁻, S₄O₆²⁻, SO₃²⁻ and SO₄²⁻) and ferric hydroxides or oxyhydroxide (Fe(OH)₃ and goethite) on residual FeS surface.

It is important to note that the experimental ratios of nH over nFe (nH/nFe) observed at 25°C decrease over a first period of time (0-4 h) of FeS oxidative dissolution from 7.97 down to 2.01. Afterwards, the nH/nFe ratio becomes lower than 2 and remains roughly constant (4-72 h). At higher temperatures (35 and 45°C) and pH 3.00, nH/nFe<2 and is quasi-invariant over the reaction time.

The experimental observations suggest a mechanism based on the protonation of FeS surface (Chirita and Descostes, 2006) followed by oxidation of FeS by dissolved oxygen to produce Fe²⁺, S²⁻ and SO₄²⁻. Fe²⁺ is unstable in oxidative conditions (Descostes et al., 2002) and transforms into Fe(OH)₃ and goethite after approximately 30 h of reaction.

Here we present results from the development of a novel in-situ approach to measure accurate and precise $^{30}$Si/$^{28}$Si and $^{29}$Si/$^{28}$Si ratios in minerals and glasses. We have developed an in situ-method for precise and rapid measurements of $^{30}$Si/$^{28}$Si and $^{29}$Si/$^{28}$Si ratios in silicates at a spatial resolution of 50 micrometers using our in-house built 196nm UV-femtosecond laser ablation system coupled to high-resolution MC-ICPMS. The use of medium resolution mode (m/Δm= 8000) permits to resolve spectral interferences on $^{30}$Si, $^{29}$Si and $^{28}$Si as verified using a three isotope plot that shows an equilibrium mass dependent fractionation law which can be represented as $\delta^{30}$Si=1.93*$\delta^{28}$Si. Sample-standard bracketing is used to correct for the mass discrimination and the possible drift occurring between two measurements and thus $\delta^{29}$Si and $\delta^{30}$Si are calculated using NIST NBS28 (synthetic quartz sand) as bracketing standard. Different types of matrices have been analysed by laser ablation. Thus $\delta^{28}$Si and $\delta^{29}$Si have been determined for the silicon isotope standard IRMM-017 ($\delta^{30}$Si= -1.26 %o $\pm$0.24 %o ; 2 s.d. n=89) and BigBatch ($\delta^{30}$Si= -10.55±0.42‰ ; 2 s.d., n=15), as well as San Carlos Olivine ($\delta^{30}$Si= -0.81±0.19‰ ; 2 s.d. n=14), Caltech Rose Quartz ($\delta^{30}$Si= 0.10±0.13‰ ; 2 s.d., n=14) and JER-diopsode glass ($\delta^{30}$Si=0±0.09‰ ; 2 s.d., n=14) samples. Silicon isotope standard IRMM-018 has also been measured and confirmed to be homogeneous.

Samples where Si is inially present in solution can also be measured. This approach has been verified by dissolving JER-diopsode glass, separating the Si [Georg et al., 2006; Brzezinski et al., 2003] and measuring $\delta^{28}$Si and $\delta^{29}$Si by laser ablation from a film of precipitated Si-gel.

First results will be presented that show that sponge needles from a given specie and environment are homogeneous within and between individual needles. In contrast, hydrothermal quartz shows substantial internal isotope zonation.

Green rust sodium/potassium sulfate

B.C. CHRISTIANSEN1, T. BALIC-ZUNIC2, C. FRANDSEN3, S. MORUP3 AND S.L.S. STIPP1

1NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Kbh. Ø, Denmark (bochr@geol.ku.dk; stipp@geol.ku.dk)
2Institute of Geography and Geology, University of Copenhagen, 1350 Kbh. K, Denmark (tonci@geol.ku.dk)
3Department of Physics, Bldg. 307, Technical University of Denmark, DK-2800 Kongens Lyngby, Denmark (fraca@fysik.dtu.dk; steen.morup@fys.dtu.dk)

Green rust (GR) is the generic name, which refers to a family of compounds consisting of brucite-like layers of Fe(II),Fe(III)-hydroxide. GR is a layered double hydroxide (LDH), also known as hydrotalcite-like materials (HLM). They have been identified in nature in soil taken from the redox boundary where groundwater is oxidised and they are important first solids during corrosion of iron in remediation barriers. The presence of Fe(II) in the brucite-like layer, makes GR very reactive towards redox sensitive elements, such as Cr, Se, Np and chlorinated solvents and pesticides. Understanding the GR system is thus interesting with regards to remediation techniques. It will also aid to better understand the redox processes taking place in the groundwater zone and to improve prediction of contaminant transport.

Previous studies have reported structurally bound water and anions in the interlayers, the thickness of which is assumed to be defined by the anion. Compounds with spherical or planar anions, such as Cl- or CO3 2-, produce similar X-ray diffraction (XRD) patterns and are known as Group 1 GR. Group 2 compounds incorporate three dimensional anions, such as tetrahedral SO4 2-, and produce larger basal-plane spacings.

If we want to predict redox reactions and contaminant transport, it is important to know the structural parameters of the various GR types. GR$_{SO_4}$, which is used in many studies, has not been characterised correctly in the past. We used several high resolution techniques including XRD, Mössbauer spectroscopy, ICP-AES and atomic force microscopy to investigate the GR$_{SO_4}$ compounds. We observed a difference in X-ray diffraction patterns depending on which monovalent cation was dominant during formation.

Within the last decade, two observations of naturally occurring sodium and sulphate-containing hydrotalcites have been described: nikischerite, NaFe$_{2+1}$Al$_3$(SO$_4$)$_9$(OH)$_{12}$•12H$_2$O and shigaite NaAl$_3$Mn$_2^+$$_2$(SO$_4$)$_9$(OH)$_{12}$•12H$_2$O. We refined the structure for green rust sodium sulfate and potassium sulfate using the nikischerite structure as a basis. The calculations, as well as careful chemical analyses, clearly indicated presence of Na or K in the structure. Thus we present new chemical formulae and new crystal structures for GR$_{Na,SO_4}$ and GR$_{K,SO_4}$: NaFe$_{2+1}$Al$_3$(SO$_4$)$_9$(OH)$_{12}$•12H$_2$O, P-3, a-axis = 9.520 Å, c-axis = 10.932 Å and KFe$_{2+1}$Fe$_{3+}$$_3$(SO$_4$)$_9$(OH)$_{36}$•XH$_2$O, P-3, a-axis = 9.530 Å, c-axis = 11.183 Å.
Zircon and whole-rock Hf isotope constraints on the petrogenesis of Transhimalayan plutonic rocks

M-F CHU1,2, S-L CHUNG1, S.Y. O’REILLY3, N.J. PEARSON3, X-H LI4 AND F-Y WU4

1Department of Geosciences, National Taiwan University
2Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan (meifei@ntu.edu.tw; meifei@earth.sinica.edu.tw)
3GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Sydney, Australia
4Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Hf isotopes of whole-rock (WR) samples and their zircon separates can be used in much the same way as Nd isotopes. Moreover, in situ zircon Hf isotopes, combining U-Pb ages, often record “hidden” information that allows more detailed studies of the petrogenetic processes. This study reports Hf isotope data from principal Transhimalayan intrusions, which include Jurassic, Cretaceous and Paleogene I-type Gangdese batholiths, resulting from Neotethyan subduction prior to the India-Asia collision. Major conclusions are reached: (1) There are significant variations in Hf isotopes of magmatic zircons, up to ~15 ε-units in some samples, suggesting magma mixing and/or magma-source isotopic heterogeneity to be common features; (2) A “hidden” DM (depleted mantle) component, with εHf(T~80Ma) values to +19.8, is identified in the Gangdese magmatic zircons. This DM-type component has never been revealed by any WR isotope analysis (WR-εHf(T): -0.1 to +13.5); (3) According to the linear correlation between the Gangdese WR Hf and Nd isotope ratios, this DM endmember has an equivalent εNd(T~80Ma) value of ca. +8 and thus shows an affinity to the India rather than Pacific DM source involved in the petrogenesis.

Figure 1. Hf isotopes of zircons and host rocks from the Gangdese batholiths, southern Tibet.

Particularities of Mn\(^{2+}\) uptake by living and dead *Shewanella putrefaciens*

NATALIA CHUBAR, THILO BEHRENDS AND PHILIPPE VAN CAPPELLEN

Utrecht University, Department of Earth Sciences – Geochemistry, Utrecht, The Netherlands (n.chubar@geo.uu.nl, behrends@geo.uu.nl, pvc@geo.uu.nl)

Sorption to microbial cell walls influences the fate and cycling of metals in the environment. Sorption of Mn\(^{2+}\) by living and dead *Shewanella putrefaciens* (widely spread in the environment gram-negative reducing bacterium) was studied in batch conditions: pH effect, kinetics of adsorption, equilibrium isotherms, the effect of the bacteria doses on adsorption, and speciation of dissolved forms in the experimental solutions.

Although FR-IR spectra of live and autoclaved cells of the facultative anaerobic bacterium *S. putrefaciens* do not reveal differences in cell wall functional groups, sorption of Mn\(^{2+}\) by suspensions of living and dead cells deviate significantly from one another. Sorption to dead cells is characterized by rapid equilibration and the data can be described by an isotherm. In contrast, sorption to live bacteria exhibits complex time-dependent kinetics, which cannot be captured by a single isotherm. Although the live bacteria release proteins and carbohydrates to solution, electrochemical analyses do not indicate strong aqueous complexation by organic ligands. FT-IR spectra of the (initially) live bacterial suspensions show evidence for the presence of MnO\(_2\) after 24 days, implying the occurrence of manganese oxidation. Mn\(^{2+}\) oxidation by living *S. putrefaciens* is a temperature dependent process.
Field relations and petrography in the Wadi Haymiliyah, Oman ophiolite: Evidence for a very heterogeneous plutonic lower crust

S. CICHY1, K. ZIAJA1, J. KOEPEK1, J. BERNDT2 AND F. BOUDIER3

1Institut für Mineralogie, Leibniz Universität Hannover, Germany (sbc.pele@arcor.de)
2Institut für Mineralogie, Universität Münster, Germany (jberndt@uni-muenster.de)
3ISTEEM, University Montpellier, France (boudier@dstu.univ-montp2.fr)

According to the "ophiolite model", the lower oceanic crust formed at fast-spreading ridges is regarded to consist of a relatively simple "pan cake" sequence: from bottom to top, Moho-transition zone (MTZ), layered gabbros developing to isotropic gabbros, and sheeted dikes. Actually, this model is mainly based on Oman ophiolite studies. However, the "real" lower oceanic crust of the Oman may show a much higher complexity which is expressed by numerous intrusions of late plutonics of different rock type. We studied a special section of lower crust of the Oman ophiolite in the Wadi Haymiliyah (Halyn block), which is well-known for its complexity (Juteau et al., 1988). Here, we started small-scale mapping projects for a detailed structural, petrographic and geochemical characterization of selected outcrops within the lower parts of the plutonic crust.

The data presented here result from field work in a 250 m long river section in the Wadi Haymiliyah, which is geographically situated at N 23°33.975 and E 57°11.963. The mapping project uncovers typical layered gabbros probably emplaced during the on-axis accretion stage of a fast-spreading oceanic spreading center forming the basic matrix of the crust. Subsequently, the layered gabbro sequence was intruded by magmas or crystal mushes of different lithologies resulting in a variegated suite of late-stage plutonic rocks: poikilitic wehrlites, olivine gabbros, clinopyroxene gabbros, "hydrous" gabbros, as well as oceanic plagiogranoites. The contacts of the intrusions exhibit no chilled margin or any major textural discontinuity. Furthermore, plastic deformations are practically absent, implying that the layered gabbros were still very hot or even in a state of dense mush during the intrusion of the later magmas. Thus, it is indicated that the late intrusives also belong to the on-axis accretion stage. The gabbro in direct contact with the wehrlites shows those typical microstructures characterized by zones of An-enriched plagioclase on grain boundaries (Koepke et al., 2005), implying that water-rich fluids derived from the wehrlites triggered hydrous partial melting reactions in the gabbro.

Origin and Re-Os systematics of bitumen hosted in Lower Cretaceous volcanic rocks, northern Chile

MARÍA EUGENIA CISTERNAS1 AND FERNANDO BARRA1,2

1Instituto GEA, Universidad de Concepcion, Casilla 160-C, Concepcion, Chile (mcistern@udec.cl)
2Department of Geosciences, The University of Arizona, Tucson, AZ 85721, USA (Barra@email.arizona.edu)

Bitumen-bearing strata-bound copper deposits hosted in volcanic-volcanoclastic sequences of Lower Cretaceous age are common in northern and central Chile. Solid bitumen and pyrobitumens (residual petroleum) are intimately associated with Cu-(Ag) sulfides. These deposits have several similar characteristics, such as the same type and age of the host rocks, the same number and type of hydrothermal stages (an early Fe-rich stage followed by a late Cu-rich stage); and the same ore paragenesis. In all locations, the textural relationships between bitumen and sulfides indicate that bitumen was present prior to the precipitation of the Cu-sulfides.

The origin of these Cu-(Ag)-bitumen deposits is associated to the evolution of the Lower Cretaceous back-arc basin. The source of the hydrocarbons is attributed to the thermal maturation of marine organic-rich facies accumulated in the back-arc basin during Jurassic and Early Cretaceous time. The necessary heat for distillation of hydrocarbons from source rocks has a probable origin in the burial temperature, coupled with the high thermal gradient associated with the extension and thinning of the crust under the ensialic floor of the back-arc basin and/or the hydrothermal fluid circulation associated with active magmatism during the Early and Late Cretaceous. Fe-rich hydrothermal fluids first removed the hydrocarbons from their source rocks and then precipitated them in the upper levels of the Lower Cretaceous sequence. Later, Cu-rich hydrothermal fluids precipitated the Cu-sulfides and contributed to the thermal maturation and cracking of the migrated oil to form pyrobitumens. The temperature of about 130ºC obtained from bitumen reflectance indicates the temperature of the first Fe-rich hydrothermal event and indirectly the regional maturation level, whereas temperatures between 170 and 380ºC, obtained from the reflectance of pyrobitumens, indicate the temperatures of the second Cu-rich hydrothermal event, which physically and chemically altered the original bitumen.

Preliminary Re-Os analyses of bitumen from the Copiapo area show high Re and Os concentrations (~670 ppb and ~2 ppb, respectively). The 187Re/188Os ratios are very high with values between ~11500 and 12800, and the Os isotopic composition is very radiogenic, with 185Os/185Os ratios over 50. These preliminary results indicate a very radiogenic source for the Os contained in the bitumen. Further Re-Os work on other bitumen samples and Cu-sulfides is in progress to determine time constraints for the formation of bitumen and sulfides in these deposits.
Vegetation regulates dissolved B in forested watershed

D. CIVIDINI1, D. LEMARCHAND, F. CHABAUX AND R. BOUTIN
1(damien.cividini@illite.u-strasbg.fr)

The mechanisms by which the vegetation influences geochemical fluxes at the catchment scale remain difficult to describe because of a lack of knowledge on their links and feedbacks. In particular, it is still a question to know at what level the nature of the vegetal cover can regulate the river water chemistry or influence the reactivity of soil horizons.

To address these points, we have conducted a comprehensive study of B isotopes in a small-forested watershed (Strengbach, NE France). Water was sampled along the hydrological pathways from rainwaters down to springs via throughfalls and soil solutions in two distinct parcels covered by spruces and beeches.

It comes out that the amount of B yearly cycled by vegetation is about twice the amount of B exported out of the basin. This demonstrates that the biological activity is the key factor that regulates the B geochemical cycle in forested area. Moreover, the B isotopic signature of the vegetation is enriched in $^{11}$B far from any other reservoirs. These two features make B a highly reliable and easy-to-follow element for investigating the mechanisms of geochemical transport that involve the vegetation cycle.

In soil solutions, there is an exponential-like decrease of the $[^{11}B]$ indicating that B mostly originates from throughfalls. Associated with the isotopic analyses, the behavior of B primarily reflects the reactivity of soil horizons in terms of ion exchange intensity. At depth greater than 60 cm, soils developed under spruces and beeches show distinct isotopic composition, each fingerprinting the corresponding spring water. It then strongly suggests that the nature of the vegetal cover directly influences the reactivity of the soil from which it growths and then drives the B isotopic composition of the sub-surface waters.

Overall, this study demonstrates that the geochemical cycle of B isotopes in forested catchment is controlled by vegetation cycling and that B can be used for closer investigation of the relative impact of the biosphere on the mass transfer at regional scale.

Sulfate, methane, and the rise in atmospheric oxygen

M.W. CLAIRE1, D.C. CATLING2 AND K.J. ZAHNLE3
1Astrobiology Program/Dept. of Astronomy, University of Washington, Box 351580, Seattle WA 98195, U.S.A

2Dept. of Earth Sciences, University of Bristol, Queen’s Rd., Bristol BS8 1RJ, U.K. (David.Catling@bristol.ac.uk)
3MS 245-3, Space Science Division, NASA Ames Research Center, Moffett Field, CA 94035, U.S.A
(Kevin.J.Zahnle@nasa.gov)

Using two distinct numerical models, we have developed a conceptual picture that implicates sulfate as a key player in ushering in the late Archean global ice age and ultimately leading to complex-life sustaining levels of atmospheric oxygen. We attempt to provide a theoretical framework for understanding the Archean records of increasing mass-dependent sulfur isotope fractionation ($\delta^{34}S$) concurrent with a decrease in the mass-independent signal $\Delta^{33}S$ (MIF-S). Increasing $\delta^{34}S$ is commonly linked to increasing oceanic sulfate availability. First, we describe results from a global redox box model which investigates how slight increases in oceanic sulfate concentration could affect anaerobic methanotrophy in the Archean/Proterozoic biosphere. We show that this metabolism enhances a positive feedback on the atmospheric destruction of methane by oxygen, by acting as a throttle for methane fluxes from the seafloor. We next describe results from a 1-D photochemical model which is used to explore the transition between weakly reduced and weakly oxidizing atmospheres. We show that the disappearance of MIF-S is better explained by a decline in atmospheric methane levels, rather than by a rise in oxygen levels. Increasing oceanic sulfate thus hastens a collapse in atmospheric methane to below 10 ppm, which halts the MIF-S signal. These conditions can lead to a global ice age, and are favorable for increasing amounts of free oxygen in the atmosphere. Oxygen levels and climate stabilize in the early Proterozoic once sufficient ozone forms to allow methane to re-rise to levels of approximately 100 ppm.

Comparative geochemistry at Gusev Crater and Meridiani Planum, with implications for aqueous activity

BENTON C. CLARK AND THE ATHENA SCIENCE TEAM
Lockheed Martin, POB 179, MS S-8000, Denver, CO, USA 80201 (benton.c.clark@LMCO.com)

Correspondences and Similarities
Soils, sediments and even certain rock compositions at the Mars Exploration Rover landing sites have geochemical correspondences in spite of their far-separated locations (nearly diametrically opposite sides of the planet). Yet, as we shall show here, there are diagnostic discriminators and significant differences in their history of aqueous alteration.

Soils at Meridiani are typically quite similar to soils measured at other sites, including Gusev, but are often somewhat enriched in Fe, presumably from fragments of hematite-rich spherules that form an abundant lag. However, they record little if any of the signature of obviously-weathered sulphate-rich outcrop that pervades the Opportunity site.

The Meridiani outcrop materials themselves evidence a rich mineralogy. Certain samples derived from the whitish materials at Tyrone area in Gusev have almost identical levels of Si, S, Fe, Mg, Al, Na and P.

Geochemical Discriminators
Minor elements Cl, K, Ti, Mn and Zn are lower at Gusev, while Cr, Ca, and Ni are higher. Inferred mineralogies and explanation of the sources of the Meridiani outcrop are quite different from the Gusev Tyrone-derived samples.

Tyrone samples can be explained as salt-silica-soil mixtures, whereas outcrop geochemistry can be explained as derivation from “source basalt(s)” and a very acidic brine. Although the hypothetical source basalt is not in evidence at Meridiani or in the martian meteorite collection, a very good match for all elements (with the sole exception of trace element Ni) is provided by rock class Irvine discovered at the Gusev site. Whereas Paso Robles class ferric sulphate-rich salts from the Tyrone area must have formed by a strong enrichment process, such as extensive aqueous processing, the Meridiani outcrop material also is very high in sulphate, but with a significantly different outcome.

Geochemical Variability
The range of chemical variability in the Columbia Hills at Gusev crater is startling, with virtually every element present in at least one or more rocks at anomalously high or low concentrations. Some of these extremes can be traced to igneous differentiation processes, but others clearly must be due to aqueous alteration in sedimentary or metasomatic processes. In contrast, except for some meteoritic materials, Meridiani outcrop lies within a well-defined geochemical range – variations in Mg, S and other elements can be readily explained as salt migration in an evaporitic sandstone formation.

Re-establishing recycled sediment in mantle plumes – Evidence from Gough Island

C. CLASS¹, A.P. LE ROEX², D.J. LONG² AND S.L. GOLDSTEIN³
¹Lamont-Doherty Earth Observatory, POB 1000 RT 9W, Palisades, NY 10964, USA (class@ldeo.columbia.edu)
²University of Cape Town, Private Bag, Rondebosch, 7701, South Africa

Sediment is an integral part of recycling slabs and has long been held responsible for enriched signatures found in many ocean island basalts associated with mantle plumes. However, to date the evidence for deep recycled sediment is generally weak and our knowledge on the modification of recycled sediment in the subduction factory is limited, which resulted in a recent surge of alternative models of mantle metasomatic enrichment processes and lower crustal recycling. An important characteristic of pelagic clays, calcareous oozes and chert is their negative Ce anomaly inherited from seawater, resulting frequently in negative Ce anomalies of present day subducting sediment. The presence of negative Ce anomalies in arc volcanic rocks is a strong indication for the preservation of Ce anomalies to the depth of arc magma formation. Thus, Ce anomalies present themselves as a useful tracer for deep sediment subduction.

A sediment contribution to the Gough mantle source has previously been suggested based on high La/Nb, Ba/Nb and 207Pb/204Pb ratios compared to other OIB, though the lack of raised oxygen isotope ratios limits bulk sediment to <1.5%. High precision trace element data (acquired by ICPMS) on mafic volcanic rocks from Gough Island reveal negative Ce anomalies, with Ce/Ce* values in Gough lavas extending down to values as low as ~0.92. Weathering processes, identified as the cause for Ce anomalies in some OIB, can be excluded here based on element-element systematics, indicating magmatic trends rather than weathering-induced element mobility. Shallow-level contamination by local sediments can be excluded on Ce/Pb systematics. We suggest that Ce anomalies in Gough lavas demonstrate the presence of recycled, subduction-modified sediment in the mantle source of the Gough Island magmas. With the exception of fluid mobile elements, the trace element systematics of Gough lavas can be reproduced by adding up to ~10% subducting sediment with negative Ce anomaly (using estimates of present-day subducting sediment columns as a proxy to ancient oceanic sediment) to the mantle source of Gough magmas. These calculations suggest loss of fluid-mobile elements in the subduction zone. Low degree melting of the sediment at some stage can explain the lack of a sediment oxygen isotope signature. We explore scenarios of sediment modification in the subduction factory in order to match the enriched trace element systematics in the Gough mantle source.
Genesis of K-enriched felsic magmas:
A collection of contrasting crustal connexions

JOHN D. CLEMENS
School of Earth Sciences & Geography, CEESR, Kingston University, Penryn Rd, Kingston-upon-Thames, Surrey KT1 2EE, UK (j.clemens@kingston.ac.uk)

High-K calcalkaline granitic (s.l.) magmas are formed in late orogenic, post-orogenic and anorogenic settings. Proposed origins include; assimilation of crustal rocks by basaltic magmas, partial melting of the enriched mantle with fractionation, reactive assimilation of wall rocks by normal-K magmas, magma mixing, and melting of composite sources with interlayered pelites and amphibolites. Metabasaltic rocks are not suitable sources; nor are any experimentally studied metagreywackes, metatonalites or metadacites. High-K are andesites and certain metaluminous Bt-Pl-Qtz gneisses could be suitable protoliths, so neither the protoliths nor the conditions in high-K magma genesis need to be special or complicated. Nevertheless, sometimes the main protoliths are not crustal, and the processes involved are very complex.

K-rich adakites occur over wide areas and lack either temporal or spatial association with subduction. They have all the geochemical attributes of typical subduction-related adakites except that K₂O/Na₂O > 0.95, over a broad range of SiO₂ (≈ 58 to 74 wt%), so low-degree partial melting or fractionation are not viable origins. Isotopes indicate strong crustal involvement. Near-liquidus experiments were carried out on a typical K-adakite, at 2, 4 and 6 wt% H₂O, with the constraint that the assemblage should contain Grt but not Pl. This work showed that K-adakites were high-T (> 1075 °C), very hydrous magmas (~ 6 wt% H₂O) formed by fluid-absent partial melting of metatonalites, meta-andesites, and possibly potassic metabasalts at P > 2 GPa.

Felsic sanukitoids are Late Archean, post-tectonic, K-rich, high-Mg rocks that have geochemical characteristics similar to both mantle- and crust-derived magmas. High-T (1200 °C?) melting of Phl peridotite could explain their peculiar chemistry. Near-liquidus experiments on a monzodiorite from Panozero produced Phl near the liquidus, confirming residual mica in the protolith. However, neither Ol nor Grt is present. Thus, the source may have been phlogopite clinopyroxenite, rather than peridotite, formed in a global enrichment event.

In conclusion, K-enriched, metaluminous, felsic magmas have a wide variety of origins. The K sometimes originates directly from a crustal protolith but is commonly from the enriched mantle, subduction-zone fluids being the ultimate source. Given the difficulty of forming the more mafic granitoids by crustal melting, we should take a fresh look at the mantle for the origin of many granitic series, not through direct derivation but through fractionation of enriched mafic magmas.

Identification of aromatic organic matter from comet 81P/Wild 2

SIMON J. CLEMETT¹, KEIKO NAKUMA-MESSENGER², DAVID S. MCKAY³ AND SCOTT A. SANDFORD⁴

¹ERC, Inc. / NASA JSC, JE-23, Houston, TX 77058 (simon.j.clemett@jsc.nasa.gov)

⁴NASA Ames, MS 245-5, Moffett Field, CA 94305 (ssandford@mail.arc.nasa.gov)

Comets provide a unique perspective on the formation of the Solar System and provide a missing link to the progenitor dense molecular cloud from which it arose. Due both to their small size, and site of accretion in the outer reaches of the Solar System, comets have escaped large-scale differentiation and thermal alteration and so may retain much of their original presolar volatile inventory. The study of cometary material can therefore help to reconstruct the early history of our Solar System.

We have used the technique of ultrafast two-step laser mass spectrometry (µlatra-L²MS) to investigate the nature and distribution of aromatic organic matter from comet P/Halley and returned by the STARDUST sample return mission. [1] We have identified complex aromatic hydrocarbons in cometary particles entrained along several aerogel tracks. Although terrestrial contamination issues from the aerogel remain a concern, a substantial fraction of the observed organics appears indigenous. [2] The aromatic fraction of the total organic matter present appears to be lower than that typical of carbonaceous and ordinary chondrites, but shows a greater spectral complexity. Simple fused ring polycyclic aromatic hydrocarbons (PAHs) such as benzene (C₆H₆), naphthalene (C₁₀H₈), acenaphthalene (C₁₂H₁₀), phenanthrene (C₁₃H₁₀) and pyrene (C₁₆H₁₀) are present along with their homologous alkylation series, Ar-(CH₂)n-H, extending up to n ~ 6. In addition, prominent odd-mass peaks are interspersed within these familiar PAH series and are consistent with several interleaved alkylation series of N-containing PAHs (NPAs).

We have used the technique of ultrafast two-step laser mass spectrometry (µlatra-L²MS) to investigate the nature and distribution of aromatic organic matter from comet 81P/Wild 2 dust particles collected in aerogel and returned by the STARDUST sample return mission. [2] The aromatic fraction of the total organic matter present appears to be lower than that typical of carbonaceous and ordinary chondrites, but shows a greater spectral complexity. Simple fused ring polycyclic aromatic hydrocarbons (PAHs) such as benzene (C₆H₆), naphthalene (C₁₀H₈), acenaphthalene (C₁₂H₁₀), phenanthrene (C₁₃H₁₀) and pyrene (C₁₆H₁₀) are present along with their homologous alkylation series, Ar-(CH₂)n-H, extending up to n ~ 6. In addition, prominent odd-mass peaks are interspersed within these familiar PAH series and are consistent with several interleaved alkylation series of N-containing PAHs (NPAs).

The N is unlikely to be present in the form of N-heterocycles given the experimental conditions of the µlatra-L²MS analysis, rather the most probable form of the N functionality is as nitrile (Ar-CN). This may be related to the 2.3 & 4.6 μm absorption features observed in the spectra of many young stellar objects and some comets, and which has been attributed to a solid material known as “XCN” believed to be synthesized by ultraviolet and/or ion bombardment of presolar icy grains in circumstellar environments. [3] Comparison of the STARDUST spectra with a range of other astromaterials analyzed by µlatra-L²MS under comparable experimental conditions show a striking similarity with several cluster IDPs.

U-Pb dating of stable isotope records in Alpine speleothems from the late Pliocene/early Pleistocene

R.A. CLIFF1, M.C. MEYER2 AND CH. SPÖTL2

1School of Earth & Environment, University of Leeds, Leeds, LS2 9JT, UK (bob@earth.leeds.ac.uk)
2Institut für Geologie und Paläontologie, Leopold-Franzens-Universität Innsbruck, Innrain 52, 6020 Innsbruck, Austria (michael.meyer@uibk.ac.at)

Speleothems from the Wilder Mann and Wildmahd caves in the Allgäu Alps, western Austria have well-preserved, probably annual, microscopic laminae and high resolution stable isotope records suggesting no post-depositional alteration. These samples encapsulated a detailed history of environmental variations at the time of speleothem growth. These speleothems are characterised by high uranium concentrations, typically around 10 ppm, and coupled with some initial lead concentrations as low as 2 ppb this leads to highly radiogenic lead compositions at the present day.

Two flowstones and two stalagmites have been dated using the U-Pb isotopic system. All four samples yielded sufficient spread in isotopic composition to define chords on the Tera-Wasserburg diagram from which concordia ages were calculated using an iterative procedure to account for the effects of isotopic disequilibrium. Ages are in the order of 2 Ma and for samples of this age ‘normal’ levels of initial $^{234}$U excess are no longer detectable. The Wildmahd sample All 1 is the youngest at 1.73 Ma with a probable uncertainty of 0.03 Ma allowing for unknown initial $^{238}$U excess within a range of ± 40‰. The Wilder Mann samples range from 2.30±0.07 to 1.99±0.05 Ma on the same basis. One of the stalagmite samples shows significant variation along its length from 2.11±0.04 to 2.03±0.03; further analyses on the oldest parts are in progress.

The results demonstrate that these speleothems date from the late Pliocene/early Pleistocene interval and thus provide (a) a minimum age for these high-altitude caves (2450m asl), and (b) a continental record of environmental change at an early stage in the late Cenozoic glaciations.

Tectonic subduction erosion, arc magmatism and the maintenance of the continental crust

PETER D. CLIFT1,2

1School of Geosciences, University of Aberdeen, Aberdeen, AB24 3UE, United Kingdom (pclift@abdn.ac.uk)
2Geowissenschaften, Universität Bremen, 28359 Bremen, Germany

Estimates of modern continental crustal recycling in subduction zones can be made from plate convergence velocities, the thicknesses of trench sediments, volumes and ages of accretionary complexes together with rates of trench retreat. Plate convergence rates appear to be the primary control on crustal subduction, with convergence >7.5 cm/yr associated with tectonic erosion. Collision of aseismic ridges with trenches drives around two thirds of forearc tectonic erosion over periods >10 m.y.. Globally material subduction at least as deep as the magmatic roots of arc systems is around 3.0 Armstrong Units (1 AU = 1 km$^3$/yr), of which 1.65 AU comprises subducted sediments, with 1.33 AU of eroded forearc crust. Recycling rates along a single margin may show strong temporal variation over 1 m.y. periods. Isotopic variations in Costa Rican tephra suggest that sediment accretion is the most common mode of tectonism, but this is separated by short periods of dramatic erosion that cause net crustal loss. Even where erosion is continuous this can operate in a fast steady-state mode or a slower temporary style. On the Central Andean margin tectonic erosion since 20 Ma has caused trench retreat, but slow subsidence under the coastal zone implies steepening of the forearc taper rather than large scale retreat. The Neogene mass loss rate of 13 km$^3$/m.y./km is 5-10 times lower than the long-term average. Since 2 Ma this rate has slowed further due to underplating under the coastal zone. A climatic role in driving continental erosion and moving the margin into a more accretionary state has been suggested but is hard to demonstrate. Average global mass loss requires that Cenozoic arc productivity lies close to 75 km$^3$/m.y./km if the volume of the continental crust is to be maintained. Efficient accretion of oceanic arc crust is essential in maintaining the total crustal volume. In the classic Taiwan-Luzon example local crustal mass balancing implies that ~90% of the igneous arc crust is accreted.
Pb elemental concentrations and isotopic compositions in environmental survey: Is lichen transplantation efficient?

C. CLOQUET, D. DE MUYNCK AND F. VANHAECKE
Ghent University, Department of Analytical Chemistry
Proeftuinstraat 86, 9000 GHENT, Belgium
(Christophe.Cloquet@UGent.be)

Lichens are known to be sensitive to various pollutants and are considered a good biological indicator of the air quality. Lichens are epiphytic, which means that their influx is exclusively atmospheric (precipitation, fog, mist, particles, gas...), so they integrate the atmospheric fallout signal and generally contain much higher concentrations of trace metals than, e.g., rain. Another advantage of lichens is their ubiquity and the ease of sampling. However, lichens are not found everywhere. To compensate for the absence of lichens in certain areas, transplantation techniques have been developed and are now commonly used. These techniques consist in an importation of lichens from one area to another one, in which they are originally absent.

In this work, lichens (Hypogymnia physodes) have been transplanted from one reference site to 5 different sites including the reference site itself and 2 peri-urban sites. The other 2 sites have been chosen for their proximity to a highway and the proximity to an industrial site. The impact of two different system set-ups (one covered and one non-covered) has been tested. The main difference between the two set-ups is protection from the rain for the covered set-up. Samples have been collected 14, 34 and 68 days after transplantation. Pb concentrations and Pb isotopic compositions already accumulated in thallus have been measured by ICP – mass spectrometry.

A systematic difference between the two set-ups (covered and non-covered) is found for Pb concentrations. Lichens coming from the non-covered set-ups provide higher Pb concentrations. Lead concentrations in covered set-ups have been found lower than or equal to the original concentration, whereas the Pb concentration in lichens from the non-covered set-ups is higher for all the sites after 68 days. Pb isotopic compositions also show a systematic difference between the two set-ups, with the Pb isotopic composition of lichens from the non-covered set-up being more radiogenic. Pb isotopic compositions of lichens coming from the covered set-ups remain in the same range, whereas substantial changes in the Pb isotopic composition are recorded for lichens coming from the non-covered set-up, even after only 34 days of transplantation in some cases. Nevertheless, interpretation of the Pb isotopic composition variation is not straightforward.

Nano-spinel synthesis using Fe(III)-reducing bacteria

VICTORIA COKER¹, CAROLYN PEARCE¹, RICHARD PATTRICK¹, GERRIT VAN DER LAAN¹,², NEIL TELLING², JOHN CHARNOCK¹, ELKE ARENHOLZ³ AND JON LLOYD¹

¹-⁴,⁶,⁸SEAES, University of Manchester, UK

³LBL, Advanced Light Source, USA (earenholz@lbl.gov)

Geobacter sulfurreducens is a bacterium capable of reducing amorphous iron(III) oxide through electron transfer coupled to organic matter oxidation, converting the iron to nano-sized magnetic particles of magnetite (Fe₃O₄), with a size of approx. 20 nm [1] (Fig. 1).

Nano-spinels of the general chemical formula MₓFe₃₋ₓO₄, where M is a transition metal cation other than Fe, such as Co, Ni or Mn, have been produced using the capability of G. sulfurreducens to form nanomagnets[2]. These materials have different electrical, magnetic, and structural properties, from coarse grained materials making them ideal for use in technical devices. Characterization of these nanoparticles has been carried out using the synchrotron radiation spectroscopies XMCD (x-ray magnetic circular dichroism) and EXAFS in addition to SQUID magnetometry and TEM.

Figure 1. SuperSTEM images of (A) Co-biospinel, (B) Ni-biospinel.

The extraordinary capability of bacteria to produce nanomagnets has not yet been exploited by industry and such processes have enormous commercial potential. In addition, the ability of the bacteria to precipitate magnetite from Fe(III) oxides could be used as a bioremediation strategy to clean up environments contaminated by Fe(III)-oxides, such as acid mine drainage (AMD) sites, inexpensively and effectively.

³Chemical Engineering Department, Universitat Politècnica de Catalunya, Barcelona, Spain.

The use of cement in engineered barrier systems of radioactive waste repositories emphasize the proper understanding of uranium interaction with hardened cement paste. This study presents experimental and modelling results on uptake of U(VI) in batch experiments by hydrated and degraded cement in contact with MilliQ and aged cement pore water respectively.

Kinetic experiments show that equilibrium between cement and U(VI) is reached in less than two days. Equilibrium uranium concentration denotes a high uranium uptake by cement phases (up to 99% in some cases). Rd values for hydrated cement (with S/L ranging between 0.05 and 10 g/L) vary between 7 and 65 m³/kg (for initial uranium concentrations of 1·10⁻⁶M) and between 5 and 30 m³/kg (for initial uranium concentrations 1·10⁻⁸M). Regarding degraded cement, Rd values (with S/L ranging between 0.1 and 20 g/L) are in the range 10-25 m³/kg for [U]₀= 1·10⁻⁶M. At [U]₀=1·10⁻⁸M, the aqueous concentration of U(VI) at the equilibrium falls below the detection limit of the used analytical technique.

A surface complexation model has been used to explain the experimental results on uranium interaction with hardened cement paste. This model takes into account both, aqueous U(VI) speciation and speciation of silanol sites in the typical C-S-H phases of cement. The possible precipitation of solid uranium phases has been also assessed in this work.

Hydrogen solubility in synthetic rutile

C.V. COLASANTI¹, E.A. JOHNSON¹,² AND C.E. MANNING³

¹Department of Earth and Space Sciences, University of California, Los Angeles, 595 Charles Young Drive East, Los Angeles, CA 90095, United States (colasant@ess.ucla.edu)
²Department of Geology and Environmental Sciences, James Madison University, MSC 6903, Harrisonburg, VA 22807, United States (johns2ea@jmu.edu)
³Department of Earth and Space Sciences, University of California, Los Angeles, 595 Charles Young Drive East, Los Angeles, CA 90095, United States (colasant@ess.ucla.edu)

Hydroxyl solubility in rutile was determined as a function of pressure, temperature, and fO₂ (buffered with nickel-nickel oxide NNO, or magnetite-hematite, MH). Pure, synthetic rutile and H₂O were sealed in a Pt or Pd/Ag inner capsule and placed within a Au outer capsule containing an fO₂-buffering assemblage. Experiments employed a piston-cylinder apparatus and NaCl-graphite furnaces. OH concentrations were determined using FTIR spectroscopy and the calibration of Maldener et al. 2001. The [OH] in rutile increases from 108 to 956 ppm H₂O at 1 GPa over the range 500-900ºC at the NNO buffer; a fit to the data produces the relationship [OH] (ppm H₂O wt.) = 4.73 e0.006T, R²= 0.96. The higher fO₂ of the MH-buffered experiments produced a similar T dependence, but lower overall [OH]; at 1 GPa, [OH] increases from 84 to 267 ppm H₂O from 600-900ºC ([OH] (ppm H₂O wt.) = 7.28e0.0039T, R²= 0.97). The effect of pressure on the [OH] in rutile is less pronounced than the temperature effect. At the MH buffer and 800ºC, [OH] (ppm H₂O wt.) = 79±13 x P(GPa) + 88±15 from 0.5-2 GPa. For the experiments conducted at NNO and 800ºC, [OH] (ppm H₂O wt.) = 169±31 x P(GPa) + 409±33 from 0.5 to 2 GPa. Over the 25 seconds it takes to quench the experiments, loss of OH from rutile along the c crystallographic axis is significant — a 33% decrease in [OH] over a distance of 0.35 mm for an unbuffered experiment at 1000ºC and 1 GPa was observed. Measurements of OH concentration should be obtained in the center of rutile grains at least 0.5 mm in diameter along the c-axis to obtain equilibrium values.

Melt inclusion records of degassing from persistently active volcanoes: Etna, 2006

S.J. Collins1, D.M. Pyle2, J MacLennan1 and T.A. Mather2

1Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK. (sjc233@cam.ac.uk)
2Department of Earth Sciences, University of Oxford, Oxford OX1 3PR, UK

Introduction

Mt Etna, Sicily, is Europe’s laboratory volcano. Etna is persistently active, and responsible for 5-10% of global annual volcanic emissions of CO2, SO2 and volatile trace metals (Pyle & Mather, 2003). Activity on Etna has changed dramatically over the past 5 years. In 2001 – 2003, the eruptions were vigorous and volatile-rich, in contrast, eruptions in 2004 and July 2006 started with the slow effusion of gas-poor magma. We collected a suite of olivine hosted melt inclusions and matrix glasses in newly erupted products from Mt Etna, Sicily, spanning the major eruptions of the previous 5 years. These glasses have been measured for the concentrations of volatile (H, C, Cl, F) and selected trace elements (Li, Zr) by ion microprobe at the University of Edinburgh and for major and trace elements with a particular focus on the volatile trace metals by electron microprobe and laser ablation ICP-MS at the University of Cambridge.

Discussion

Preliminary results will provide data to constrain the nature of the relationship between the earlier (2001-2003) volatile-rich magmas and the later (2004, 2006) volatile-poor magmas. As expected, many of the 2006 melt inclusions show evidence for shallow storages and degassing: dissolved water contents are low; dissolved Li contents are variable, and don’t correlate with involatile incompatible tracers; and melt inclusions extend to more evolved compositions than those erupted rapidly during the 2001-2003 eruptions. When combined with new data on dissolved C contents of melt inclusions, we will be able to determine the coupled effects of fractional crystallization, gas loss and gas accumulation on the compositions of Mt Etna magmas.

Conclusion

This thorough investigation into the degassing processes of Mt Etna will not only provide new information into the importance of volatiles for determining the eruptive character and processes of Mt Etna volcano but will also have implications for the environmental and economic effects of the behaviour of metals in such systems.

**Introduction**

The use of platinum group elements (PGEs) in vehicle exhaust catalyst (VECs) represents a source of highly dispersed environmental contamination and these metals have been identified in a variety of airborne samples, dusts, soils and waters. The VEC-emitted PGEs can interact with several ligands in the environment and be transformed into soluble species that can enter the food chain with potential environmental and health risks. In order to evaluate the potential pathways of PGEs from VECs into humans, physiologically based tests were used to study the uptake of PGEs by the human respiratory and digestive tracts.

**Method**

The tests were used to provide quantitative data on the bioavailability of PGEs from road dust, powdered exhaust catalyst and metal hydroxide samples. The digestive assay was implemented in two phases, simulating the passage of ingested dust from the acidic environment of the stomach to the near neutral conditions of the small intestine. The respiratory tests employed various simulated lung fluids. All the extracted samples were analyzed for PGE content by inductively coupled plasma mass spectrometry.

**Discussion and conclusions**

The results show that PGEs in road dust samples provide the greatest fractions of bioavailable PGEs (up to 87%), probably due to transformation into soluble and mobile species through complexation by ligands common in the roadside environment. The highest PGE releases were observed in lung solutions analogous to the fluid with which inhaled particles would come into contact after phagocytosis by cells.

A high % of PGEs from VEC-emissions (i.e. road dust) is dissolved in the respiratory and digestive tracts. From the toxicological perspective, it is important to consider the possible formation of PGE-chloride complexes due to the presence of Cl ions in the stomach and lung environments, perhaps with increased health risks because of their known toxic and allergenic effects on animals and human beings.

**Geodynamical transition in the mantle at the end of the Hadean**

**N. COLTICE¹ AND B. MARTY²**

¹Laboratoire de Sciences de la Terre, Université de Lyon ; Université Lyon 1, Bât Géode, 43 Bd du 11 novembre 1918, 69100 Villeurbanne, France (coltice@univ-lyon1.fr)
²CRPG, BP 20, 54501 Vandoeuvre-Les-Nancy Cedex, France (bmarty@crpg.cnrs-nancy.fr)

The rock record begins around 3.9–Ga ago. Before, very little observations exist for what is called the Hadean eon. Our knowledge of mantle dynamics in the early Earth comes from small zircons found at Jack Hills (Australia) and Acasta (Canada) which can be as old as 4.2-4.4Ga, and from the composition of mantle derived rocks in isotopes coming from extinct radioactivities. It has been suggested, from geochemical studies on the Hadean zircons, that the Earth is already close to modern by 4.4Ga, having large continents (Harrison et al., 2005), liquid oceans (Valley et al., 2002) and potentially plate tectonics (Harrison et al., 2005). The present work confronts this hypothesis to modeling of Xe isotopes produced by extinct radioactivities. We show that the transition from the Hadean to the Archean corresponds to a change in the thermal and mechanical regime of the Earth’s mantle: the transition from magmatic to modern solid state mantle convection.
Nature of metasomatizing agents in suprasubduction and intraplate settings as deduced by glass and amphibole geochemistry

M. COLTORTI1, S. ARAI2, C. BONADIMAN1, B. FACCINI1 AND S. ISHIMARU2

1Department of Earth Sciences, Ferrara University, Via Saragat 1, 44100 Ferrara (clt@unife.it)
2Department of Earth Sciences, Kanazawa University, Kanazawa 920-1192, Japan (ultrasa@kenroku.kanazawa-u.ac.jp)

Glasses and amphiboles in spinel peridotite mantle xenoliths hosted in calc-alkaline s.l. magmas from the subduction-related Western margin of Pacific Plate (Kamchatka, Japan, Philippine) are compared with glasses and amphiboles in spinel peridotite entrained in alkaline basalts from several intra-plate localities (Cape Verde, Antarctica, Gran Comore, Lessini). At comparable SiO2, subduction-related glasses, especially those from Kamchatka, are characterized by lower alkalies contents than glasses from intra-plate settings. As a consequence the former tend to be more SiO2-saturated, as also evidenced by the widespread presence of secondary orthopyroxene in xenoliths from suprasubduction setting. Subduction-related glasses have Na2O content similar to carbonatite-metasomatised intra-plate glasses, but the latter presents consistently higher CaO and Nb abundances. Subduction-related glasses have also lower Rb, Ba, Zr, Ti and HREE contents than alkali-silicate intra-plate glasses, bearing analogies with slab-derived melt. Irrespective of textural positions, amphiboles in mantle xenoliths from intra-plate settings present much higher Nb and, to a lesser extent, Zr and Ti contents than amphiboles found in xenoliths from suprasubduction setting. Similar indications, although less robust for crystallographic and statistical reasons, can be found for clinopyroxene and orthopyroxene. These data strongly suggest that metasomatizing agents in the mantle wedge above a subduction zone are richer in SiO2 and depleted in Nb, Zr and Ti with respect to fluids migrating in intra-plate setting. The presence of accessory phases such as rutile and zircon in the downgoing slab, retaining HFSE during dehydration and/or melting and producing HFSE-depleted fluids seems to account for the observed geochemical features. The commonly observed occurrence of “plume-related” alkaline magmatism in the back-arc setting which follows in a time span of few to ten millions of years a subduction process will be also addressed in the light of the above reported data.

New SHRIMP ages from the Permo-Triassic boundary at Meishan

WILLIAM COMPSTON1 AND L.P.BLACK2

1Research School of Earth Sciences, the Australian National University, Canberra, ACT, 0200 (William.Compston@anu.edu.au)
2Lance P. Black, Geoscience Australia, GPO Box 378, Canberra ACT 2601 (Lance.Black@ga.gov.au)

Determination of the age of the Permo-Triassic boundary has been a test case for zircon geochronology in the presence of pervasive Pb loss and inheritance. SHRIMP ages are presented for zircons for five volcanic ashes from the global stratotype at Meishan, China, and compared with previous zircon ages for these beds. Subtle inheritance and Pb loss have been detected and screened in most Meishan zircons. No significant age differences are detected here between Bed 17 through Bed 36, so the Permo-Triassic boundary at Meishan is estimated as their mean age at 251.6 ± 0.2 Ma. This agrees with Bowring et al. (1998) but it is ca. 0.5% younger than Mundil et al. (2004). Rather than hidden Pb loss, the difference may be due to interlaboratory bias, which remains to be assessed by comparison of standards analyses.

Studying the subcontinental lithospheric mantle evolution and heterogeneity can be very complex for many reasons: in addition to the complex history of its own origin, after being formed, the subcontinental lithospheric mantle can be exposed to different processes related or not to the crust formation as: re-melting, delamination from the crust, re-fertilization with fluids from different origins as lithospheric, sub-asthenospheric, subduing slabs and so on. Spinel- and/or garnet-bearing ultrabasic mantle xenoliths brought to the earth’s surface by intraplate alkaline basalts provide direct information on the nature and processes involved in the modifications of the subcontinental mantle lithosphere as mantle metasomatism.

The western South American plate is a natural laboratory for petrological investigations of the subcontinental lithosphere due to the complex tectonic arrangement of the Andes. We performed noble gas analysis (He, Ne, Ar, Kr and Xe) in thirty samples of mantle xenoliths hosted by Eocene to recent alkaline basalts to determine the origin of the xenoliths and to constrain the processes that modified the mantle. Noble gases were extracted by crushing and stepwise heating method. Except for high ³He/⁴He ratios observed for few samples at low temperatures of stepwise heating indicating some cosmogenic ³He, the majority of the samples show ³He/⁴He ratio around of 7.22±0.93RA. The lower ³He/⁴He ratio than the MORB value (8±1RA) indicates higher (U+Th)/³He ratio than the MORB source mantle. ⁴⁰Ar/³⁶Ar ratios obtained with crushing method vary from 326 to 1476. The rough correlation ³He/³⁶Ar ratio of the lithospheric mantle beneath South Patagonia could argue for metasomatism by slab-derived component for some samples. However, the large variation of ²⁰Ne/²²Ne from 9.27 to 12.0 and the narrow variation of ²¹Ne/²²Ne from 0.0279 to 0.049, in addition to the good correlation between ²⁰Ne/²²Ne vs. ²³Ne/²²Ne could suggest some OIB like characteristic for the metasomatic fluid.

Geochemical characteristics of the LB-07A and LB-08A cores from the Bosumtwi Impact Structure, Ghana

L. CONEY¹, L. FERRIERE², W.U. REIMOLD³, C. KOEBERL² AND R.L. GIBSON¹

¹ICRG, Univ. Witwatersrand, Johannesburg, 2050, South Africa (ConeyL@science.pg.wits.ac.za, roger.gibson@wits.ac.za)
²Dept Geological Science, Univ. Vienna, Vienna, A-1090, Austria (ludovic.ferriere@univie.ac.at, christian.koeberl@univie.ac.at)
³Museum of Natural History, Humboldt-Univ. Berlin, D-10115, Germany (uwe.reimold@museum.hu-berlin.de)

Cores extracted from the central uplift (LB-08A) and deep crater moat (LB-07A) of the 1.07 Ma Bosumtwi impact structure, Ghana, consist of alternating suevite, polymict lithic breccia, and monomict breccia (in LB-07A only) that overlie fractured country rocks comprising metabreccia and metapelitic sediments.

In both cores, the impact breccias have compositions intermediate to the identified target rocks [1] and are well-homogenized with respect to the silicate component. Interestingly, the different lithologies in LB-07A show less variation than those from LB-08A; however, a number of major and trace elements show more variation in the metabreccia and metapelitic sediments for both cores. Impactite trace element concentrations are significantly different from other lithologies, and appear to be controlled by greywacke-phylite and shale proportions. Hydrothermal alteration, which has been noted petrographically, has affected both the CaO and MgO contents of the rocks [2 and 3, for more detail], which correlate with LOI. In general, the chemical signatures of fallout suevites from the northern crater rim and fallback suevites from the cores are similar, but different MgO, CaO, and Na₂O contents were noted. Additionally, the Ivory Coast tektites have narrower ranges of MgO and CaO content than the fallback suevites. This may be due to varying degrees of alteration, but it must be noted that the fallback and fallout suevites differ significantly in clast population [particularly with regards to calcite and granite content], as well as a higher proportion of melt fragments in the fallout suevites. Rare earth element concentrations of fallout suevites from the northern crater rim and fallback suevites from the cores are similar, but different MgO, CaO, and Na₂O contents were noted.

Siderophile element abundances in the suevites in the cores are not obviously higher than those seen in the country rocks and outer suevite occurrences; thus no evidence for a meteoritic component has been detected.

Refining step-leaching Pb-Pb dating methods for meteorites and their components

J.N. CONNELLY 1,2, M. BIZZARRO2, J.A. BAKER 3, K. THRANE4, D. ULFBECK2 and A. TRINQUIER2

1The Jackson School of Geosciences, The University of Texas at Austin, Austin, Texas, USA. 78712 (connelly@mail.utexas.edu)

3Victoria University of Wellington, Wellington, New Zealand

Whereas Pb-Pb dating potentially offers the most precise ages for old meteorites and their components, this method has been commonly compromised by terrestrial contamination, uncertainty in the initial Pb isotopic composition and analytical uncertainties related to poorly-constrained instrumental mass fractionation using a thermal ionization mass spectrometer (TIMS). With the latter issue addressed by the use of a 202Pb/205Pb double spike, we have experimented with step-leaching procedures of differentiated meteorites and chondrules in an attempt to first effectively remove terrestrial contamination and then to generate Pb fractions of sufficient size and spread in Pb-Pb space to adequately define meaningful isochrons. Samples are abraded, rinsed in an ultrasonicator, lightly crushed in the clean laboratory and then repeatedly pre-cleaned using distilled ethanol, water and acetone. Subsequent steps of weak HCl and HBr acids combined with ultrasonic agitation and modest heating effectively removes terrestrial contamination in most samples we analyzed. Subsequent exposure to warm 4M HNO3 typically isolates the least-radiogenic component of the leaching series. Leaching with HCl of increasing molarity with longer and higher temperature heating steps returns more radiogenic Pb fractions. The most radiogenic Pb fraction typically corresponds to the first warm 1M HF step with subsequent steps in stronger HF yielding progressively less radiogenic signatures. Importantly, the Pb extracted in the dissolution of the final residues with 28M HF + 14M HNO3 typically plots slightly below the isochron defined by previous leach steps, corresponding to a slightly younger $^{206}\text{Pb}/^{238}\text{U}$ model age than the inferred actual age. The wide range of total Pb contents (20 - >2000 pg) in leach fractions returned by this method requires analyses by TIMS using a high-efficiency Pb emitter and diligent monitoring of laboratory Pb blank, including running parallel Pb blank analyses for every leach fraction. ICP-MS analyses of major elements in aliquots of each leachate indicates that different combinations of minerals are breaking down throughout the sequence. As expected, U and Pb are highly and variably fractionated during the leaching step such that no U/Pb age information is recovered. Using this procedure we have revisited the ages of chondrules from CB chondrite Gujba and CV chondrite Allende and several differentiated meteorites including SAH-99555.

A view of the upper-crustal component of oceanic hydrothermal systems at fast-spreading ridges

LAURENCE A. COOGAN

School of Earth and Ocean Sciences, University of Victoria, BC, Canada (lacoogan@uvic.ca)

Hydrothermal circulation through the upper oceanic crust at mid-ocean ridge axes leads to major chemical fluxes largely between the sheeted dike complex and seawater. Metamorphic mineral assemblages, fluid inclusions and geothermometry in the sheeted dike complex requires temperatures of fluid-rock reaction of ~250°C to ≥500°C throughout the sheeted dike complex. However, models of recharge to the hydrothermal system suggest large fluxes of cold water into the crust, most likely in the near axis region. If correct, this recharge flux should cool the sheeted dike complex rapidly raising the question of when the hydrothermal metamorphism of the sheeted dike complex occurs.

To better understand the thermal evolution in the sheeted dike complex Coogan et al. (2005) developed a geospeedometer applicable to this region. The partitioning of lithium between plagioclase and clinopyroxene is strongly temperature dependent and lithium diffusion in both phases is very rapid. During subsolidus cooling of a dike lithium diffuses out of plagioclase into adjacent clinopyroxene and the closure temperature for this exchange is dependent on the cooling rate of the dike. Thus, the measured distribution of lithium between these phases can be used to determine the cooling rate (Coogan et al., 2005).

Applying this approach to ODP Hole 504B reveals very rapid cooling rates in at least the upper half of the sheeted dike complex. This is consistent with the sheeted dike complex being cooled efficiently by down-welling fluid. This suggests that the hydrothermal metamorphism of the sheeted dike complex may occur either: (i) during the cooling of an individual dike; (ii) during thermal rebound after hydrothermal recharge ceases in the off-axis; or (iii) during upflow of hydrothermal fluids. The first model appears to be inconsistent with the consistency of vent fluid compositions and experimentally determined reaction rates. The second model appears to be inconsistent with: (a) the inhomogeneity of alteration, (b) the requirement for fluid flow during alteration based on isotope tracers, and (c) thermal modelling of this process.

Current data seem to require that the hydrothermal metamorphism of the sheeted dike complex occurs largely during hydrothermal upflow. As fluids heated by an underlying magma chamber migrate upwards they reheat the surrounding rocks and react with them producing the typical greenschist facies assemblage observed within the crust. Temporal changes in the location of upflow can lead to the prograde metamorphism of the entire sheeted dike complex.

A tale of two peaks: Effects of continental insulation and the partitioning of heat producing elements on the Earth’s heat loss

C.M. COOPER1, A. LENARDIC 2 AND L. MORESI3

1Carnegie Institute of Washington, Department of Terrestrial Magnetism, 5421 Broad Branch Road N.W., Washington, D.C. 20015

3School of Mathematical Sciences, Building 28, Monash University, Victoria 3800, Australia

Continental lithosphere plays two roles in the Earth’s heat loss: (1) it locally insulates the mantle beneath it and (2) it sequesters radioactive elements from the convecting mantle. These two roles have potentially opposing contributions to Earth’s heat loss, as the former effect increases the average mantle temperature whereas the latter decreases the internal mantle temperature. Understanding this duality becomes important since the internal mantle temperature influences mantle rheology, melt production, convective vigor and other geological processes that impact the dynamics and chemistry of the Earth’s interior. To determine the net consequence of the competing influences on the Earth’s heat loss, we conducted simulations that couple the convection of a mixed internally- and bottom-heated mantle to the conduction through a radioactively enriched continental crust. While holding the total heat production within the system constant, we varied the enrichment and the surface area of the continental crust. In addition, we also varied the bottom-heated Rayleigh number. We found that increasing continental surface area enhances global heat loss for a range of heat production distributions and Rayleigh numbers explored. The effect of the enriched continents and varied heat production distributions was evident in value of the Rayleigh number that maximizes global heat loss. For mid-range ratios of continental to mantle heat production, the dependence of global heat loss on continental surface area showed two peaks. This double peak effect could reflect trade off between mantle heat production depletion and the increased continental insulation. Finally, the insulating effect of continents was shown to alter the temperature signature associated with bottom- vs. internally-heated convection. In addition, that the presence of continental lithosphere could increase average mantle temperature despite the mantle being depleted suggests that continents can significantly influence mantle potential temperature.

Alpha thermochronology of calcite

PETER COPELAND1, E. BRUCE WATSON2, MARY CANINO1, KATRINA COX1 AND TROY RASBURY3

1Dept. of Geosciences, University of Houston, Houston, Texas, USA, 77204, USA (copeland@uh.edu)
2Dept. of Earth and Environmental Sci. Rensselaer Polytechnic Institute, Troy, New York, 12180, USA (watsoe@rpi.edu)
3Dept. of Geosciences, SUNY Stony Brook, Stony Brook, New York, 11794, USA (Troy.Rasbury@sunysb.edu)

High-U minerals such as zircon, apatite and others have proven to be valuable tools in assessing the thermal history of rocks as they pass through the upper crust. However, there are many locations in which high-U minerals are absent; we are investigating the prospect of using the low-U mineral calcite as an alpha thermochronometer.

Step-heating experiments on 17 calcites from 11 different samples and 6 dolomites from 5 samples suggest a closure temperature ($T_c$) of He in carbonates ~70±10 °C for a cooling rate of 10°C/m.y. The bulk $T_c$ in some samples may tend to be slightly higher due to the presence of diffusion domains larger than the sites in which the majority of He resides. The diffusivity of He in calcite is independent of the genesis of the mineral (igneous, metamorphic or sedimentary) or the source of the He (radiogenic, common, or laboratory induced). Compilation of available diffusion data for He in calcite, dolomite and apatite shows a strong similarity with average values of $E = 32.5±3.8$ kcal/mole and log $D_0/a^2$ = 5.3±2.3 log (sec$^{-1}$) for carbonates and of $E = 32.3±3.6$ kcal/mole and log $D_0/a^2$ = 5.4±1.6 log (sec$^{-1}$) for apatite.

Although calcite is a low-U mineral, this shortcoming can be overcome by analyzing large samples. A sample 3.8 mm in diameter with concentrations of U, Th, and Sm of 0.1, 0.01, and 1 ppm, respectively will produce enough $^4$He to allow for an analysis that is 1% blank in ~1 m.y. However, this assumes no common He; our experience shows that this is usually not correct and therefore the problem is not having enough He to overwhelm the common He. Using the criteria of geologic reasonableness, we find very few samples with [U]<100 ppm to be suitable and most samples with [U]>250 ppm to give good results.

Calcite columns have shown to be potentially valuable thermochronometers; preliminary data for the shells of *Inoceramus sp.* suggests a $T_c$ similar to other calcite.

Analysis of secondary calcite from subsurface samples of the Ordovician Ellenberger Group suggest that this unit experienced karstification in the Permian in west Texas but that diagenesis in the Llano uplift area is Tertiary in age.

Early work has concentrated on coarse-grained calcite but it is clear that the diffusion domain size is less than the grain size in all material analyzed so far. We are investigating fine-grained travertine deposits in the Miocene Barstow Fm of southern California, which have [U]>100 ppm in order to determine how fine-grained calcite can be and still give geochronologically reasonable results.
Use of multiple tracers for studying the inter-relationships between climate and recharge conditions of groundwater in a region of France: The past half-millennium

5Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, 8092 Zurich, Switzerland

Temporal variations in the noble gas temperature (NGT), the excess air component (ΔNe) and the deuterium excess (δ) in groundwater from the Fontainebleau Sands Aquifer (France) reveal changes in European climate during the past half millennium. The reconstructions of the NGTs back to 1500 suggest cooler recharge conditions throughout the 16th-19th centuries than present. Moreover, the NGTs recorded periods of weak warming in the 17th-18th and cooling in the 19th that are in conformity with other temperature records for France and Europe. High ΔNe values seem to record periods of high intermittency of recharge events. Slightly lower amounts of ΔNe are observed in groundwater recharged in the 19th despite a slighty higher precipitation rate. In the 17th-18th centuries, with slightly lower precipitation rates, more intermittent rainfall events probably induced larger variability of the water table and consequently larger amounts of air were trapped during recharge. The ΔNe in groundwater from this aquifer seems to be more linked to the oscillations of the water table produced by the temporal variability of the rain events than to the total amount of precipitation.

δ varies in parallel with NGT, and indicate a maximum in the period between 1700-1750. Inter-annual variations in the seasonality of precipitation and its intensity, combined with changes of the soil coverage in the recharge area, seems to be responsible for the variation observed in the δ in groundwater.

Our reconstructed parameters (NGT, ΔNe and δ) show noticeable relationships with available climate records. Such comprehensive studies of the link between climate and recharge conditions enhance our understanding of the effects of climate change and climate variability on groundwater resources sustainability.

Timescales of melt extraction from a heterogeneous mantle beneath the Central Indian Ridge at 19.2°S

Carole Cordier1, Mathieu Benoit1, Christophe Hémond2, Jérôme Dymant2, Bernard Le Gall1 and Anne Briais3

We propose to document the timescale of the magmatic processes occurring beneath the slow-spreading Central Indian Ridge (CIR, 19.2°S) through the study of the chemical variations recorded by the lavas erupted on-axis. The samples were collected along a 40 km-long profile made transverse to the ridge and running from the axial trough up to the Branshi-Matuyama isochrone (~800 Ky, GIMNAUT cruise). The lavas are greatly homogeneous in term of Mg# (67 ± 2) but range from N-MORBs to E-MORBs in terms of trace element concentrations (0.6<La/SmN< 3.4). Their Sr-Nd isotope ratios start from the center of the isotopic field of the CIR lavas and overlap its enriched end. Trace element ratios plotted along the profile describe saw-tooth patterns characterized by enriched spikes regularly and symmetrically distributed on both sides of the ridge axis. Consequently, the lava compositions are an indicator of magmatic processes that have fluctuated periodically through time. Based on the position of the enriched lavas along the profile, the timescale of such magmatic processes has been estimated to 230 Ky. Fractional crystallization can be ruled out to explain the observed chemical variations. Thus, they reflect the variations through time of the primary melt composition, partly governed by mantle source heterogeneity according to the Sr-Nd isotopes. To reproduce the observed periodicity, we propose an interconnection between the source heterogeneity and the variation of the melting rates: The most enriched lavas are the products of very low melting of a fertile enriched mantle component. This component may have been specifically introduced in the melting column each ~230 Ky or the melt extraction modalities may have changed with the same timescale. Apart from these enriched events, mixing between enriched and depleted primary melts occurs normally due to magma genesis/aggregation and the enriched signatures are diluted into a N-MORB-type composition.
New metal-silicate partition coefficients and constraints on core composition and oxygen fugacity during Earth accretion

A. CORGNE1,2,*, B. J. WOOD1, W. F. MCDONOUGH3, S. KESHAV2 AND Y. FEI2

1GEMOC, Macquarie University, North Ryde, NSW 2109, Australia
2Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC 20015, USA
3Department of Geology, University of Maryland, College Park, MD 20742, USA
(*correspondence: acorgne@els.mq.edu.au)

High-pressure metal-silicate partitioning experiments demonstrate that the mantle contents of some moderately siderophile elements (Ni, Co, P, W, Mo, V) are consistent with core-mantle equilibration at high pressures and high temperatures (e.g. [1-4]). This conclusion is one of the bases for the magma ocean theory, in which molten core materials segregate through a largely molten silicate mantle. To constrain further such theory, one should ask whether these conditions of core formation are consistent with the mantle contents of other elements.

We present the results of new partitioning experiments between molten metal and silicate melt for a series of elements regarded as refractory lithophile and moderately siderophile and volatile. These include Si, Ti, Ni, Cr, Mn, Ga, Nb, Ta, Cu and Zn. Our new data obtained at 3.6 and 7.7 GPa and between 1850 and 2200 ºC are combined with literature data to parameterize the individual effects of oxygen fugacity, temperature, pressure and composition on partitioning.

From the derived parameterization, we predict that the silicate Earth abundances of the elements mentioned above and V, Co, P and W are best explained if core formation took place under increasing conditions of oxygen fugacity, with final conditions near IW-2. From our estimate of the most likely oxygen fugacity path during accretion, we predict that the core contains about 10 times more Cu than the Silicate Earth as well as a smaller but significant portion of the Earth’s Zn, Ga, Nb, Ta, Mn and Cr. Furthermore, our predictions show that the core should contain some Si and at least a small amount of Ti. Finally, our results suggest that in addition to volatilization, core formation would contribute to the depletion of Ga, Cr, Mn and Zn in the silicate Earth. At present, the uncertainties of our parameterization are too large to predict whether the Nb/Ta ratio of the core is superchondritic. Additional experiments are underway to constrain further our predictions.

Arsenopyrite (AsSFe) is one of the most important natural sources of Arsenic on Earth. In oxic environments, such as highly weathered soils or surficial seawater, microorganisms and higher plants produce biogenic ligands such as siderophores to mobilize Fe that otherwise would be unavailable. We conducted batch-dissolution experiments for arsenopyrite in the presence of desferrioxamine (DFO-B), a common siderophile ligand, at pH 5. Arsenopyrite specimens (0.149-0.1mm) from mines from Panasqueira, Portugal, were used for this study. Detected concentrations of Fe, As, and Pb were 0.3, 0.26, and 0.13 µM (CV < 5%), or ca. 0.06, 0.13, and 0.01 µM (CV < 2%), in the presence of DFO-B or water only, respectively (t < 100 h). The effectiveness of DFO-B for releasing Pb was found to be almost three times higher than that for releasing Fe. These results cannot be accounted for by size-to-charge considerations prevailing in metal complexation by DFO-B only. Elemental sample enrichment as evidenced by EDX analysis support the idea the Fe-S subunit bond energy is limiting for Fe release, while likely, the mechanism(s) of dissolution for Pb is independent and occurs concurrently to than that for Fe and As. Coupling between redox-induced elemental transformations and the formation of small-particle size secondary minerals will be discussed.
Sb(V) retention mechanisms in alkaline environments

GEERT CORNELIS, TOM VAN GERVEN, NABAJYOTI SAIKIA AND CARLO VANDECASTEELE

Laboratory of Applied Physical Chemistry and Environmental Technology, Department of Chemical Engineering, KULeuven, W. De Croylaan 46, 3001 Leuven, Belgium.
(Geert.cornelis@cit.kuleuven.be)

The increased application of antimony has allowed it to find its way to a number of environments such as soils and groundwaters but also to wastes and residues of industrial processes like smelting or waste incineration. The latter materials have a much higher pore water pH (>10) than average soils and sediments, often a high salinity and thus a quite distinct geochemistry which has been thoroughly studied because these residues contain relatively high amounts of toxic heavy metals. Sb has, however, received little attention due to its relatively low total content but its high mobility calls for a better understanding of the geochemistry in alkaline matrices. In most instances the most important oxidation state is Sb(V), occurring as the oxianion antimonate (Sb(OH)₆⁻) in aqueous media. It has been established that in soils of intermediate porewater pH, Sb(OH)₆⁻ is closely associated with iron (hydr)oxides. At high pH, however, the retention mechanisms are at present unknown.

To develop efficient geochemical models to predict Sb(V) leaching in alkaline environments, the precipitation equilibria of Sb(OH)₆⁻ with the most abundant multivalent cation, Ca²⁺, was studied as well as the interaction of Sb(OH)₆⁻ with commonly occurring minerals. Simultaneously, alkaline residues such as municipal solid waste incinerator bottom ash and a Sb⁵⁺-spiked cement sample were characterised with respect to leaching. It was found that regardless of pH, no other calcium antimonates other than Ca(Sb(OH)₆)₂ precipitate but modelling with the geochemical speciation code PHREEQC showed that in alkaline environments, saturation of Ca(Sb(OH)₆)₂ is seldom attained. However, Sb(OH)₆⁻ was found to associate with portlandite (Ca(OH)₂), ettringite (Ca₆Al₂(OH)₁₂(SO₄)₃·26H₂O), mono-sulphate (Ca₄Al₂(OH)₁₀·2SO₄·13H₂O) and hydrogarnet (Ca₃Al₂(H₂O)₆). It was suspected that in alkaline environments, Sb(OH)₆⁻ forms solid solutions replacing sulphate in the structure of ettringite and monosulphate. To demonstrate this, Sb⁵⁺-analogues of ettringite and monosulphate were synthesized and characterised using XRD, SEM-EDX and TGA. Solubility experiments and calculations in PHREEQC allowed the determination of the solubility product (Kₚₒ) of these analogues. It was shown that assuming ideal solid solution as an additional mechanism next to precipitation of Ca(Sb(OH)₆)₂, greatly improved modelling of Sb leaching behaviour in alkaline environments. However, the leaching potential of Sb(OH)₆⁻ was now underestimated which calls for quantification of non-ideality to allow more precise modelling.

Geochronology, geochemistry and isotopes of orthogneisses from the Greek Rhodope

N. K. CORNELIUS¹, T. REISCHMANN², D. FREI³ AND D. KOSTOPOULOS⁴

¹Institut für Geowissenschaften, Johannes Gutenberg-Universität Mainz, Germany (cornelius@uni-mainz.de)
²Max Planck Institut für Chemie, Mainz, Germany (treisch@mpch-mainz.mpg.de)
³Geological Survey of Denmark and Greenland, Copenhagen, Denmark (df@geus.dk)
⁴National and Kapodistrian University of Athens, Department of Mineralogy and Petrology, Greece (dikostop@geol.uoa.gr)

The Hellenides formed from Cretaceous to Mid-Tertiary times as a result of plate convergence and collision of Africa and Europe. The easternmost part of the Hellenides is represented by the Rhodope Massif which occupies the major part of NE Greece and S Bulgaria. Two groups of orthogneiss protolith-ages have been established in the central Rhodope Massif: A Permo-Carboniferous group (275-290 Ma), corresponding to the structurally upper part of the massif, the Thracia Terrane and a Late Jurassic-Early Cretaceous group (134-164 Ma), corresponding to the structurally upper part, the Rhodope Terrane (Turpaud & Reischmann 2003, Turpaud 2006). In this study, felsic orthogneisses from the northeastern part of the Greek Rhodope were geochemically and geochronologically investigated, to find out, if the two terrane-model is applicable here. Zircons from 15 orthogneisses from the Eastern Rhodope were dated by LA-SF-ICPMS (U-Pb) and U-Th-Pb SHRIMP, respectively. Most of the analysed samples are around 300 Ma in age and contain many inherited cores whereas zircons from one bt-gneiss gave an age of 145 ± 5 Ma. The chemistry of all samples is very similar to orthogneisses from the Thracia Terrane in the central part of the Rhodope. The protolith of the orthogneisses can be chemically classified as subalkaline granite of a volcanic-arc tectonic setting. The isotopic ratios of ⁸⁷Sr/⁸⁶Sr range between 0.7031 and 0.7167; εNd values are negative and vary mostly between –3.8 to –7.9. REE patterns show enrichment in LREE and negative Eu anomalies. We conclude that the Thracia Terrane can also be identified in the northeastern part of the Greek Rhodope whereas the identification of the Rhodope Terrane is still under question.
Residence times of silicic magmas associated with calderas

FIDEL COSTA

CSIC, Institut de Ciències de la Terra 'Jaume Almera'.c/ Lluís Solé i Sabaris s/n, 08028 Barcelona, Spain (fcosta@ija.csic.es)

In the last two decades there has been a large wealth of geochronological information produced at caldera related volcanic systems. This contribution explores what systematics can be extracted from it and how the magma residence times may be related to other parameters such as cooling times of igneous bodies, or process durations determined from chemical zoning in crystals and diffusion models. Magma residence times are obtained from the difference between the eruption age and the age obtained by radioactive clocks and phases that may be a closed system at high magmatic temperatures (e.g., U-Pb system in zircon).

Large ranges of residence times between different systems are found. The shortest are those of Oruanui and Rototoi magmas (Taupo Volcanic Zone) with 4 ky and 9 ky of residence, respectively, followed by the Dry Creek (7 ky) and Lava Creek (19 ky) Yellowstone magmas. There is not a good correlation between magma volume and residence time, although most eruptions < 10 km³ have residence times < 100 ky, and those > 100 km³ have residence times of up to ca. 400 ky (Fish Canyon Tuff). The residence times of some small (< 10 km³) pre-and post-caldera magmas reflect that they are batches extracted from the same caldera-forming reservoir because they fall on the same time evolution line (e.g., Long Valley, Taupo). In contrast, the residence times of other small volume magmas may be the result of crystals being recycled from previous cycles of caldera-forming magmas (Yellowstone), or from plutonic rocks of the same caldera cycle with or without erupted equivalent on the surface (Crater Lake, Taupo, Long Valley) or even from not completely solidified caldera-forming magma reservoir (Taupo). These interpretations are in agreement with cooling rates and solidification times obtained from simple thermal models of magma reservoirs. Magma production rates were calculated from the ratio of erupted volume and residence time, and they vary between < 0.001 km³y⁻¹ for small deposits (< 10 km³) to ca. 0.1 km³y⁻¹ for the Oruanui eruption (530 km³). Estimates for most eruptions > 500 km³ are within 2 ± 2 * 10⁻³ km³y⁻¹, values that are comparable to global eruptive fluxes from basalts (e.g., Hawaii). Most residence times are of several thousand years or more, which is much longer than the durations of processes obtained from the reequilibration of chemical gradients in minerals, which are more on the order a few hundred years. This difference may be explained by considering that the residence times could record the entire history of the system whereas some of the diffusion data only the last event that leads to the eruption.

Petrology and phase equilibria of Ti-andradite and titanite in alkaline ultramafic rocks of the Tamazeght complex, Morocco

IAN M. COULSON¹,², MICHAEL A. W. MARKS¹ AND GREGOR MARKL¹

¹Institut für Geowissenschaften, Universität Tübingen, 72074, Germany (ian.coulson@uni-tuebingen.de)
²Solid Earth Studies Laboratory, Department of Geology, University of Regina, Saskatchewan S4S 0A2, Canada

The elliptical (5 × 15 km) Tamazeght (syn. Tamazert) alkaline igneous complex (High Atlas Mountains, Morocco) was emplaced during the middle Eocene and intrudes Jurassic to Cretaceous limestone. It comprises numerous intrusive phases that document a progression from ultramafic to felsic magmatism. A wide range of lithologies are present, including ultramafic rocks, shonkinites, gabbroic to monzonitic phases, and feldspathoidal syenites, which predominate. Moreover, carbonatites and lamprophyres occur as diatremes and dykes.

This study focuses on the petrology, paragenesis and phase equilibria of the ultramafic lithologies (pyroxenite and glimmerite). Pyroxenite is dominated by cumulus clinopyroxene (aluminous diopside) and garnet, with the latter locally rimmed by mica (phlogopite) and/or titanite. Olivine, nepheline, apatite and interstitial calcite are minor phases. In glimmerite, large poikilitic mica predominates (≤ 65 %), along with minor cumulus pyroxene-I (Al-rich), garnet, perovskite (rimmed by titanite), Fe-sulphides and apatite. Occellular textures, consisting of clinopyroxene-II (Al-poor), calcite and mica, occur throughout. Garnet occurring in the ultramafic rocks have TiO₂ contents of between 5 and 11 wt. %. It is therefore Ti-andradite. Where present in some of the more evolved units (e.g., syenites) garnet occurs only as an accessory phase and TiO₂ concentrations are uniformly lower (around 4 wt. %).

Here we present petrological, electron probe and LA-ICP-MS data, and will focus on the paragenesis, phase equilibria and stability relations between the phases present in order to track the evolution of intrinsic parameters (such as T, a(Al₂SiO₅), f(O₂)) during the formation of these rocks.
Femtosecond laser ablation ICP-MS of fluid inclusions: Validation and prospects

CLEMENT COURTIEU, DAMIEN GUILLAUME, STEFANO SALVI AND REMI FREYDIER
LMTG, Université de Toulouse, CNRS, IRD, OMP, 14 Av. E. Belin, F-31400 Toulouse, France

Experimental Protocol

LA-ICP-MS is now a commonly used analytical technique in the study of fluid inclusions. Unlike typical nanosecond UV laser ablation systems (Ar:F or Nd:YAG), the new femtosecond ablation systems can provide athermic ablation. One advantage of this is a lower risk of fluid loss due to thermal shock during opening of the inclusion. In our experiments, we used a femtosecond Ti:Sapphire 800 nm laser ablation system, following the analytical protocol outlined by Heinrich et al. (2003).

The fluid inclusions studied are hosted in quartz from the Trimouns talc-chlorite deposit (Ariège, France). Before ablating the inclusions, we performed petrographic and microthermometric studies, and calculated Na concentrations ablating the inclusions. Femtosecond laser enabled both precise and reproducible ablation of fluid inclusions and NIST glasses, following the analytical protocol outlined by Heinrich et al. (2003).

Results and discussion

We could measure the concentration of a wide range of elements within the fluid, including major cations and anions (e.g., Na, Ca, K, Cl), minor elements such as Li, Mg, and REE (La, Nd). Reproducibility of NIST 610 data were 5% for every element studied, except for K (20%) and Cl (50%). We were able to measure a very large range of concentrations within a single analysis: from 200,000 ppm for major elements like Ca to about 5 ppm for the Rare-Earth Elements (La).

This study validates the use of a femtosecond laser ablation system used for LA-ICP-MS analysis of fluid inclusions. Femtosecond laser enabled both precise and reproducible ablation of fluid inclusions and NIST glasses. However, using a NIST glass as an external standard leads to important errors on some major elements in the fluid (about 50% on Cl), which are probably due to 1) very low concentration of some of the elements in NIST 610 compared to the sample, and 2) interferences or low output of the ICP-MS.

Anhydrite as a tracer of sub-seafloor hydrothermal circulation and vent deposit formation

P.R. CRADDOCK¹ AND W. BACH¹,²

¹Woods Hole Oceanographic Institution, Dept. Marine Chemistry and Geochemistry, Woods Hole, MA 02543 (pcraddock@whoi.edu)
²University of Bremen, Dept. Geosciences, Klagenfurter Str., 28359, Bremen

The mineral assemblage and geochemistry of seafloor hydrothermal vent deposits are dictated by temperature, pH and redox conditions, and by concentrations of aqueous species in circulating fluids, during deposition. These variables are, in turn, influenced by near-seafloor fluid circulation and mixing of fluids of distinct origin (e.g., high-temperature seawater-derived hydrothermal fluid, locally entrained seawater, magmatically-derived volatile-rich fluid). Anhydrite (CaSO₄) is a useful tracer of these processes and conditions, being precipitated during mixing of high-temperature hydrothermal fluid with seawater.

Abundant anhydrite has been recovered from the PACMANUS hydrothermal system, eastern Manus Basin, both at the seafloor [Tivey et al. 2006] and from depth subsurface (ODP Leg 193 [Binns et al., 2007]). This affords the first opportunity to directly explore subsurface processes associated with hydrothermal activity in a back-arc basin.

In situ microbeam techniques (laser ablation-ICP-MS) are used to explore fine-scale variability in isotopic (Sr, S) and elemental (Mg, Sr, Ba, REE, Y, etc.) signatures of anhydrite, from various depths and locations at PACMANUS. First analyses indicate significant differences in Sr-isotope ($^{87}$Sr/$^{86}$Sr > 1000 ppm), S-isotope ($^{34}$S > 5 %) and REE content of anhydrite are observed between and within sites at PACMANUS over scales ranging from m’s to mm’s. Variable and light $^{34}$S (+16.6 to 19.0 %) in anhydrite from depths ~ 300 mbsf indicate possible contribution from an isotopically-light magmatic source in the high-temperature fluid. Large grain-scale variability in $^{87}$Sr/$^{86}$Sr (0.7043 to 7.089) indicates significant variation in the extent of mixing between the hydrothermal fluid and seawater. REE patterns range from light-REE enriched to light-REE depleted, both with positive and negative Eu-anomalies, to flat, non-fractionated REE. While the majority of data is still to be collected, the patterns recorded thus far suggest fractionation of REE during anhydrite precipitation or differences in fluid compositions. Isotopic data indicate three end-member mixing, including a possibly magmatic component. Comprehensive coupled elemental and isotopic microanalyses will enable us infer the effects of fluid source versus fractionation process during anhydrite precipitation.

Geochemical and isotopic variation of Mt. Etna volcanic rocks: The role of a heterogeneously metasomatized source region of magmas

RENATO CRISTOFOLINI AND MARCO VICCARO

Dipartimento di Scienze Geologiche, Università di Catania, Corso Italia 57, 95129 Catania, Italy (m.viccaro@unict.it)

New clues for investigating on some features not yet clarified at Mt. Etna (Italy), such as the genesis of magmas and the intrinsic characteristics of the source region, come from an extensive sampling of historic (pre-1971) and recent (1971-2007) volcanic rocks, carried out prevalently on the southern flank of the volcano. In spite of the relatively similar major element compositions, recent volcanic rocks are clearly distinct in terms of incompatible trace elements and Sr – Nd – Pb isotope ratios from the historic ones. Post-1971 volcanics, and especially those later than 2001 eruption, show enrichment trends for K, Rb and $^{87}$Sr/$^{86}$Sr and a progressive decrease especially for Th contents and Pb isotope ratios. The role of crustal contamination at shallow levels in generating such a variation has been ruled out on the basis of trace elements and of the restricted $\delta^{18}$O variability within the entire examined sequence. In alternative, we suggest a geochemical and isotopic evolution of the source region of magmas highly consistent with the presence of an increasingly amount of hydrous phases, prevalently phlogopite, involved in the partial melting process. A reason for the short-term evolution of magmas may then be found by considering a partial melting process which occurs in mantle domains affected by variable and increased degree of metasomatism with time, revealing the heterogeneous nature of the source at the melting scale.

Trace element geochemistry provides also evidence that the generation of recent magmas would derive from a higher degree of partial melting in respect to the previously emitted products. This feature may be connected with the higher amounts of metasomatic influxes that have stabilized fluids into the mantle, enhancing in turn the extent of partial melting. In such an articulated context, a limited mantle upwelling, related to the intrinsic convective processes (plume-like) and/or to the lithospheric stretching due to extensional deep faults, could rather easily trigger partial melting processes of these metasomatized peridotites, generating melts different in composition depending on heterogeneities. Furthermore, since the increased extent of partial melting will result in an increased melt production at the source, such a geochemical evolution of the mantle with time is consistent with the development of volcanic phenomena at the surface. The occurrence of such a heterogeneously metasomatized mantle would therefore explain the increased frequency of events and emission rates of volatile-rich magmas observed just following the 1971 and especially during the 2001-2007 eruptive period.
**Pb isotopes and glacial/interglacial weathering intensity**

**K.C. Crocket**¹, **D.A. Richards**¹, **G.L. Foster**² and **D. Vance**²

¹School of Geographical Sciences, University of Bristol, UK
(kirsty.crocket@bristol.ac.uk; david.richards@bristol.ac.uk)

(g.l.foster@bristol.ac.uk; d.vance@bristol.ac.uk)

To gauge the impact of weathering on Quaternary CO₂ cycles, we need better constraints on the flux of cations from the continents. For the substantial portion of the continents that have been glaciated in the Quaternary, early stage weathering of U+Th rich accessory phases freshly exposed during glacial periods should preferentially release radiogenic Pb. Thus the seawater Pb isotopic composition might act as a regional proxy for the riverine alkalinity flux to the oceans. Here we discuss the development of this proxy at high resolution and its application to sediments from Feni Drift (ODP Site 980) spanning the last 45 ka.

Pb isotope data from ferromanganese crusts (1) have been used to postulate greater weathering intensity during interglacial than glacial periods, but low temporal resolution precluded investigation of the detailed structure of the record at glacial inception and termination. To obtain higher resolution, we applied a tested method of Pb extraction from authigenic Fe oxide phases in marine sediments (2). The results contrast with existing crust data in that the Pb isotope variation is much larger (²⁰⁸Pb/²⁰⁶Pb ranges from 18.90 to 21.09 cf with 18.96 to 19.22 in crusts) with the most radiogenic Pb occurring at the Last Glacial Maximum. The Pb signal shows strong correlation to other proxy records from the same and nearby sites. A pronounced ~1.2 to 2 ka periodicity, particularly during MIS 3, most likely reflects the same and nearby sites. A pronounced ~1.2 to 2 ka signal shows strong correlation to other proxy records from North Atlantic land masses. This preliminary investigation raises several issues pertaining to the direct interpretation of leached Fe oxides as archives of seawater Pb isotopic composition. Although the radiogenic signal is consistent with early stage weathering, the extreme variation in Pb isotope ratios may reflect a predominance of Fe oxide formation in terrestrial rather than marine environments, thus highlighting the importance of understanding continent-ocean Pb transport pathways and their implications for environments of Fe oxide formation prior to marine deposition.

**Mechanisms of Fe isotope fractionation during dissimilatory Fe(III) reduction by *S. putrefaciens* and *G. sulfurreducens***

**H. Crosby, E. Roden, C. Johnson and B. Beard**

Univ. Wisconsin - Madison (hacrosby@wisc.edu; eroden@geology.wisc.edu; clarkj@geology.wisc.edu; beardb@geology.wisc.edu)

Microbial dissimilatory iron reduction (DIR) is widespread in anaerobic sediments and is a key producer of aqueous Fe(II) in suboxic sediments that contain reactive ferric oxides. Here we compare Fe isotope fractionations produced by similar cultures of *G. sulfurreducens* and *S. putrefaciens* during reduction of hematite and goethite. Both species produce aqueous Fe(II) that is depleted in the heavy Fe isotopes, as expressed by a decrease in ⁵⁶Fe/⁵⁴Fe ratios or δ⁵⁶Fe values. The low δ⁵⁶Fe values for aqueous Fe(II) produced by DIR reflect isotopic exchange among three Fe inventories: aqueous Fe(II) (Fe(II)aq), sorbed Fe(II) (Fe(II)sorb), and a reactive Fe(III) component on the ferric oxide surface (Fe(III)rec). The fractionation in ⁵⁶Fe/⁵⁴Fe ratios between Fe(II)aq and Fe(III)rec was 2.95 ‰, and this remained constant over the timescales of the experiments (280 d). The Fe(II)aq-Fe(III)rec fractionation was independent of the ferric Fe substrate (hematite or goethite) and bacterial species, indicating a common mechanism for Fe isotope fractionation during DIR. Moreover, the Fe(II)aq-Fe(III)rec fractionation in ⁵⁶Fe/⁵⁴Fe ratios during DIR is identical within error of the equilibrium Fe(II)aq-ferric oxide fractionation in abiologic systems at room temperatures. This suggests that the role of bacteria in producing Fe isotope fractionations during DIR lies in catalyzing coupled atom and electron exchange between Fe(II)aq and Fe(III)rec so that equilibrium Fe isotope partitioning occurs.

Although Fe isotope fractionation between Fe(II)aq and Fe(III)rec remained constant, the absolute δ⁵⁶Fe values for Fe(II)aq varied as a function of the relative proportions of Fe(II)aq, Fe(II)sorb, and Fe(III)rec during reduction. In the case of hematite reduction, the effect of Fe(II)aq on the δ⁵⁶Fe values for Fe(II)aq was insignificant, <0.05 ‰. Sorption of Fe(II) produced small, but significant effects during reduction of goethite, reflecting the higher proportion of Fe(II)sorb and larger measured Fe(II)aq-Fe(II)sorb fractionation. The isotopic effects of sorption on the δ⁵⁶Fe values for Fe(II)aq were largest during the initial stages of reduction when Fe(II)sorb was the major ferrous Fe species during goethite reduction, on the order of 0.3 to 0.4 ‰, but decreased to <0.2 ‰ with continued reduction; our results show that the effect of sorption is much less than has been proposed in other studies. These experiments provide a breakthrough in our understanding of the mechanisms that produce Fe isotope fractionation during DIR, and form the basis for interpretation of Fe isotope variations in modern and ancient natural systems where DIR may have driven Fe cycling.
Fe- and Mg-cordierite: A calorimetric and thermodynamic study

E. DACHS¹ AND C.A. GEIGER²

¹Department of Material Science & Physics, University of Salzburg, Austria (edgar.dachs@sbg.ac.at)
²Institute for Geosciences, University of Kiel, Germany (chg@min.uni-kiel.de)

Cordierite is a key phase in many metamorphic rocks and it also has important technical applications in industry. Thus, knowledge of its thermodynamic properties is necessary for a variety of investigations. In order to enable more quantitative calculations, heat capacity measurements between 5 and 300 K were carried out on milligram-sized synthetic samples of anhydrous low Fe-cordierite (Fe-Cd), as well as on anhydrous and hydrous low Mg-cordierite (Mg-Cd), using heat-pulse calorimetry (HPC).

From our HPC results, the standard entropy values at 298.15 K for anhydrous Fe-Cd, anhydrous Mg-Cd and hydrous Mg-Cd were calculated as 460.5 ± 0.5, 406.1 ± 0.4 and 450.9 ± 0.5 J/(mol·K), respectively. Heat capacity (Cp) polynomials for anhydrous Fe- and Mg-cordierite at T > 250 K are:

$$C_{P,Fe-Cd} = 911.1 \pm 9.7 \cdot T - 5829.2 \pm 363 \cdot T^{0.5} - 13.9424 \cdot 10^6 \cdot T^{-2} + 1470.4 \pm 454.84 \cdot 10^6 \cdot T^{-3},$$

$$C_{P,Mg-Cd} = 882.0 \pm 4.9 \cdot T - 5155.8 \pm 167 \cdot T^{0.5} - 20.7584 \cdot 10^6 \cdot T^{-2} + 2736.0 \pm 112.73 \cdot 10^6 \cdot T^{-3},$$
as derived from the HPC data and published DSC data.

Lattice and non-lattice contributions to the Cp values were modeled for Fe-Cd. The values $S_{vib}^{0} = 447.7$ J/(mol·K) and $S_{el}^{0} = 13.6$ J/(mol·K) were obtained for the vibrational and electronic contributions to the standard third law entropy.

Using phase equilibrium data for the reaction $3Fe-Cd\cdot H_2O = 2almandine + 4sillimanite + 5quartz + 3H_2O$ (Mukhopadhyay & Holdaway 1994), $\Delta H^{\circ} = -8448.26$ kJ/mol was obtained for anhydrous Fe-Cd and the values $\Delta H^{\circ} = -8750.23$ kJ/mol and $S^{0} = 520.6$ J/(mol·K) were derived for hydrous Fe-Cd.

Phase relations in the FeO-Al₂O₃-SiO₂(+/-H₂O) system and isohydrons for H₂O in Fe-Cd were calculated and respective phase diagrams constructed.

Gas-particle partitioning, atmospheric deposition and long range transport of persistent organic pollutants over the oceans

JORDI DACHS, SABINO DEL VENTO, NAIARA BERROJALBIZ AND MARI-CARMEN VALLE

Dept of Environmental Chemistry, IIQAB-CSIC. Jordi Girona 18-26, Barcelona 08034, Catalunya, Spain. jdmqam@cid.csic.es (J.D.)

Gas-particle partitioning of persistent organic pollutants plays an important role on the atmospheric deposition and long range transport potential of persistent organic pollutants. Aerosol organic and elemental carbon composition has been recognized as important bulk composition parameters controlling the distribution of POPs between gas and aerosol phases. However, sea salt aerosols and desert dust could play a role over some oceanic regions. Furthermore, atmospheric deposition of POPs will also be affected depending on this partitioning processes. On the other hand, trophic status of the ocean does also play a role as controlling factor of gaseous exchange and to lesser extent of dry deposition. In this work, gas-particle partitioning, deposition and long range transport are assessed in terms of aerosol and surface receiving geochemical processes. Results are shown for the tropical Atlantic, the Mediterranean sea and polar (Antarctic) waters.
Mo isotope variations in meromictic Lake Cadagno

T.W. DAHL\textsuperscript{1}, A.D. ANBAR\textsuperscript{2}, G.W. GORDON\textsuperscript{2}, R. FREI\textsuperscript{1} and D.E. CANFIELD\textsuperscript{4}

\textsuperscript{3}Nordic Center for Earth Evolution (NordCEE) Campusvej 55, 5230 Odense M, Denmark

Mo isotope systematics can be used to infer the extent of ocean oxygenation in the past. Isotope fractionation during adsorption to Mn-oxides exerts an important influence on the isotopic composition of the oceanic Mo reservoir. Measurements indicate that this process was less important between 1.7 - 1.4 Ga compared to today (Arnold et al. 2004) consistent with other lines of evidence (Canfield 1998). However, quantitative interpretation of Mo isotope variations in ancient sediments requires an understanding of how Mo isotopes fractionate in sulfidic environments in which Mo removal from the water column is not quantitative.

The alpine Lake Cadagno in Switzerland offers an opportunity to examine Mo isotope fractionation in a sulfidic water column. Mo exists as the soluble molybdate anion in the oxic surface zone. Mo concentration decreases by 30-50\% below the chemocline, where Mo speciation presumably is dominated by particle-reactive oxythiomolybdates. Isotopically, in the oxic part of the lake we find $\delta^{97/95}$Mo = 0.5-0.6‰, matching the riverine inflow. In contrast, the sulfidic deeper waters are heavier: $\delta^{97/95}$Mo = 1.1-1.2‰.

The mechanism by which this isotope shift occurs is at present uncertain. It is possible that heavy Mo enters the deep waters from dolomitic subaquatic springs. Alternatively, isotope fractionation may occur at or below the chemocline. The data could be explained by preferential adsorption of light Mo onto ferromanganese particles below the chemocline. In cases of incomplete Mo removal in euxinic waters the isotope effect is unknown and needs to be studied.

Nd isotopes in Bering Strait and Chukchi Sea water

R. DAHLQVIST\textsuperscript{1}, P.S. ANDERSSON\textsuperscript{2} and D. PORCELLI\textsuperscript{1}

\textsuperscript{1}University of Oxford, Dept. of Earth Sciences, Oxford OX1 3PR, UK, (Ralf.Dahlqvist@earth.ox.ac.uk)
\textsuperscript{2}Swedish Museum of Natural History, Lab. for Isotope Geology, Stockholm, Sweden, (per.andersson@nrm.se)

The Nd isotopic composition, $\varepsilon_{Nd(0)}$, was determined for the first time in filtered (0.22 μm) water samples collected from the Bering Strait and the Chukchi Sea in the Arctic Ocean. Vertical profiles and surface waters were collected in the east and west passages of Bering Strait, the Chukchi Sea, and the Chukchi Abyssal Plain.

In Bering Strait $\varepsilon_{Nd(0)}$ vary between -4.02 and -5.94, with slightly more radiogenic values at the surface. Temperature and salinity profiles show a well mixed water column with a surface layer of 5-10 m depth, which is warmer and less saline. The isotopic composition is primarily influenced by inflow from the north Pacific Ocean with values of -4 to -5. The slightly lower surface values can be explained by input from local sources to the Bering Sea, e.g. Yukon River water.

Two surface water samples collected in the Chukchi Sea have more negative $\varepsilon_{Nd(0)}$ compared to Bering Strait water, indicating a different source than Pacific Ocean water, possible river water from Russian rivers.

In the Chukchi Abyssal Plain $\varepsilon_{Nd(0)}$ decreases with depth from -6.52 at the surface to -11.47 close to the bottom. Salinity and temperature profiles show a well-defined stratification, and the variation with depth is clearly related to the origin of these different water masses. The surface value of -6.52 demonstrate the significance of Chukchi Sea shelf waters, while less radiogenic values at depth are related to warm Atlantic derived water and Canada Basin bottom water.

Nd concentrations (C$_{Nd}$) determined with isotope dilution vary between 24.6 and 39.5 pM in the Chukchi Abyssal plain and Bering Strait respectively. In this filtered fraction no significant variation in C$_{Nd}$ can be observed with depth in Bering Strait or the Chukchi Abyssal Plain.

$\varepsilon_{Nd(0)}$ values in samples from Bering Strait and the Chukchi shelf are more negative than reported values from the North Pacific surface water. This indicates that the isotopic signal changes in water flowing from the Pacific Ocean into the Arctic. This shift may be caused by interaction with suspended particulate matter on the shallow shelf surrounding Bering Strait and in the Chukchi Sea. Support for this theory can be observed in measured C$_{Nd}$ in this study, which show higher concentrations on the shelf area compared to North Pacific surface water.

These new data are setting important constraints for inflow and mixing of Pacific Ocean water with the general circulation of Arctic Ocean water.
Soft x-ray scanning transmission spectromicroscopy of cementitious materials

3Present adress: Université J. Fourier, B.P. 53, 38041 Grenoble Cedex 9, France

Cement-based materials play an important role in multi-barrier concepts developed worldwide for the safe disposal of hazardous and radioactive wastes in underground repositories. Cement is used to condition the waste materials and to construct the engineered barrier systems. Therefore, a mechanistic understanding of the processes governing the binding of heavy metals in cement systems is essential for long-term predictions of the environmental impact of cement-stabilized waste forms. From a chemical standpoint, cement is a very heterogenous material with discrete particles in the nano to micrometer size range, which makes it an ideal system to be investigated with scanning transmission x-ray microscopy (STXM).

In this study the soft x-ray STXM end station at the Advanced Light Source-Molecular Environmental Science (ALS-MES) Beamline 11.0.2 has been utilized to investigate metal precipitates formed in Ni- and Co-doped cement pastes. The ALS-MES STXM collects both images and near-edge x-ray absorption fine structure (NEXAFS) spectra with a spatial resolution of 30 nm. NEXAFS spectra of the Ni and Co 2p edge were utilized to collect spectroscopic information on the Ni- and Co-precipitates formed in the cement matrix. This study complements previous micro-spectroscopic investigations on the speciation of Ni(II) and Co(II) in cement pastes (Vespa et al., 2006, 2007). For Ni(II)-doped cement pastes, the formation of a Ni(II)-Al layered double hydroxide phase was observed by Vespa et al. (2006). In Co(II)-doped cement pastes, however, partial oxidation of the initially added phase was observed by Vespa et al. (2006). In Co(II)-Al doped cement pastes, the formation of a Ni(II)-Al layered double hydroxide phase was observed by Vespa et al. (2006). In Co(II)-doped cement pastes, however, partial oxidation of the initially added phase was observed by Vespa et al. (2006).

Xingcheng abiogenic alkane gas field in Songliao Basin, China

J.X. DAI1, S.C. ZHANG2, Y.Y. NING3 AND J. LI4

Research Institute of Petroleum Exploration & Development (1djl@petrochina.com.cn, 2szhang@petrochina.com.cn, 3wht1972@263.net, 4ningyunyan@yahoo.com.cn)

Xingcheng gas field is located in the Daqing and Anda city of Heilongjiang province and geologically in the volcanic uplift zone in the centre of Xujiaweizi rift, Songliao basin. Six exploration wells have been drilled in this gas field. The proved geologic reserve of natural gas in Lower Cretaceous volcanic and conglomerate rocks is 459.84×10⁶m³ within an area of 41.70 km². Xuxi, Xuxi and Xuzhong faults developed in a long period in Xujiaweizi rift. Xuxi and Xuzhong faults extend 58 and 96 kilometers, respectively, and the faults throw is up to 1800m. Faults cut off the basement rock, reach the mantle magma chamber, lead to violate volcanic movements during multiple stages. The main stage of volcanic eruption is Yingsheng Formation of Lower Cretaceous.

The natural gas geochemistry characteristics show that: CH₄ accounts for more than 93%, and the hydrocarbon gases above C₂ account for ~3%. The δ¹³C values which range from -25.9‰ to -28.9‰ are the heaviest among the alkane gases, and the trend of δ¹³C values gets lighter with increasing carbon numbers (δ¹³C₁>δ¹³C₂>δ¹³C₃>δ¹³C₄). So the gases of Xingcheng gas field is abiogenic (Dai et al., 2005). The δ¹³C values of volcanic-magmatic and mantle genetic carbon dioxide are -6±2‰ (Dai et al., 2005). The δ¹³C values of Xingcheng gas field are within the range of -4.8‰~8.2‰, so the CO₂ is of magma-mantle genetic characteristic; The values of ³He/⁴He in the upper mantle are between 1.1×10⁻⁵ and 1.4×10⁻⁵, and the values of ⁴He/³He in radiogenic strata are from 10⁻⁵ to 10⁻⁴ (Wang, 1989). The value of ³He/⁴He in the gas field is 10⁻⁶, which may be the results of ³He from the mantle. It also proves that some of the alkane gases originate from the mantle; Many experiments show that catarinite can catalyze the reaction between CO₂ and H₂ to form CH₄ in hydrothermal fluid (Horita J et al., 1999), and chromites can catalyze the reaction to form CH₄, C₂H₆ and C₃H₈ (Foustoukos D I et al., 2004). In Xingcheng gas field, CO₂ exists widely and H₂ is discovered in some wells. The active stage of volcano and hydrothermal fluid movements are multiple. At present, the average temperature gradient in Songliao basin is 3.7°C/100m and the maximum reaches 6.1°C/100m. All the conditions are favorable for the reaction of Fischer-Tropsch synthesis to form abiogenic alkane gas.

Hf, Sr, Nd and Pb isotopes in primitive Tongan lavas: Constraining mobility in slab fluids

C.W. DALE1, C.G. MACPHERSON1, D.G. PEARSON1, G.M. NOWELL1, S.J. HAMMOND2 AND R.J. ARCULUS3

1Dept of Earth Sciences, Durham University, Durham, DH1 1LE, U.K. (christopher.dale@durham.ac.uk)
2Dept of Earth Sciences, CEPSAR, The Open University, Milton Keynes, MK7 6AA, U.K.
3Dept of Earth & Marine Sciences, Australian National University, ACT 0200, Australia

This study presents new Hf, Sr, Nd and Pb isotope data for a suite of glassy submarine basalts and basaltic andesites dredged from the Fonualei Rift zone and the Tongan arc north of Tongatapu.

The Tongan arc is a prime example of an intra-oceanic arc with a geochemical signature dominated by prior depletion of the mantle wedge and a slab-fluid input. Depletion of the mantle wedge is thought to increase northwards along-arc, and probably results from melt extraction during the opening of the Lau backarc basin. In addition, trace element and isotopic compositions indicate that the northern extremity of the arc contains a contribution from volcanioclastic material derived from the subducted Louisville Ridge Seamount Chain, and possibly an input from ‘Samoan-type’ mantle.

Southern submarine volcanoes (south of Fonualei) have trace element characteristics (e.g. extremely high Ba/Th ratios) indicative of slab fluid being the major subduction flux along this part of the arc. Lower 143Nd/144Nd, higher 206Pb/204Pb and elevated Ta/Nd in samples north of Fonualei are consistent with proposals by previous authors that these melts have a signature. The volcaniclastic input (or plume influence) of high field strength elements (HFSE) in subduction zone fluids.

Is Lichades the northern end of the Hellenic Volcanic Arc? Clues from helium isotopic composition in gases

W. D’ALESSANDRO1, L. BRUSCA1, K. KYRIAKOPOULOS2

1Istituto Nazionale di Geofisica e Vulcanologia, Palermo, Italy (w.d Alessandro@pa.ingv.it)
2University of Athens, Greece (ckiriako@geol.uoa.gr)

The Hellenic Volcanic Arc (HVA) straddles across the Southern Aegean Sea. Its activity started in the late Pliocene and it comprises many volcanic systems most of which are considered active at present. The westernmost active volcanic system is considered to be Methana, a peninsula in the Saronikos Gulf and remnants of Plio-Pleistocene volcanic activity are found at Sousaki, some tens of km further north, close to the isthmus of Corinth.

About 100 km further north, in the northern Evoikos Gulf, sparse trachy-andesitic volcanic rocks of Quaternary age crop out. The most important of these form the islet of Lichades. Although this volcanic system is generally considered to be due to back-arc extension, recently Papoulia et al. (2006), on the basis of seismological studies, consider it to be the most northern end of the HVA.

The area is also affected by distensive tectonic that formed a graben between the island of Evia and mainland Greece, limited on both sides by a series of important direct fault systems. Along these tectonic structures many thermal springs (water temperatures 40 - 90 °C) are found. Most of these are characterised by the presence of a CO2-rich gas phase whose helium isotopic composition ranges from 0.06 to 1 R/Ra. The highest mantle contribution (4-12 %) is attributed to the progressive contamination of the mantle source with crustal material (Parello et al., 2001). The similar trend, observed in the volcanic systems of southern and central Italy (from 7.3 to 0.5 R/Ra in the north direction), is attributed to the progressive contamination of the mantle source with crustal material (Parello et al., 2000). The similar geologic history and the geographic closeness of the Greek region could suggest a similar process governing the trend of helium isotopic composition in the HVA. If this would be confirmed by further studies, the mantle contribution to the gases collected close to Lichades would be even greater.

Possible paleo-climatic record from fossil hydrothermal systems in the Ross Sea area, Antarctica

L. DALLAI and R. BURGESS

1CNR, Institute of Earth Sciences and Resources, Pisa, Italy (dallai@igg.cnr.it)
2SEAES, University of Manchester, UK (ray.burgess@manchester.ac.uk)

During Cenozoic time, diffuse alkaline magmatism related to the rifting in the Ross Sea Embayment intruded the northeastern region of the Wilson Terrane, Antarctica. Plutons with syenitic-monzonitic to gabbroic compositions provided the necessary heat source for local hydrothermal systems to occur in fractured rocks.

Oxygen and hydrogen isotope investigation of altered granitoids along the Ross Sea coastline were undertaken to constrain the characteristics of Eocene fossil hydrothermal systems. These were combined with Ar-Ar ages of the intrusions to provide a temporal framework for interpreting isotopic data. δ18O values, as low as 4 ‰ in K-feldspar of country rocks, and δD values of biotite/amphibole in the range of -100 ‰ to -200 ‰, indicate that these minerals interacted with meteoric-dominated hydrothermal waters.

Altitude, latitude, local climate conditions and tectono-thermal histories were considered similar for all the outcrops; thus the hydrogen isotope composition of hydrothermal minerals was used as a proxy for paleo-climatic reconstructions, provided the water-vapor hydrogen fractionation in the atmosphere is temperature-dependent.

By combining δD values of the hydrothermal waters with Ar-Ar ages, the isotopic compositions for meteoric recharge waters could be calculated for a fairly continuous time interval between 52 and 26 Ma. This low resolution palaeo-climate curve shows several similarities to the high-resolution curve between 52 and 26 Ma. This low resolution palaeo-climate curve may provide a proxy based on continental records for palaeo-environmental reconstruction in the southern sector of Antarctica.

Zircon growth and resorption in an incrementally filled granite pluton: Insights from in situ U-Pb, trace element and Hf isotopic analyses

J. STEPHEN DALY, DAMIEN GAGNEVIN and MARTIN J. WHITEHOUSE

1UCD School of Geological Sciences, Belfield, Dublin 4, Ireland (stephen.daly@ucd.ie, damien.gagnevin@ucd.ie)
2Laboratory for Isotope Geology, Swedish Museum of Natural History, Stockholm, Sweden (martin.whitehouse@nrm.se)

High uranium contents and lack of radiation damage due to its young age, permit high precision U-Pb zircon dating of the Monte Capanne monzogranite (Elba, Italy), one of the youngest granitic plutons exposed on Earth. The results are consistent with field relationships and indicate that the last zircon growth increment ranges from 7.85 ± 0.11 Ma in a mafic microgranular enclave (MME) to 7.27 ± 0.15 Ma in a mafic (Orano) dyke of similar monzogranitic to granodioritic composition. The spatial distribution of ages is consistent with incremental intrusion of the three petrographically-defined facies of the pluton (Dini et al. 2002). The San Marino porphyry (7.84 ± 0.14 Ma) was immediately succeeded by the San Francesco facies (7.76 ± 0.17 Ma) while the San Piero (7.53 ± 0.07 Ma) and Sant’Andrea facies crystallized later (7.57 ± 0.46 Ma) before the Orano dykes (7.27 ± 0.15 Ma). Importantly each component of the pluton displays a range of magmatic zircon ages spanning up to two million years, tentatively interpreted as dating the duration of magmatism. Much older inherited zircons occur, particularly in the San Francesco facies. These range in age from Archaean to Mesozoic and are interpreted as being derived from the source or wall rocks. Petrographically and in their trace element and Hf isotopic signatures, the zircons record repeated episodes of growth, partial resorption and regrowth, interpreted as evidence of iterative magma mixing and recharge (Gagnevin et al., 2007) consistent with previous models for the evolution of the Monte Capanne pluton derived from chemical and isotopic zoning in K-feldspar megacrysts (Gagnevin et al., 2005a, b) as well as whole-rock geochemical studies(Gagnevin et al., 2004).

**In situ** high P-T melting and phase equilibria experiments on the Allende meteorite

L.R. Danielson1, K. Righter1, K. Leinenweber2 and Y. Wang3

1NASA JSC, 2101 NASA Road One, Houston, TX 79058, lisa.r.danielson@nasa.gov, kevin.righter-1@nasa.gov
2Dept. of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1604, kurtl@asu.edu
3GSECARS, APS ANL, 9700 South Cass Ave., Bldg. 434A, Argonne, IL 60439, wang@cars.uchicago.edu

Because chondritic materials are thought to be the building blocks of terrestrial planets and planetesimals, crystallization of chondritic and peridotic material can be used to simulate accretion and differentiation of a bulk planet. The objective of this study is to measure the liquidus phases and temperatures in situ for a number of planetary mantle analog materials at P > 20 GPa.

Experiments were conducted in the Large Volume Press at the Advanced Photon Source, Argonne National Laboratory. Phases were identified using energy-dispersive X-ray diffraction (EDXRD) with a fixed diffraction angle (2θ) of ~6° and data collection times of 60 sec. Heating runs up to 2200 °C were performed at 400, 600, and 700 tons, sampling a pressure range from 18-32 GPa.

A 3mm TEL beamline modified Fei-type assembly was used in experiments. MgO was used as the pressure standard. Temperature at the hotspot, the region of interest for analyses, was calculated using the thermal modeling program developed by [1].

Radiography image of compressed sample though the Re slits and alumina windows. Maximum pressure achieved was 19.1 GPa. The pressure standard was located immediately above the sample. The dark area in the upper left is an area where the slit in the Re foil ends.

The solidus is comparable to previous results, but the majorite liquidus temperature occurs near 2250 °C, compared to previous results of 2000 °C [2,3]. The majorite-Mg-perovskite coticet occurs before 22 GPa, as opposed to around 25 GPa [2,3]. Although Mg-perovskite was identified as the liquidus phase above 22 GPa, the ferropericlase-out line is very steep, and may become the liquidus phase above 23 GPa. The higher liquidus temperature with the large field of melting would tend to support a shallow magma ocean model with a large zone of crystal mush.

Mineralogical characterization of Mn ores of shallow marine origin in northeast Vietnam

DUY ANH DAO AND RETO GIERÉ
Mineralogisch-Geochemisches Institut, Albert-Ludwigs-Universität, Freiburg (anh.dao@jupiter.uni-freiburg.de)

Geological and mineralogical properties

Important Mn deposits occur in the Halang basin, located in the Cao Bang Province in the northeastern part of Vietnam. The Mn ore in this region is of neritic origin, representing a chemical sediment, and was described as consisting of primarily pyrolusite and “psilomelane” (Le, 1988). The Mn ore seams are hosted by grey recrystallized limestone of Devonian age. The Mn deposits are distributed mainly at the margin of Devonian synclines or at their juncture. The productive Mn-bearing seam varies in thickness from 0.2 to 2 m, and is overlain by black siliceous rocks. The average chemical composition of the deposits is as follows: Mn = 30 wt%; Fe = 6.38 wt%; SiO₂ = 22.79 wt%; P = 0.224 wt%. The reserves have been estimated at more than one million tons.

The banded Mn deposits were strongly affected by various geological processes, which postdate ore formation. Folding and faulting led to a complicated distribution pattern of the ore seams. Weathering in the humid subtropical climate has resulted in supergene enrichment in Mn as well in the formation of various secondary minerals, thus producing a mineralogically complex ore. Layers of secondary calcite and quartz are intercalated with the Mn-rich seams.

X-ray diffractometry, EMPA analysis and mineral formula calculations based on the procedure of Saini-Eidukat (1993) revealed that the following minerals are present as major Mn hosts [average composition in brackets]: pyrolusite [MnO₂]; hausmannite [Mn₂⁺₀.₀₁Mn³⁺₁.₀₁O₁]; manganite [Mn³⁺₀.₉₄O(OH)₃]; jacobsite[(Mn³⁺,Fe³⁺)₀.₀₇(Mn³⁺,Fe²⁺)₁.₇₅O₄]; hollandite [(Ca₀.₁K₀.₄₄Ba₀.₀₂Fe₂⁺₀.₃₄,Mn²⁺₀.₄₃,Mn⁴⁺₀.₄₃)O₁₆H₂O] and possibly birnessite. In addition, the ores contain hematite, Mn-rich hematite [(Fe³⁺₁.₂₆,Mn²⁺₀.₆₈)O₁], bixbyite [Mn²⁺₁.₁₇,Fe³⁺₀.₈₃]O₃], goethite, ferrihydrite, quartz, and apatite. The Mn minerals are often intimately intergrown, on a µm-scale, with other minerals.

Discussion of results

The results indicate that not all the Mn minerals are of sedimentary origin but rather, that some of the Mn phases were formed during subsequent alteration. Based on these results we can establish an effective processing technology to improve the ore grade.

The application of chrome-spinel in the tectonic discrimination of mafic-ultramafic rocks: New developments from the analysis of gallium

S.A.S. DARE¹, J.A. PEARCE¹, I. MCDONALD¹ AND M.T.S. STYLES²

¹School of Earth, Ocean and Planetary Sciences, Cardiff University, Cardiff, CF10 3YE, U.K. (DareSA@cf.ac.uk)
²British Geological Survey, Keyworth, Nottingham, NG12 5GG, U.K.

Chrome-spinel, [(Mg,Fe)(Al,Cr)₂O₄], is well-established as a useful, alteration-resistant petrogenetic and tectonic setting indicator for mafic-ultramafic rocks (e.g. Dick and Bullen, 1984; Barnes and Roeder, 2001). Among its many applications, chrome-spinel geochemistry provides a means of interpreting ophiolites and serpentinites emplaced along continental suture zones, and of interpreting mafic-ultramafic intrusions in the deep crust.

The most effective fingerprints are based on occupancy of the Y (Cr,Al) site of the chrome-spinel with covariations between Cr# [Cr/(Cr + Al)], Fe³⁺# [Fe³⁺ / (Fe³⁺ + Cr + Al)], V and Ti providing sensitive indicators of degree of melting, oxygen fugacity and melt-rock interaction. This work extends this suite of elements by including gallium, analysed by LA-ICP-MS using a 213nm UV laser and well-characterised chrome-spinel standards. Ga values for a suite of peridotite samples from modern-day tectonic settings range from 70 ppm to just above the L.O.D. of 5 ppm.

Of particular significance is the covariation of Ga and Fe³⁺. These elements have similar ionic radii but only Fe³⁺ is redox-dependent. Thus, melting and fractionation trends retain a near-constant Fe³⁺#/Ga ratio, but spinels from supra-subduction zone dunites have higher Fe³⁺#/Ga ratios than those from non-subduction dunites. This Fe³⁺#/Ga fingerprint has been tested on crustal and mantle dunites from the northernmost blocks of the Oman ophiolite, where it confirms lava and dyke evidence for an evolution from a mid-ocean ridge to a supra-subduction zone setting.

Rapid melting of small planetesimals

A. DAS AND G. SRINIVASAN

Department of Geology, University of Toronto, Toronto, ON, M5S3B1 (das/srini@geology.utoronto.ca)

The presence of highly non-radiogenic 182W in Fe meteorites has been used to estimate that rapid formation of Fe meteorites took place in < 1.5 Ma of formation of solar system [1]. The timing of formation of solar system is determined from 206Pb/208Pb ages of constituents of primitive meteorites the Cal-Al-rich Inclusions (CAIs) [e.g., 2]. The CAIs have some of the highest observed abundance of short lived radionuclide Al26 (half-life ~ 0.7 Ma) which decays to Mg26, with 26Al/27Al ~ 5×10^{-5} [3]. The early melting and differentiation of planetary bodies is attributed to the decay of heat generating 26Al [4, 5]. The ability of 26Al to melt an object will be determined by its abundance and the size of the planetary body [6]. Bodies with radii < 20km will not undergo complete melting; however a part of the inner core temperatures may exceed the solidus (~1200°C) when radius > 5km [6]. The radii of parent bodies of Fe-meteorites range from 3-165km [7]. Melting of a small planetary body with ~ 3 km radius and chondritic composition cannot be easily explained. Furthermore, based on 26Al abundance a hiatus of ~ 2 Ma is estimated between formation of CAIs and chondrules [e.g., 8]. If CAIs formed at a rapid rate they would have experienced gas drag resulting in their spiralling in to the early Sun [9]. The two possible mechanisms suggested to preserve CAIs is turbulent flow or rapid accretion of CAIs into small bodies. We report preliminary results of thermal evolution of small planetary bodies with CAI abundance greater than chondritic bodies resulting in higher than normal Al abundance. This will increase the 26Al content per unit mass of the body, resulting in higher energy generation due its radioactive decay. In our calculations we observe that if the CAI content is varied between ~25% and 50% in a 3 km (radius) body, ~66% and 76% of the inner core of the body will respectively exceed solidus resulting in large scale differentiation and formation of Fe-cores. Bodies with very high CAI were recently reported [10]. The early sequestration of CAIs may be responsible for early formation of Fe-meteorites and angrites [1, 11].

An investigation of basaltts from the Central Indian Ocean Basin

PRANAB DAS AND SRIDHAR D. IYER

National Institute of Oceanography, Dona Paula, GOA-403 004, INDIA; (pinku.dass@gmail.com, iyer@nio.org)

Basalts were recovered along with manganese nodules and encrustations from the Central Indian Ocean Basin (CIOB). The basaltts are from the oceanic crusts and from a few seamounts, the latter being the manifestations of propagative fractures that formed from the ancient conjugate crusts of the South East and Central Indian Ridges. Magnetic anomalies (A26-A22) suggest the crust of the CIOB to be 60-52 Ma. Petrologically, the basaltts are aphyric to moderately porphyritic with plagioclase forming a dominance of phenocrysts and microphenocrysts embedded in a glassy groundmass. Pyroxene and olivine occur in lesser amount together with a few opaque minerals.

Bulk-rock analyses indicate that the basaltts from the CIOB are mainly hypersthenic normative (3 – 19% hypersthene). Major element of the CIOB basaltts show a wide range of variation of SiO2 (~46 – 51 wt%) and MgO (~2.8 – 7.14 wt%). FeO (~9 to 17 wt%), TiO2 (1.27 to 4 wt%) and Na2O (2.43 to 4.26 wt%) exhibit an increase for a given MgO concentration. The concentrations of K2O (0.24-1.6 wt%) and P2O5 (0.09-0.31 wt%) in the CIOB basaltts are relatively higher than the general MORB and relatively lower than the K-P type basaltts indicating a slight enrichment of K and P, similar to ferrobasaltic melts. The CIOB basaltts typically have high incompatible contents (TiO2, La = 2.7-16.31 ppm, Rb > 6 ppm) and moderate LREE concentration.

A quantitative major and trace element modeling indicate that most of the variations are attributable to low-pressure fractional crystallisation under low fO2 condition of olivine, pyroxene and Ca-plagioclase. This plausibly led to the formation of Fe-Ti-rich basalt in the CIOB. The decreasing CaO/Al2O3 ratios and relatively constant Sc abundance with decreasing Mg# (55 to 31), supports the above view. The incompatible element ratios (Zr/Nb= 25-166; Y/Nb= 7-63; (La/Sm)_N= 0.58-1.46) are similar to ‘normal’ or ‘enriched normal’ mid-oceanic ridge basalt.

The above investigation of basaltts from the CIOB indicates a similar formation history of magmas from different source regions or alternatively a single magmatic source followed a similar elemental enrichment trend prior to eruption from the ancient South East and Central Indian Ridges.
Phosphorus sedimentation and release processes in a shallow hyper-eutrophic lake, Zeekoevlei in South Africa

SUPRIYO K. DAS¹, JOYANTO ROUTH¹ AND ALAKENDRA N. ROYCHOUDHURY²

¹Department of Geology and Geochemistry, Stockholm University, Stockholm, SE-10691, Sweden (supriyo.das@geo.su.se; joyanto.routh@geo.su.se)
²Department of Geological Sciences, University of Cape Town, Rondebosch 7700, South Africa (aroy@geology.uct.ac.za)

We investigate phosphorus (P) accumulation and release processes in a shallow alkaline hyper-eutrophic lake Zeekoevlei, in South Africa by analysing dissolved phosphate (PO₄³⁻) in waters and sediment pore waters, and organic P (OP), inorganic P (IP), calcium (Ca) and iron (Fe) bound P (HCl-P and NaOH-P respectively) fractions in sediments. Zeekoevlei is suspected for considerable internal P release from P-rich surface sediments that have accumulated from extensive cultural input by seasonally controlled catchment runoff. Absorption and coprecipitation by CaCO₃, planktontic P assimilation and aggregation of Ca-P with planktons control dissolved PO₄³⁻ removal from the water column and its subsequent sedimentation. Moreover, PO₄³⁻ absorption on iron (Fe) oxy-hydroxides contribute to the P absorption process in aerobic lake sediments. Low (10-12) atomic carbon/nitrogen (C/N) ratio indicates algae is the main source of sedimentary organic matter, and lake primary productivity, which is affected by dredging in 1983, controls the OP and IP sedimentation. Significant refractory OP fraction in surface sediments indicate higher recycling of algal-bound P in water and restricts aerobic OP mineralization by benthic bacteria. Low (2-3) Fe/P ratio in surface sediments and high pore water PO₄³⁻ concentration (1.69-4.07 mg L⁻¹) indicate higher P saturation and the fully utilised binding capacity of Fe for P. However, the high carbonate content (~6%) leads to continuous absorption of PO₄³⁻, and results in high P retention in sediments. An upward decreasing concentration gradient of pore water PO₄³⁻ suggests insignificant diffusion-mediated upward transport of P, which is consistent with the above finding. These imply ineffectiveness of internal P release process from the calcareous oxic sediment towards the TP pool in Zeekoevlei.

Kinetic and equilibrium iron isotopic fractionation at high temperature

N. DAUPHAS

Origins Laboratory, Department of the Geophysical Sciences and Enrico Fermi Institute, The University of Chicago, 5734 South Ellis Avenue, Chicago IL 60637 (dauphas@uchicago.edu)

Because of a small relative mass difference between adjacent isotopes and because equilibrium fractionation decreases in magnitude with increasing temperature, detection of isotopic fractionation of Fe at high temperature has only recently been explored. Using MC-ICPMS, δ⁵⁶Fe can now be analyzed accurately with precisions of better than 0.05 ‰ (e.g., Dauphas & Rouxel, 2006). Iron isotopic variations at high temperature have been documented in bulk rocks and individual minerals. In some instances, the mechanisms responsible for these variations can be identified.

Subsolidus diffusion. Mullen (1961) first showed that diffusion of Fe in metal could cause isotopic fractionation. During cooling of iron meteorites, growth of kamacite out of taenite is limited by diffusion. Several groups have measured Fe and Ni isotopic fractionation between taenite and kamacite in iron meteorites (e.g., Poitrasson et al., 2005; Horn et al., 2006). Modeling shows that this is best explained by differences in the diffusivities of the isotopes of Fe and Ni during diffusion at temperatures in the range ~450 to 650 °C.

Evaporation and condensation. The kinetic theory of gases predicts that there should be isotopic fractionation during evaporation or condensation, controlled by the degree of under or super saturation of the gas. Experiments of free evaporation of molten FeO and a complicated mixture of oxides show that Fe is indeed isotopically fractionated during these processes (e.g., Dauphas et al., 2004). A zoned metal grain in a chondrite shows correlated zonings for Fe and Ni isotopic compositions (down to ~6 ‰/amu at the core), demonstrating that it formed by condensation (Alexander & Hewins, 2004).

Inter-mineral equilibrium fractionation. Polyakov et al. (2007) showed that measurable equilibrium fractionation between mineral pairs such as pyrite-siderite or magnetite-siderite should exist at temperatures in excess of 500 °C. We measured the Fe isotopic fractionation between magnetite and siderite/pyroxene in BIFs metamorphosed to amphibolite and granulate facies. The measured compositions are in agreement with predictions, validating Fe isotopes as potential geothermometers in regionally metamorphosed terranes.

Carbonation of Ca- and Mg-rich silicates: Experimental investigations and kinetic modeling

D. DAVAL1,2, I. MARTINEZ1, B. GOFFE2 AND F. GUYOT1,3

1IPGP, Paris, France (daval@ipgp.jussieu.fr, martinez@ipgp.jussieu.fr, guyot@ipgp.jussieu.fr)
2Laboratoire de Géologie, ENS, CNRS, Paris, France (bruno.goffe@cnrs-dir.fr)
3IMPMC, Paris, France.

Among the different ways considered to store CO2, the safest one involves the conversion of CO2 to its geologically stable carbonate form. The corresponding reaction (where M is a divalent species):

MxSiOy+(2x-y)(OH)2y+xCO2 ⇌ xMCO3 + ySiO2 + tH2O

is thermodynamically favoured for Ca- and Mg-rich silicates like (ultra)basic minerals (e.g. olivine, serpentine) (Robie & Hemingway, 1995). The efficiency of this method to store large amounts of CO2 essentially depends on the overall reaction rate of carbonation, for which experimental data are scarce.

Recent studies (e.g. Giammar et al., 2005; Huijgen et al., 2006; McGrail et al., 2006) have demonstrated that such a reaction could occur relatively rapidly in hydrothermal conditions. However, kinetic modeling remains absent in most of those investigations.

Our ongoing work both combines laboratory experiments and kinetic modeling, at conditions relevant for geological storage (T=363 K, pCO2 = 25 MPa). Experiments are performed in separated batch capsules filled with monomineral powders and water, introduced in a Ti-autoclave. Different reaction times (from few hours to months) are tested to follow the reaction advancements. Reaction products are identified using SEM, TEM and Raman spectroscopy, and carbonation rates are determined by different analytical methods (Rietveld refinement of X-Ray diffractograms, mass balance, and selective acid attack of carbonates followed by dosage of produced positive ions). These investigations are coupled with kinetic modeling (CHESS, van der Lee, ENSMP, Paris) using data from the literature for each main step of the reaction (silicate dissolution, carbonate precipitation).

We will present our results, focusing on the carbonation of wollastonite (CaSiO3). Then we will discuss some causative factors to explain discrepancies between modeling and our experimental results, such as the general form of kinetic rate laws or armouring effect.

Amphibole control in the differentiation of arc magmas

J. DAVIDSON1, C. MACPHERSON1 AND S. TURNER2

1Department of Earth Sciences, University of Durham, DH13LE, UK (j.p.davidson@durham.ac.uk and colin.macpherson@durham.ac.uk)
2Department of Earth Sciences, Macquarie University, Sydney, Australia, (sturner@els.mq.edu.au)

Subduction-related volcanic rocks are commonly porphyritic, with a typical gabbroic assemblage of plag ± px ± ol. Rock suites from arc volcanoes, can, in terms of major elements, be modelled as due to extraction of this assemblage. However, three observations mitigate against this simple interpretation;
1. Petrographic observations suggest that many of the “phenocryst” phases are not in equilibrium with the liquid in which they were erupted – these phases are, in many cases, more appropriately referred to as antecrysts.
2. A significant amount of crystallisation (microlites, rims on antecrysts) occurs rapidly in response to decompression during ascent, and this material is not efficiently removed/fractionated from the liquid, and
3. Trace element characteristics are difficult to reconcile with simple gabbro fractionation

We compiled REE data from several cogenetic arc suites, and found compelling evidence for a significant role for amphibole in the majority of cases (Fig. 1). A significant decrease in Dy/Yb with SiO2 can only be attributed to amphibole partitioning, either as a directly fractionating phase, or as a residual phase in more complex melting-mixing mechanisms. The implication is that there is a major amphibole–bearing reservoir formed in the arc crust as a result of differentiation of ascending magmas. This reservoir can 1) sequester a fraction of the mantle-derived water from primary magmas, and 2) provide a potentially fertile source for intracrustal melting, producing hydrous silicic magmas.

Note that trends in Fig 1 do not back-project to a common parent, implying that parental compositions are defined by another control (deep early differentiation, possibly with garnet, or mantle source variation with different slab components)

Figure 1. Compilation of differentiation suites from arc volcanoes showing evidence for amphibole fractionation.
The origin of silica-rich Kaapvaal lithospheric mantle
G.R. DAVIES1, L. WASCH1, F. VAN DER ZWAN1, M.L.A. MOREL1, O. NEBEL1, W. VAN WESTRENEN1, D.G. PEARSON2 AND E.W.G. HELLEBRAND3
1Department of Petrology, Vrije Universiteit Amsterdam, NL.
2Department of Earth Sciences, Durham University, UK.
3SOEST - University of Hawaii, USA.

The Archaean Kaapvaal lithospheric mantle is residual after extensive melt removal but is characterised by high silica content and is often enriched in incompatible trace elements [1]. The timing and nature of the silica enrichment process is not understood partly because interpreting the temporal evolution of mantle xenoliths is complicated by recent interaction with kimberlite. Here we report a combined petrology and in situ major and trace element and mineral Sr-Nd-Hf-Os isotope study of extremely silica-rich and undeformed xenoliths from Kimberley, S.A. Silica enrichment is manifested in two forms: i) orthopyroxene (opx)-rich clots (75% opx, 15% garnet (gnt), 10 % olivine) and veins (5-20 cm) that have mutual gnt and opx exsolution; ii) gnt-rich clots (80% gnt, 15% opx, 5 % ol). Some samples appear recently metasomatised. This process is manifested by clinopyroxene (cpx) and is associated by LREE enriched whole rock patterns with YbN~2, NdN~15. All minerals are in chemical equilibrium and the rocks have isotopic systematics indicating interaction with the host kimberlite. In contrast, Opx and Gnt-clots have “S” shaped REE patterns with YbN~0.5, NdN~10, LaN~0.1 with a maximum at Sm or Nd. Opx-clots have time integrated low Lu/Hf, down to εHf ~15 but variable Sm/Nd ratios, whereas the gnt-clots have time integrated LREE depleted isotopic signatures (εHf + 10). The combined trace element and isotopic data are used to formulate a model for the nature and timing of the silica addition to the Kaapvaal lithosphere.

The ion nanoprobe: A new instrument for isotopic and chemical analysis at the few-nanometer scale
A. M. DAVIS1,2, I. V. VERYOVKIN2,3, M. J. PELLIN2,3 AND M. R. SAVINA2,3
1Department of the Geophysical Sciences and Enrico Fermi Institute, University of Chicago, Chicago, IL 60637 (a-davis@uchicago.edu)
2Materials Science Division, Argonne National Laboratory, Argonne, IL 60439 (verigo@anl.gov; pellin@anl.gov; msavina@anl.gov)
3Chicago Center for Cosmochemistry

A variety of techniques have been developed or are under development to study the properties of materials at the nm scale, including transmission electron microscopy (TEM) and nm-size x-ray beams. These techniques are unsurpassed for studying the distribution and local environment of atoms on this scale, but are unable to measure isotopic composition. At the µm scale, the secondary ion mass spectrometer (SIMS), commonly known to geochemists as the ion microprobe, is widely used to measure isotopic compositions. The most advanced SIMS instruments can produce isotopic images with 100 nm resolution.

The increase in spatial resolution from the earlier generation SIMS instruments such as the Cameca ims-3f to the latest Cameca NanoSIMS-50 led to important new discoveries, such as the discovery of isotopically anomalous ~500 nm presolar silicates. We plan to build a new instrument that will take another substantial leap forward in spatial resolution, to 5–10 nm. This is perhaps the last such leap, as there are so few atoms in a few-nm analysis spot (a 5 nm diameter sphere of SiC contains only 3200 atoms). In order to make isotopic and trace element analyses at this spatial scale, very high sensitivity is essential. The ionization efficiency in SIMS is typically 10–3, but can be higher for selected elements. The useful yield (ions detected per atom consumed) in SIMS can exceed 1% in only a very few cases. We have developed techniques for laser postionization of ion-sputtered or laser-desorbed/laser-ablated neutral atoms that have much higher ionization efficiency, which results in a remarkably high useful yield (exceeding 20% in the latest generation instrument built by us) and approaching the atom-counting limit. The new instrument will combine a recently developed high resolution liquid metal ion gun, tunable solid state lasers, and an improved time-of-flight mass spectrometer. By analogy with the ion microprobe, a common name for SIMS, we dub the new instrument the “ion nanoprobe”. Development of this instrument will fill a major gap in analytical capability between chemical composition at the nm scale and isotopic composition at the µm scale.

The ion nanoprobe is perhaps best suited to analysis of interstellar and cometary dust returned by the Stardust mission as well as presolar grains in meteorites, where large isotopic variations occur on very fine scales, but a wide variety of applications are envisioned.
Sub-m.y. age resolution for Precambrian igneous events by thermal extraction (TE-TIMS) Pb dating of zircon: Application to progressive crystallization of the 1849 Ma Sudbury impact melt

DONALD W. DAVIS
Department of Geology, University of Toronto, 22 Russell St.,
Toronto, Ontario, Canada M5S 3B1
(dond@geology.utoronto.ca)

Age precision of Precambrian zircon dated using ID-TIMS is usually limited to about 1 m.y. by variable isotopic fractionation in the mass spectrometer and by secondary Pb loss. Thermal pre-heating of cracked and/or altered zircon grains to 1550°C removes most Pb from damaged domains as noted by Kober (1986, 1987), but extraction of primary Pb by evaporation produces relatively small ion beams. Embedding a pre-treated zircon in silica glass by fusion with silica gel on a Re filament allows the primary radiogenic Pb isotopic composition to be measured to high precision on a multi-collector mass spectrometer during thermal extraction of Pb into the silica melt. \(^{206}\text{Pb}\) emission from embedded grains shows a rapid increase at 1600°C to several 100 mv and can be maintained for up to an hour. \(^{207}\text{Pb}/^{206}\text{Pb}\) ages, corrected for common Pb on a cycle-by-cycle basis, generally show a plateau around maximum emission with no systematic increase due to fractionation until near the end of the run. Comparison of TE-TIMS ages on Archean rocks precisely dated by ID-TIMS consistently shows an isotopic fractionation factor of 0.18%/AMU, slightly higher than with ID-TIMS. This new approach has been applied to two phases of the Sudbury impact melt, previously dated at 1850 \(\pm \) 1 Ma by Krogh \textit{et al.} (1982, 1984). TE-TIMS on five single zircon grains from one phase, collected near the northern boundary of the intrusion (Felsic Norite), defines an age of 1849.53 \(\pm \) 0.21 Ma. Six grains from a second phase, collected from the middle of the intrusion on its southern side (Mafic Norite), yielded a younger age of 1849.11 \(\pm \) 0.19 Ma. No difference was found between abraded and unabraded grains from each sample. Errors are 95\% confidence limits and include no error for fractionation. MSWD is 2.0 for both data sets but adding an error of 0.01\% (0.18 m.y.), to account for variability of fractionation, to the age of each grain reduces the MSWD’s to about 1 and results in essentially the same errors for the weighted averages as above. New, less precise ID-TIMS results on abraded zircon from the Felsic and Black Norite agree with TE-TIMS results, with intercept ages of 1849.6 \(\pm \) 0.8 Ma and 1849.1 \(\pm \) 1.2 Ma, respectively. This ca. 0.4 m.y. time interval is longer than expected for passive cooling. It suggests that either the impact melt volume was much larger than previously thought or excavation of the crust resulted in decompression melting and advection of heat from the underlying mantle, which maintained a long-term thermal anomaly beneath the zone of crustal melting.

Stable isotopic evidence of evolving Laramide landscape in the central North American Cordillera

S. J. DAVIS\(^1\), A. MULCH\(^2\) AND C. P. CHAMBERLAIN\(^3\)

\(^1\)Stanford University, Department of Geological and Environmental Sciences, Stanford, California (sjdavis@stanford.edu)
\(^2\)Leibniz Universität Hannover, Institut für Geologie, Hannover, Germany (mulch@geowi.uni-hannover.de)
\(^3\)Stanford University, Department of Geological and Environmental Sciences, Stanford, California (chamb@pangea.stanford.edu)

A growing dataset of stable isotopic records from the western United States is evidence of an evolving landscape during the early Cenozoic. New isotope records from three intraforeland basins of Paleogene Utah are characterized by large (>5‰), diachronous shifts in \(\delta^{18}\text{O}\) values. Combined with previous studies of provenance and paleoflow, these isotopic results are interpreted to reflect changes in hydrology and catchment hypsometry as the basins responded to growing relief in the foreland.

Decreasing isotopic trends indicate an increase in hypsometric mean elevation of catchments feeding each of the studied basins during the Middle and Late Eocene. Along with isotopic trends, evidence of hydrology, sediment provenance and active tectonism supports the development of relief as the subsiding foreland was segmented by Laramide uplifts. Although hypsometry of catchments increased, there are no signs that mean elevation in the foreland increased. Thus, we prefer a model of landscape evolution in which the area of catchments decrease, and sources of water to intraforeland basins are increasingly confined to elevated bounding structures.

The timing and magnitude of isotopic shifts in the studied Utah basins is coincident with the previously observed pattern of similar shifts spreading southward from Montana to southern Nevada between Early Eocene and Oligocene, suggesting that a progression of large-scale topographic development affected both hinterland and foreland. With this study, we increasingly favor an explanation for topographic modification wherein relief grows but mean elevation stays the same or possibly decreases.
Significance of Magmatic epidote in the Azna pluton, Iran

D. ALI REZA DAVOUDIAN1, B. NAHID SHABANIAN2 AND MAMOUD KHALILI3

1Shahrekord University, Shahrekord, Iran (alireza.davoudian@gmail.com)
2Isfahan University, Isfahan, Iran (nahid.shabanian@gmail.com)
3Isfahan university, Isfahan, Iran (mahmoud_khalili@hotmail.com)

Magmatic epidote can be a good indicator for the pressure, temperature and original water content of a granitoid body. The Azna syn-tectonic pluton is emplaced within shear zone of the Azna in magmatic-metamorphic belt of Sanandaj-Sirjan. Based on the relationships of Zr + Nb + Ce + Y vs. 10000*Ga/Al suggest an A-type character for these granite. On the tectonic discrimination plots, these granites indicate a within-plate granite character.

The main minerals in the pluton are quartz, plagioclase, microcline-perthite, biotite and phengitic muscovite and the accessory minerals are zircon, allanite, epidote and tourmaline. Plagioclase is as coarse porphyroclast. They do not display any alteration. Biotite is euhedral to subhedral. Biotites are concentrated in the main foliation. Epidote tends to be associated with the biotites; therefore epidote is abundant in the main foliation with biotite. Fine grain epidote crystals are anhedral to subhedral. They occur as faintly to conspicuously pleochroic crystals. Allanite forms cores of some epidote crystals. Generally the epidote crystals are homogenous. Electron microprobe analyses of epidotes from Anza pluton revealed low TiO2 and pistacite content is equal to 0.27.

The lack of alteration of minerals in the rocks suggests that a late vapour phase may have been absent. The textural relations of epidote, biotite and plagioclase as described above, the lack of alteration of minerals and the involvement of epidote in the main foliation show that the epidote is truly a magmatic mineral. Magmatic epidote in a plutonic rock signifies that the rock probably crystallized at pressures of at least 8 Kbar (25-30 km depth) and they must have been removed since emplacement of the pluton.

Isotopic and Geochemical characteristics of kimberlite from Raipur and Tokapal, Chattisgarh, Central India

A.M. DAYAL
National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India (dayalisotope@yahoo.com)

Four kimberlite fields have been located from Mainpur kimberlite filed (MKF) in Raipur district, Chattisgarh, central India. These Kimberlite fields are Payalikhand, Bahradih, Jangra and Kodamalli. Later Tokapal and Bhejripadar kimberlite fields (TKF) in Bastar district were reported by Geological survey. Kodamalli kimberlite of MKF was intruded in the Late Proterozoic sediments. These kimberlites occur close to the junction of Bastar craton (BC) and Eastern Ghat Mobile Belt (EGMB). Mainpur kimberlite field is located within Bastar craton close to its contact with the granulite terrain of the lower to Middle Proterozoic Eastern Ghts Mobile belts in the east. Based on mineral assemblages and texture it can be classified as hypabyssal facies group I kimberlite.

The concentration of incompatible elements for Kodamalli kimberlite is higher than kimberlite from Tokapal from the same craton. The REE concentration at Kodamalli kimberlite is similar to Bhejripadar and Tokapal. The variation of abundance ratio for Zr/Hf indicates variable intensity of metasomatism by carbonates and suggests that the source magma of the Kimberlite of Kodamalli and Bhejripadar/Tokapal are different and was metasomatically enriched in different degrees prior to kimberlite generation. The Zr/Nb vs La/Yb ratios of Kodamalli and Bhejripadar/Tokapal kimberlites show that the Kodamalli kimberlites have high Zr/Nb ratio and low La/Yb ratios. The plot of Ce/Yb vs Zr/Nb shows that the source rock for Kodamalli kimberlite is different than Bhejripadar and Tokapal kimberlites. The highly fractionated REE distribution (La/Yb >50) in kimberlites indicates that the source lithologies contain garnet and that partial melting occurred in the presence of garnet. The positive anomaly for Ta and Nb in both the kimberlite indicates the mantle source with residual titanite. The presence of Rb anomalies suggests the presence of residual phlogopite in the mantle.

Strontium isotopic data for these kimberlites gives an initial ratio of ~0.7045 at 1100 Ma. Lehman et al. (2002) reported εNd = +11.8 at 1080 Ma for this kimberlite, which is quite different than kimberlite, which is quite different than kimberlite, from Tokapal, Bhejripadar, Majhgawan and Lattavaram (εNd ~+2 at 1080 Ma).

Integrated geochemical studies of hydrocarbon in Proterozoic basins

A.M. DAYAL\(^1\) AND S.V. RAJU\(^2\)

1National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India. (dayalisotope@yahoo.com)
2Directorate General of Hydrocarbon, Floor No.4, Hindustan Times House, K.G. Marg, New Delhi 110001.

There are number of unexplored Proterozoic basins for hydrocarbon in India. These basins are characterized by varied geology, age, tectonics and depositional environments. Hydrocarbons generated and trapped beneath the sub-surface seeps to the surface in varying but detectable quantities. Diffusion, effusion, and buoyancy allow these hydrocarbons to escape from reservoirs and migrate to the surface where they are retained in the sediments, diffuse to atmosphere or water columns. Based on these assumptions, surface geochemical prospecting lab has been developed to identify the surface or near surface occurrences of hydrocarbons. The facility includes adsorbed soil gas surveys in light hydrocarbon (C\(_1\)-C\(_4\)), \(^{13}\)C/\(^{12}\)C measurement on C\(_1\)-C\(_4\) and microbial techniques. Surface geochemical research for hydrocarbon was carried out in various in parts of Vindhyan basin, Cuddapah basin, Kaladgi basin, Kutch basin and Jamnagar sub-basin. Soil samples from Vindhyan, Cuddapah and Kaladgi basins were analysed for light hydrocarbon, Carbon isotopic ratio and microbial analyses. Cross plot between C\(_1\)-C\(_2\), C\(_1\)-C\(_3\), C\(_2\)-C\(_3\) show linear correlation which indicates that light hydrocarbon migrated from thermogenic source. Pixler plot (C\(_1\)/C\(_2\) and C\(_1\)/C\(_3\)) plot distinguish the non productive zone from oil/gas producing zone. \(^{13}\)C analyses of C\(_1\)-C\(_4\) suggest thermogenic source for these hydrocarbon. Microbial analyses for MOB and POB also show anomalous concentrations in some of the samples. Integrated geochemical studies in these Proterozoic basins suggest warm area for hydrocarbon exploration.

Lu-Hf and Sm-Nd isotopic study of Martian meteorites: Implications for early differentiation on Mars

V. DEBAILLE\(^1\), Q.-Z. YIN\(^2\), A.D. BRANDON\(^3\) AND B. JACOBSEN\(^4\)

1Lunar and Planetary Institute, Houston, USA (debaille@lpi.usra.edu)
2University of California Davis, Davis, USA (yin@geology.ucdavis.edu; jacobsen@geology.ucdavis.edu)
3NASA-Johnson Space Center, Houston, USA (alan.d.brandon@nasa.gov)

We present a new study of \(^{176}\)Lu-\(^{176}\)Hf and \(^{142}\)Sm-\(^{142}\)Nd isotope systematics in 12 SNC meteorites including 3 nakhlites (Nakhla, MIL03346, Yamato000593), 3 depleted shergottites (SaU008, SaU094, DaG476), 1 intermediate composition shergottite (EETA79001), 4 enriched shergottites (Shergotty, Zagami, Los Angeles, NWA856) and the orthopyroxenite (ALHA84001). The objective is to provide constraints on processes occurring during the early differentiation of Mars and the subsequent crystallization from a magma ocean, resulting in compositionally distinct cumulates. All the shergottites define a mixing trend between a depleted end-member, likely represented by depleted shergottites, and an enriched end-member. Shergottites also plot to the right of a 1:1 line for their calculated time-integrated mantle sources \(^{147}\)Sm/\(^{144}\)Nd vs. measured ratios in lavas. This can be explained by two successive partial melting events that are close in time in the depleted shergottite source. This results in an increased Sm/Nd in the source and in turn produces magmas with Sm/Nd ratios that are greater than time-integrated Sm/Nd ratio inferred from \(^{143}\)Nd/\(^{144}\)Nd. This implies that all the shergottites share a common depleted source and that the enriched shergottites are not corresponding to the enriched end-member of the mixing trend. Shergottites plot to the left of the 1:1 line in a similar diagram using \(^{142}\)Nd/\(^{144}\)Nd. This is because ilmenite is unlikely significant in the Martian mantle, the only other prevalent mantle mineral able to efficiently fractionate these Lu/Hf and Sm/Nd ratios is magnesio-perovskite. This would place the depleted shergottites source in the lowermost Martian mantle, close of the core-mantle boundary. This source may be early cumulates crystallizing from a magma ocean. Acquisition of \(^{142}\)Nd/\(^{144}\)Nd data should give a clearer answer to this problem. Nakhlites are characterized by low \(\varepsilon_{\text{Hf}}/\varepsilon_{\text{Nd}}\) ratios, consistent with a source having experienced ancient garnet segregation.

Finally, Lu-Hf and Sm-Nd systematics of the orthopyroxenite ALHA84001 require a reassessment of the crystallization age of this sample, because a 4.5 Gy crystallization age produces an unrealistically depleted source \(^{147}\)Sm/\(^{144}\)Nd of 0.66 and \(^{176}\)Lu/\(^{177}\)Hf of 0.23. A crystallization age of 3.9 Gy gives more consistent results and is therefore preferred.
Biological versus chemical sulfide oxidation in Beggiatoa inhabited sediment

DIRK DE BEER, ANNA LICHTSCHLAG, GAUTE LAVIK AND BO BARKER JORGENSEN
Max-Planck-Institute for Marine Microbiology, Celsiusstrasse 1, 28359 Bremen, Germany

We investigated the contribution of metal cycling and biological processes in the oxidation of sulfide in organic-rich marine sediments, covered with Beggiatoa mats. Beggiatoa are large gliding filamentous sulfur bacteria, that can store high concentrations of nitrate in vacuoles. They use their nitrate stores to oxidise sulfide in the 2-4 cm thick suboxic zone, which is their typical habitat. We evaluated the importance of Beggiatoa to chemical oxidation of sulfide, i.e. by metal cycling.

The sulfide oxidation rate by Beggiatoa was quantified from their distribution and cell-specific activity, and by 15N-tracer experiments. Microsensors for H2S, pH, NO3- and O2 were used to characterize the microenvironment and to calculate fluxes of sulfide, NO3- and O2. The sulfide supply into the suboxic zone was determined from sulfate reduction rates and sulfide fluxes from deeper sediments, determined with microsensors.

The sulfide input in the suboxic zone was dominated by a diffusional flux from deeper sediments, while the local production by sulfate reduction was low. The total influx of sulfide was much higher than the sulfide oxidising capacity of the Beggiatoa community. Thus most of the sulfide was removed by chemical processes, mainly binding to Fe(II) and oxidation by Fe(III). This was confirmed by highly characteristic pH profiles, showing a maximum value in the zone where sulfide dissipated. The Fe(II) formed by Fe(III) reduction diffused upward where it was oxidised by Mn(IV), detected by a strong pH decrease. Indeed geochemical analyses showed a distinct Mn(IV) peak in the upper sediments, and the distributions of Fe(II) and Fe(III) confirmed this scenario.

Thus the steep sulfide gradient and high sulfide flux, a typical characteristic of Beggiatoa habitats, is not needed for their metabolic performance. Beggiatoa can glide long distances before nitrate is depleted. We concluded that the free sulfide below the suboxic zone is used as a chemotactic cue by the highly motile filaments to avoid getting lost at depth in the sediment. This means that the distribution of Beggiatoa is a response to- rather than a determinant of the sulfide distribution.

Low-density geochemical mapping in Australia: Pilot projects and outline of a continental-scale geochemical survey

P. DE CARITAT1,2, M. E. LECH2 AND A. MCPHERSON2
1Cooperative Research Centre for Landscape Environments and Mineral Exploration (CRC LEME)
2Geoscience Australia (GA), GPO Box 378, Canberra ACT 2601, Australia (Patrice.deCaritat@ga.gov.au)

Pilot projects

Over the past few years, CRC LEME and GA have carried out 4 pilot geochemical surveys aimed at developing and field-testing a low-density sampling strategy adapted to Australian landscapes and climatic conditions. Further, protocols for sample collection, preparation and analysis were developed to ensure quality data were acquired.

The pilot projects were undertaken in the Curnamona region of western New South Wales (NSW) and eastern South Australia (SA), and in the Riverina (southern NSW and northern Victoria), Gawler (central SA) and Thomson (northern NSW) regions. We tested various:

- sampling media (soils, overbank/floodplain sediments, ‘outlet sediments’, groundwater, vegetation),
- sampling depths (‘top’: 0-10 cm, ‘bottom’: a 10 cm interval at ~60-95 cm depth, complete profiles),
- fractions (<2 mm, 2-1 mm, 1000-500 μm, 500-180 μm, <180 μm, 180-75 μm, <75 μm, heavy minerals),
- digestions (total, multi-acid, aqua regia, Mobile Metal Ion Technology®, sequential extractions), and
- analytical methods (INAA, XRF, ICP-MS, GF-AAS, ISE, XRD, PIMA).

The National Geochemical Survey of Australia

Based on lessons learned from the pilot projects, a National Geochemical Survey of Australia (NGSA) project was developed, which recently received funding through the Australian Government’s Onshore Energy Security Initiative. The aim of the NGSA project is to provide pre-competitive data and knowledge to support exploration for energy resources in Australia. The survey will sample sediments at the outlet of ~1400 catchments covering >90% of the Australian mainland, giving an average sampling density of ~1 site/5500 km2. Materials will be collected from 2 depths (0-10 cm and ~60-70 cm) and separated into 2 size fractions (<2 mm and <75 μm). Analysis of these materials, mostly by XRF and ICP-MS, will yield total concentrations for ~60 elements. The project will result in Australia’s first continental-scale, internally consistent geochemical data layer. The data will be useful for an array of applications, such as identifying geological domains likely to host specific uranium and thorium deposit types, and correlating geochemical data with airborne radiometrics data. The NGSA project will run from 2007 to 2011 and will deliver a publicly available geochemical database and atlas on the web.
Reactivity of a rhyolitic glass

J. DECLERCQ1 AND E.H. OELKERS2

1Department of Geoscience, University of Oslo, P.B. 1047 Blindern, 0316 Oslo, Norway
(julien.declercq@geo.uio.no)
2Géochimie et Biogéochimie Expérimentale, LMTG, Université Paul Sabatier/CNRS-UMR 5563, 14 rue Ave Edouard Belin, 31400 Toulouse, France
(oelkers@lmtg.obs-mip.fr)

The dissolution mechanism of basaltic glass had been defined by Oelkers and Gisladson (2001), but very little is know about acidic glass such as rhyolitic glass.

Ryolitic glass was processed in a mixed flow reactor ParrTM. As a proxy for the dissolution rate we have used the outlet concentration of Si and Al. The conditions of the experiment was from 40 to 200°C and a pH from 2 to 10.6.

The dissolution mechanism of the basaltic glass is defined by the following equation (1):

\[ r_e = A \exp \left(\frac{E_a}{R} \left(\frac{a_3}{a_3^{0.18}}\right)^{1/\alpha}\right) \]

With A a constant, Ea the activation energy, R the perfect gas constant, T the temperature and ai the activity of i.

Assuming that the dissolution mechanism is the same for both glasses we determined each parameter separately and obtained the following equation:

\[ r_e = 0.031 \exp \left(\frac{-77300}{RT} \left(\frac{a_3^{0.18}}{a_3^{0.18}}\right)^{0.18}\right) \]

The good fit of the computed (eq.2) and predicted data (fig.1) shows that this equation can predict the dissolution rate of the rhyolitic glasses implying that the same mechanism.

Figure. 1: Comparison between the predicted dissolution rate and the rate measured.

Because the dissolution mechanism for the rhyolitic and basaltic glass is the same it is possible to develop a general equation for the dissolution of natural glass.

Sr-Nd isotope data on diorite-trondhjemite associations from the central Norwegian Caledonides

H. DE COCK1 , J. HERTOGEN1 AND J. KOŠLER2

1Geo-Institut, K.U.Leuven, B-3001 Leuven, Belgium
(helena.decock@geo.kuleuven.be)
2Dept. Earth Science, University of Bergen, N-5007 Bergen, Norway (jan.kosler@geo.uib.no)

The Trondheim Nappe Complex (TNC) comprises several slightly metamorphosed ca. 435 Ma old leucocratic igneous bodies and dykes. They often have ‘trondhjemitic’ affinity, but not all the leucocratic rocks share the typical characteristics of trondhjemites, such as a high Na/K ratio and strongly depleted heavy REE. The trondhjemitic rocks in the TNC are generally associated with dioritic rocks having mafic to intermediate composition. Since it seems unlikely that this close association in the field is fortuitous, it should be considered a significant pointer to the petrogenesis of the trondhjemitic series. Interest in trondhjemites has been revived because of the similarities to Cenozoic felsic rocks called adakites, which are thought to be melting products of the young, still hot subducted slab. If a similar origin applies to the Phanerozoic and older trondhjemitic rocks, it could help to understand the evolution of subduction-related petrogenetic processes throughout Earth’s history.

A detailed petrographical and geochemical investigation of these TNC felsic trondhjemitic series and associated mafic/intermediate rocks is in progress with the aim to reveal the petrogenetic relationship between the two series. Most of the leucocratic rocks show the pronounced depletion of heavy REE, which is generally attributed to partial melting of eclogitic parent rocks. The absence of negative Eu-anomalies in the REE patterns precludes derivation of trondhjemitic rocks from protracted fractional crystallisation of melts of intermediate composition. The associated mafic to intermediate rocks have REE patterns that are not depleted in heavy REE. They show geochemical characteristics typical of Cenozoic subduction related calc-alkaline series.

In contrast to the differences in major and trace element composition the trondhjemitic and associated mafic rocks have very similar isotopic composition of Sr and Nd. The ‘initial’ (i.e. at a nominal 435 Ma age) \(^{87}Sr/^{86}Sr\) ratios and \(\varepsilon\)Nd values of the greater part of the analyzed samples define an array between \(^{87}Sr/^{86}Sr\approx 0.703\); \(\varepsilon\)Nd= +6 and \(^{87}Sr/^{86}Sr\approx 0.706\); \(\varepsilon\)Nd= -4. The positive \(\varepsilon\)Nd data suggest that a depleted mantle or mantle-derived end-member was involved in the petrogenesis, while the higher \(^{87}Sr/^{86}Sr\) and negative \(\varepsilon\)Nd values seem to imply an additional enriched crustal component. Formation of the trondhjemitic rocks by melting of old crustal material appears improbable. Though it is premature to decide on the most plausible petrogenetic model for the TNC trondhjemites, a viable option is remelting of lower crustal plutonic equivalents of the mafic rocks that have been emplaced together with the trondhjemites at higher crustal levels.
Evaluation of the possibility of uranium 238 series dating for the Pliocene-Holocene basalt

E.V. DEEV1, S.V. PASESSKIY1, M.A. PHEDORIN2, I.V. NIKOLAEVA1 and G.S. DYAGILEV1

1Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (deev@uiggm.nsc.ru, stac@uiggm.nsc.ru, inikol@uiggm.nsc.ru, gesha@uiggm.nsc.ru)
2Institute of Petroleum Geology and Geophysics SB RAS, Novosibirsk, Russia (mikeph@mail.ru)

Evaluation of the degree of disequilibrium of the isotopes of U-series (U238) in recent basalts of Central Mongolia was carried out by means of inductively coupled plasma mass spectrometry (ICPMS).

The basalts of Taryat areal (Khangay, Mongolia) are conventionally dated as belonging to the Quaternary on the basis of paleomagnetic investigations, K/Ar dating and stratigraphic data [1,2]. However, the development of novel procedures of absolute dating of these recent vulcanites is urgent.

Measurements of the isotope ratios U238/U234, U238/Th230, U238/Th232 and U238/U235 were performed with a high-resolution mass spectrometer ELEMENT Finnigan MAT after leaching uranium and thorium from a weighed portion (0.1g) of the crushed rock with concentrated nitric acid under heating. Measurements were carried out in medium mass resolution mode (M/ΔM=4000). This mode allowed ion counting for all the mentioned isotopes, which resulted in a decreased interference of low-abundant U234, Th230 with abundant U238, Th232, the concentrations of which differ by 5 orders of magnitude.

The results show that the degree of modern disequilibrium of Th230 with U238 in the investigated samples is 0.7 to 1.2 for the Pliocene and Holocene basalts.

The observed deviation from the U234/U238 equilibrium, exceeding the measurement error, can be explained by different leaching of uranium isotopes in post-eruptive processes.

The achieved accuracy of measurements allows one to determine isochronous age of these basalts with the relative error of about 15% as a mean.

Impact of gold mining on levels of naturally occurring radionuclides in aquatic ecosystems of the Witwatersrand Basin, South Africa

G. DEISSMANN AND R. BARTHEL

BS Associates (Pty) Ltd, Bedfordview, South Africa
(g.deissmann@brenk.com, r.barthel@brenk.com)

For more than a century, uraniferous gold ores have been exploited by various mines in the “West Rand” and “Far West Rand” goldfields located in the catchment area of the Wonderfonteinspruit, west-southwest of Johannesburg, South Africa. The long-lasting mining-related discharges of naturally occurring radionuclides from point and diffuse sources into the Wonderfonteinspruit catchment area, which forms the eastern catchment of the Mooi River, result in a complex pattern of radioactive contamination of water bodies, sediments and soils throughout the area. As a consequence of the different sources of radionuclides (mine waters and slimes dams), their different geochemical and transport behaviour in the environment, and variations in the source term (intermittent mine water discharges, infrequent seepage water emission, sporadic erosion from slimes dams after heavy rainfalls) a high temporal and spatial variability of the contamination levels and the activity ratios of the various radionuclides in water and sediments/soils was observed.

Activities measured for the $^{232}$Th decay chain in water and sediment samples are predominantly low and near to natural background levels. In general, the activity concentration levels in surface waters are dominated by $^{238}$U and $^{234}$U, which are in secular equilibrium and in natural ratio with the $^{235}$U activity, and by $^{226}$Ra. At slimes dams, where acidic seepage occurs, secular equilibrium and in natural ratio with the $^{235}$U activity, and by $^{226}$Ra. At slimes dams, where acidic seepage occurs, elevated activity concentrations of $^{210}$Pb and $^{210}$Po in water ponds were encountered, indicating specific impacts of acidic seepage from old mining legacies in the long-term. The activity of sediments and (floodplain) soils is dominated by $^{238}$U decay chain nuclides, exhibiting distinct spatial variations in activity levels and ratios depending on radionuclide source terms and relevant transport processes and environmental conditions.

In the frame of a radiological impact assessment carried out on behalf of the National Nuclear Regulator of South Africa, incremental effective doses (above the natural background) were calculated for members of the public living in the Wonderfonteinspruit catchment area, based on the South African Licensing Guide LG-1032 and IAEA recommendations. Taking into account realistic exposure scenarios and pathways, potential radiation exposures of the public above the effective dose limit of 1 mSv/a were calculated for various of the investigated sites, with maximum effective doses up to some tens of mSv/a.

LA-MC-ICPMS $^{87}$Sr/$^{86}$Sr analysis on tooth enamel – Pitfalls and problems

H.N. DE JONG$^1$, G.L. FOSTER$^2$, C.J. HAWKESWORTH$^2$ AND A.W.G. PIKE$^1$

$^1$Department of Archaeology and Anthropology, University of Bristol, Bristol BS8 1UU, UK (h.n.dejong@bristol.ac.uk; alistair.pike@bristol.ac.uk)
$^2$Department of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (g.l.foster@bristol.ac.uk; c.j.hawkesworth@bristol.ac.uk)

LA-MC-ICPMS on human teeth using $^{87}$Sr/$^{86}$Sr to trace intra-individual mobility has been hampered due to the difficulty in generating reproducible radiogenic Sr ratios. Diagenetic uptake of REE into teeth enamel and Krypton in the introductory gases interferes with measurements and are primarily responsible for the analytical difficulties in archaeological samples. Consequently, despite success of LA-MC-ICPMS for biological calcite (Christensen et al. 1995, Ramos et al. 2004, McCulloch et al. 2005), the methodology has not lent itself as readily to analyses of calcium hydroxyapatite.

However, molecular interferences and oxide formation can be eliminated by torch and gas flow manipulation (Foster and Vance 2006), the deviation of $^{84}$Sr/$^{86}$Sr from the natural value of 0.056490 can be used as a qualitative assessment, and the Y intensity can be used as a proxy for REE interferences (e.g. McCulloch et al. 2005). The $^{86}$Kr contribution to the 86 intensity is usually ~1%, and hence can be discounted as a major influence on the normalized $^{87}$Sr/$^{86}$Sr. A further assessment of accuracy and precision is through shark teeth that routinely yield marine $^{87}$Sr/$^{86}$Sr ratios (0.709167 ± 0.00003). Despite these manipulations, our LA-MC-ICPMS data for human teeth consistently show an offset from the bulk solution MC-ICPMS and TIMS, which we attributed to REE concentration heterogeneity within an enamel layer and between those layers combined with the much lower overall concentration of Sr in those samples.

Our data contributes to the understanding of inherent problems in applying LA-MC-ICPMS to biological apatite such as teeth. We also assess the best method for obtaining reproducible $^{87}$Sr/$^{86}$Sr ratios for whole teeth and intra-tooth $^{87}$Sr/$^{86}$Sr variability using LA-MC-ICPMS, MC-ICPMS, and TIMS.

Eastern Mediterranean sapropel formation and preservation; Diagenesis versus palaeoceanography

5NIOZ, Texel, NL

Organic-rich intervals (sapropels) occur in eastern Mediterranean sediments at an astronomically determined cyclicity, related to relatively humid climatic periods. The intervening, arid periods are characterized by organic-lean sediments, and the deposition of rather high dust fluxes indicated by Ti/Al. The last of such ‘humid periods’ occurred from 10.4 to 5.7 kyr ago, simultaneous with the sustained wet period in the circum Mediterranean area. At the end of this humid period, the rapid increase in aridity (indicated by Ti/Al) coincides with a peak of high Mn-oxide content. This peak in all 30 studied cores occurs in response to a relatively abrupt re-ventilation event, and is confirmed by several other proxies. From the comparison of organic C and Ba/Al it is clear, that in the sediments of all cores, the upper part of the youngest sapropel, S1, has been removed. Following the ventilation event, at 5.7 kyr, oxygen has continued to progressively move downward into the sediment oxidizing e.g. organic C. In line with these observations, microfossil assemblages indicate environmental changes occurring at the lower- and upper S1 boundary of the initial S1 sapropel. From the organic geochemical data it becomes clear that although siliceous microfossils have entirely disappeared even from the unoxidized S1-interval, their ‘signature’ is still there (e.g. diatoms, represented by loliolide). Other marine biomarkers are dinosterol and δ44/42Ca of a few tenths of permil associated with the production of carbonate sediments (Δcalc). It has been proposed that shifts in the concentration of Ca2+ in seawater can be reconstructed from the calcium isotopic composition (δ44/42Ca) of sedimentary calcium carbonate, giving information on past weathering fluxes of Ca2+ to the oceans and atmospheric concentrations of CO2. The 18 million year record presented here of the δ44/42Ca of planktonic foraminifers from ODP site 925, in the Atlantic, on the Ceara Rise, provides an opportunity to critically analyze Ca isotope based reconstructions of the Ca cycle.

δ44/42Ca in this record averages +0.37 ± 0.05 and ranges from +0.21 ‰ to +0.52 ‰. This falls within error of previously published Neogene records based on foraminifers, but is not similar to the record based on bulk carbonates which has values that are as much as 0.25 ‰ lower, especially further back in time. Fairly recent bulk carbonates and planktonic foraminifers (i.e. from core tops), on the other hand, differ only by 0.06 ± 0.06 ‰ (n = 5). The cause of the greater difference in the isotopic composition of the two materials further back in time remains an open question.

Modeling the global Ca cycle from downcore variations in δ44/42Ca by assuming fixed values for the isotopic composition of weathering inputs (δ44/42Caaw) and for isotope fractionation associated with the production of carbonate sediments (Δcalc), has as been commonly done in the past, results in unrealistically large variations in the mass of Ca2+ in the ocean during the Neogene. This suggests that δ44/42Caaw and Δcalc instead fluctuate over time. Indeed, variations of ± 0.1 ‰ in the isotopic composition of weathering inputs or in the degree of isotopic fractionation during the formation of calcareous sediments could entirely account for the observed variations in δ44/42Ca. Ca isotope fractionation during weathering processes, such as has been recently documented, could easily result in variations in δ44/42Caaw of a few tenths of permil associated with climate change. Likewise the differing degree of isotope fractionation associated with aragonite versus calcite formation could drive shifts in Δcalc of several tenths of permil with shifts in the relative output of calcite and aragonite from the ocean. Until variations in δ44/42Caaw and Δcalc over time are better constrained, modeling the mass of Ca2+ in the oceans from Ca isotope curves should be approached cautiously.

Interpreting the Ca isotope record from marine biogenic carbonates

Computer modelling of organic/biomineral interfaces

NORA H. DE LEEUW

Department of Chemistry, University College London, 20 Gordon Street, London, UK, WC1H 0AJ (n.h.deleeuw@ucl.ac.uk)

Geologically important minerals such as hydroxyapatite \( \text{Ca}_10(\text{PO}_4)_6(\text{OH})_2 \) and calcite \( \text{CaCO}_3 \) often have a biogenic origin, resulting from exo-skeletons, bones and shells. Unlike inorganic minerals, these biominerals have been grown under controlled conditions within organisms, where organic templates have usually played a crucial structure-directing role, often leading to unusual and thermo-dynamically unfavourable mineral morphologies.

The study of biomineralisation is a rapidly expanding field of research, where computer simulations can contribute significantly to our atomic-level understanding of the processes occurring at the interface between the growing mineral and the organic reagents.

We present a comprehensive computational study of the interaction of surfaces of calcium carbonate (calcite and aragonite) as well as the natural bone mineral apatite with a number of organic molecules that have important growth enhancing or inhibiting effects. We calculate both the energies of the adsorption of the organic molecule to each surface, hence providing a quantitative measure of the strength of interaction to particular surface features, and the surface energies of the adsorbate/substrate system, which allows us to calculate the effect of the adsorbate on the crystal morphology.

For the calcium carbonates, it is found that carboxylic acids often adsorb preferentially to particular surface features, such as growth steps on the calcites surface, leading to asymmetric surface morphologies in agreement with experiment. In addition, the presence of organic adsorbates is found to drastically alter the morphology of the aragonite crystal.

A number of citric acid derivatives are known to affect apatite growth, whereas the citric acid itself is instrumental in its dissolution. Simulation of its adsorption to hydroxyapatite shows a distinct preference of the citric acid to adsorb to the \( \{10\overline{1}0\} \) and \( \{11\overline{2}1\} \), planes compared to the \( \{0001\} \) surface, which affects both the morphology and the growth behaviour of the mineral.

Search for Cr isotopic anomalies in unequilibrated carbonaceous chondrites

S. DE LEUW\(^1\), D.A. PAPANASTASSIOU\(^2\) AND J.T. WASSON\(^{1,3}\)

\(^1\)Department of Earth and Space Sciences, University of California, Los Angeles, USA (sdeleuw@ucla.edu)
\(^2\)Science Div., Jet Propulsion Laboratory, Pasadena, USA
\(^3\)Institute of Geophysics and Planetary Physics, University of California, Los Angeles, USA

Previous leaching studies [e.g., 1-2] revealed the existence of both negative and positive \(^{54}\text{Cr}\) anomalies in carbonaceous chondrites, with the highest excesses in the CI chondrites (up to 250 \( \varepsilon \)-units) [3]. In such studies, direct mineralogical and chemical information regarding the carrier phase of the isotopic anomalies is lost. The main focus of this work is to find the carrier phase of the \(^{54}\text{Cr}\) anomalies by physically separating different phases from primitive carbonaceous chondrites (e.g., low-FeO and high-FeO chondrules, refractory inclusions, matrix enriched material etc.), to characterize the separated phases by electron probe, and to measure the \( \text{Cr} \) isotopic composition by TIMS.

To assure that the high excesses in \(^{54}\text{Cr}\) found in the CI and CM chondrites also exist in the most unequilibrated chondrites such as the CO3.2 chondrite Kainsaz, we will first carry out leaching studies following the procedures of [1] and [2] before physically separating different chondritic components. Each leachate is measured by atomic absorption to determine the \( \text{Cr} \) content in the leaching fractions before carrying out the \( \text{Cr} \) chemistry and measuring the \(^{54}\text{Cr}\) isotopic composition.

Most of the previous \(^{54}\text{Cr}\) studies were concentrated on CI and CM chondrites. Our study will focus on chondrites from the petrographic subtypes 3.0 to 3.2 as these meteorites have largely avoided aqueous alteration and metamorphic events. It is possible that these secondary processes have dissolved some of the carrier phase(s) of the isotopic anomalies and that leaching studies of the most unequilibrated chondrites may display larger \(^{54}\text{Cr}\) anomalies.

We chose the CO3.2 chondrite Kainsaz because it is a highly unequilibrated fall and because the least altered CO chondrites experienced much less aqueous alteration than the least altered CV chondrites.

Geological importance of paleokarsts and neptunian dykes in the Lower Jurassic rocks at the Beytepe village-Çayyolu area (South west Ankara, Turkey)

ARIF DELI AND VE HüKMÜ ORHAN
Selçuk Univ. Müh. Müh. Bölümü Konya Türkiye (adeli@selcuk.edu.tr, horhan@selcuk.edu.tr)

The geometric pattern of paleokarsts and the depositional characteristics of their laminated fillings and the development of the Neptunian dykes in Lower Jurassic microbialitic limestone in the study area located 14 km south west of Ankara were investigated by using field observations and examining polished rock slabs and acetate peels.

There are several cross cutting paleokarsts developed several karstification phases in shallow marine limestone of the Bayırköy formation in the study area (Deli 2005). The voids of karsts were filled with pink, laminated peloidal marine sediments. A few conformities were observed among lamina in sediments filling the karstic voids. The synsedimentary Neptunian dykes coexist together with karstic dykes and were filled with the same sediments. In the study area, crinoidal facies with erosional base overlies the microbialitic limestone point that the area were exposed to the atmosphere more than once (Jimenez de Cisneros et al., 1991).

Laminations developed in different lineations and dipping of a single paleokarstic filling and irregularities among laminae in sediments filling the karstic voids. The syngenic Neptunian dykes coexist together with karstic dykes and were filled with the same sediments. In the study area, crinoidal facies with erosional base overlies the microbialitic limestone. Large Neptunian dykes, up to 3 meters, were developed at the upper part of the facies and were filled with red colored mudstone of the Ammonitico Rosso facies (Lower Toarcian, Alkaya and Deli, 1998). Multiphase karstic features developed in the Sinemurian microbialitic limestone point that the area were exposed to the atmosphere more than once (Jimenez de Cisneros et al., 1991).

Laminations developed in different lineations and dipping of a single paleokarstic filling and irregularities among laminae as well as the presence of Neptunian dykes prove that seismic activities were repeated within short periods. Especially the presence of large Neptunian dykes beneath the Ammonitico Rosso facies which is typical for deposits of the Pelagic carbonate platforms (PCP ; Santantonio, 1993) implies that the facies were deposited in a shallow marine pelagic environment resulted from syngenic faulting in the area.

Non-conservative behaviour of molybdenum in coastal waters

O. DELLWIG1,2, M. BECK2, A. LEMKE2, M. LUNAU2,3, K. KOLDITZ2, B. SCHNETGER2 AND H.-J. BRUMSACK2
1IOW, Rostock, Germany, (olaf.dellwig@io-warnemuende.de)
2ICBM, Oldenburg, Germany, (last name@icbm.de)
3AWI, Bremerhaven, Germany, (lunau@awi.de)

Introduction
Molybdenum is the most abundant trace metal in ocean water and generally displays a conservative behaviour unaffected by biological activity. However, several authors observed deviations from conservative behaviour, which they attributed to scavenging by MnOx phases, utilisation by plankton, and complexing by organic particles (Head & Burton, 1970; Berrang & Grill, 1974; Yamazaki & Gohda, 1990; Tuit & Ravizza; 2003). In this contribution we postulate a conceptual model for non-conservative behaviour of Mo in coastal waters, which is based on the tight coupling of geochemical, biological, and sedimentological processes (Dellwig et al., 2007).

Results and Discussion
Non-conservative behaviour of dissolved Mo was observed during specific time periods in coastal waters of the Southern North Sea. In July 2005 a loss of about 60% of Mo\textsubscript{Diss} was observed within 36 hours. In contrast, in August 2002 Mo\textsubscript{Diss} revealed a tidal cyclicity with maximum values up to 158 nM at low tide. The decrease in Mo\textsubscript{Diss} was accompanied by Mo enrichments on SPM. Parallel to decreasing Mo\textsubscript{Diss} concentrations Mn\textsubscript{Diss} showed an increasing trend while Mn\textsubscript{part} decreased. Such finding is compatible with the formation of oxygen-depleted zones in aggregates, which provide suitable conditions for the rapid fixation of Mo and parallel release of Mn by chemically and/or microbially mediated processes. This assumption is supported by biological and sedimentological parameters. The production of organic components (e.g. TEP) during breakdown of an algae bloom in July 2005 led to the formation of larger Mo-enriched aggregates, which depleting the water column in Mo\textsubscript{Diss}. After deposition on and incorporation into sandy tidal flats these aggregates are rapidly decomposed by microbial activity. Pore water profiles document that during microbial decomposition of these aggregates, substantial amounts of Mo are released and may replenish and even enrich Mo in the open water column as seen in August 2002.

Reconstructing ancient commercial routes between the Roman Empire and the Indian subcontinent via lead isotope ratio analysis

D. DE MUYNCK1, P. DELRUE2, C. CLOQUET1 AND F. VANHAECKE1

1Ghent University, Department of Analytical Chemistry, Proeftuinstraat 86, B – 9000 Ghent, Belgium (David.DeMuyck@UGent.be)
2Ghent University, Research Unit Near Eastern Archaeology, Sint-Pietersplein 6, B – 9000 Ghent, Belgium

Ed-Dur is a large coastal archaeological site on the Arabian side of the Persian Gulf. The main occupation phase at this site dates from the 1st century BC until the 2nd century AD. International sea-trade between the Roman Empire and the Indian subcontinent peaked during this period and the many imported products excavated at ed-Dur (Roman glasswork, Indian ceramics, Parthian coins,…) show that also this region was involved in the trade system.

Several metallic objects from ed-Dur with a lead content ranging from trace up to main element level – local coins made from copper/silver alloys, copper base alloy objects, silver rings and bracelets, lead and litharge fragments and a few lead objects of known origin – have been subject to study. After complete sample digestion with quantitative lead recovery, lead was isolated both quantitative and pure using an extraction chromatographic separation based on a lead-selective crown ether (Pb spec™, Eichrom Environment, France). Isotope ratio measurements were carried out using a PerkinElmer SCIEX Elan 6100 DRCplus ICP-MS instrument, equipped with a dynamic reaction cell. Ne was used as a collision gas in the cell in order to obtain a better isotope ratio precision. Finally, the external precision obtained was 0.11% RSD for 207Pb/206Pb, 0.10% RSD for 208Pb/206Pb, 0.09% RSD for 206Pb/207Pb, and 0.2 – 0.3% RSD for the 3Pb/204Pb ratios, where X = 206, 207 and 208. Mass discrimination correction was performed both by standard bracketing using NIST SRM 981 Common Lead and internal correction using Tl; both techniques gave rise to the same result.

So far, 2 samples of known origin can be used as a proxy of lead sources: (i) an ingot found in the Kingdom of Characene, a vassal state from the Parthian Empire, and (ii) a bulla (coin) which is an imitation of a Roman original and originates from India. However, at least one more source needs to be identified to explain the isotopic range of the investigated samples. The provenance of the lead from the sources and the objects investigated will be determined by comparison to an extended database containing lead isotopic compositions from ores and objects from all over the old world.

These and additional results of this study will be presented, along with archaeological conclusions concerning trade relations in the Arabian region at that time.

Comparing GC- and LC-C-IRMS methodologies to quantify formation and turnover rates of microbial-derived soil organic matter

K. DENEF, C. DECOCK, J. VERMEULEN, O. VAN CLEEMPUT AND P. BOECKX

Ghent University, Coupure Links 653, 9000 Gent, Belgium (karolien.denef@ugent.be; charlotte.decock@ugent.be; jan.vermeulen@ugent.be; oswald.vancleemput@ugent.be; pascal.boeckx@ugent.be)

Amino sugars are the building blocks of microbial cell walls and can be stabilized in the soil after cell death. Their abundance in the soil has been suggested to be a more useful indicator of time-averaged soil microbial responses to land-use or environmental change than the living microbial biomass. Since bacteria and fungi have different cell wall structures, relative abundance of their characteristic amino sugars has been used to assess fungal and bacterial contributions to soil organic matter. However, little is known about the dynamics of fungal and bacterial amino sugar-C. Compound-specific stable isotope analysis forms a powerful tool to quantify production, stabilization and turnover rates of organic compounds. To date, compound-specific stable isotope analysis of non-volatile biomarkers such as amino sugars has only been attempted through gas chromatography – combustion – isotope ratio mass spectrometry (GC-C-IRMS) or GC-MS, which requires derivatization to facilitate GC analysis. Yet, derivatization of amino sugars adds a large number of exogenous carbon atoms with different 13C signature. This necessitates complex 13C corrections which increase the error on the final δ13C values of the amino sugars. A recently developed analytical technology, i.e. high performance liquid chromatography – combustion – IRMS (HPLC-C-IRMS), has enabled the high-precision 13C/12C determination of polar and thermo-labile compounds that can be chromatographically separated in aqueous phase. By avoiding the requirement for derivatization, this technology has greatly broadened the types of biomarkers that can be analyzed in conjunction with stable isotope analysis. In this presentation, an alternative method is described for 13C analysis of amino sugars through HPLC-C-IRMS, and compared with GC-C-IRMS analysis in terms of reproducibility and experimental error. In addition, results will be presented from an incubation study with uniformly labeled 13C-plant residues to quantify formation rates of newly produced amino sugars under laboratory conditions, and to investigate the impact of substrate quality on the turnover of fungal and bacterial residues.
Experimental determination of pyrite dissolution rate in acidic media at 21° to 61°C

JUN DENG1,2, QINGJIE GONG1,2, LIQIANG YANG1,2, QINGFEI WANG1,2, JING ZHANG1,2 AND WANMING YUAN1,2

1State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (djun@cugb.edu.cn; qieiegong@163.com)
2Faculty of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China

The dissolution of pyrite is important in the formation of acid mine drainage. The dissolution rates of pyrite were experimental determined in the laboratory at 21° to 61°C using short-term batch experiments. The rate experiments were performed on crushed, pretreated and sieved size-fractions of pyrite sampled from Dongguashan large copper deposit in Tongling district, Anhui province, China. Particles of pyrite between 20 and 40 mesh were used at 35°C and between 40 and 60 mesh at 21°, 34°, 52° and 61°C. Dissolution occurred in HCl aqueous solution at pH=2 in contact with air at room pressure. Five to six samples were collected at different reaction time, half to twelve days, in each temperature and were analyzed for iron concentrations using colorometry with precision less than 5%.

The relationship of iron concentration in solution with the reaction time is linear at each temperature, which indicates the pyrite dissolution was at far from equilibrium state. The dissolution rates were calculated by the equation: \( R = \frac{[\text{d}C/\text{d}t] \times [M/A]}{} \), where \([\text{d}C/\text{d}t] \) was calculated in iron concentration-reaction time diagram by linear regression, \( M \) represents the mass of reaction solution and \( A \) is the total geometric surface area of the reaction pyrite particles. The determined dissolution rates are 2.59×10⁻⁹mol·m⁻²·s⁻¹ at 35°C, and 2.12, 3.94, 11.0 and 12.4×10⁻⁹mol·m⁻²·s⁻¹ at 21°, 34°, 52° and 61°C respectively. These slow dissolution rates derived the activity energy of the pyrite dissolution reaction is 40.3kJ·mol⁻¹ by Arrheius equation, which indicates that the pyrite dissolution is a surface controlled process at far from equilibrium state. These results can be used to evaluate the quantity of the dissolved pyrite to the acid mine drainage in Dongguashan large copper deposit.

A crack in the lithosphere cannot make: Geodynamics and mantle geochemistry

DONALD J. DEPAOLO

Department of Earth and Planetary Science, Univ. California, Berkeley, CA 94720 (depaolo@eps.berkeley.edu)

There may be some issues that can be raised concerning the existence of mantle plumes, but one that cannot be ignored is the high rate of magma production far from plate boundaries, and in many cases, beneath thick lithosphere. This is not explained by lithosphere weakness; volcanism occurs where magma is produced by active mantle processes, not where lithospheric weakness “allows” magma to come up. Exceptions to this rule, if any, involve trivial amounts of magma, such as the tiny seafloor volcanoes on the western Pacific seafloor. Adding pyroxenite and water to lherzolite to increase the fertility of hotspot mantle does not remove the requirement for active upwelling and elevated temperature. Hotspot longevity requires that fresh mantle be continually brought into the melting region.

Improving geodynamic models of mantle plumes are allowing more information to be gleaned from their geochemistry. In Hawaii the thick lithosphere allows only the hottest, axial part of the plume to melt. Consequently, the geochemical structure observed is attributable to the base of the mantle – either the CMB or the top of a dense layer; virtually none of the entrained mantle material melts. Some plume components, especially ³He, could come from the core. Another challenge is to deduce plume structure from the volcanic output, which requires models for magma production within the plume as well as magma mixing prior to eruption. These models are still crude, but are helpful for constraining plume structure and source characteristics.

Longstanding issues about plume sources and mantle dynamics still revolve around the contrasts between MORB and OIB geochemistry, the roles of crust-mantle versus intra-mantle differentiation, and the existence of primordial mantle structure. The relative enrichment and heterogeneity of OIB sources is generally identified with recycled lithosphere. The origin of the MORB reservoir is more mysterious, but could be explained as recycled, incipiently-depleted sub-lithospheric oceanic mantle produced as a result of the presence of water in both MORB and hotspot magma sources.
Kinetic isotope effects in snow crystal growth: Lattice-Boltzmann approach

DONALD J. DEPAOLO AND GUOPING LU
Earth Sciences Division, E.O. Lawrence Berkeley National Laboratory, Berkeley, CA 94720

The fractionation of the major water isotope species (HDO, HDO, H218O) during ice crystal (snow) formation is critical to understanding the global distribution of isotopes in precipitation, and for interpreting ice core data. The morphology of snow crystals is also a subject of continuing interest in physical chemistry and atmospheric science (Libbrecht, KG, Rep. Prog. Phys., 68, 2005). Although it is known that crystal growth rate, which depends largely on the degree of vapor over-saturation, determines crystal morphology, there is no general model to relate morphology to vapor saturation. Since kinetic (vapor phase diffusion-controlled) isotopic fractionation also depends on growth rate, there should be a direct relationship between vapor saturation, crystal morphology, and crystal δ18O and δD.

We use a 2D Lattice-Boltzmann model to simulate diffusion-controlled ice crystal growth from vapor-oversaturated air. The two-dimensional, nine-speed model of Kang et al. (Geophys. Res. Lett. 31, L21604, 2004) was modified to accommodate the specific boundary conditions needed. In the model, “crystals” grow solely according to the diffusive fluxes just above the crystal surfaces, and hence morphology arises only from the initial and boundary conditions. The input parameters are the isotope-dependent vapor deposition rate constants (k) and vapor diffusivities in air (D). The values of both k and D can be computed from kinetic theory, and there are also experimentally determined values of D. The values of k depend on the sticking coefficient (or accommodation coefficient) for ice, which we assume is independent of position on the crystal surface. The ratio D/k is a length (≈ 0.2 to 0.5 µm) that allows us to scale the numerical calculations to atmospheric conditions using a dimensionless Damkohler number: Da = kh/D, where h × h is the size of the 2D calculation domain.

Our calculations confirm that the crystal/vapor isotopic fractionation approaches the equilibrium value, and the crystals are compact (circular in 2D) as the saturation factor approaches unity (S = 1.0). At higher oversaturation (e.g. S = 1.2), dendritic crystals of millimeter size develop on timescales appropriate to cloud processes and the isotopic fractionations are dominated by kinetic effects. The results help clarify the controls on dendritic crystal growth, and the relationships between saturation state, growth rate, crystal morphology and isotopic fractionation. They also show the extent to which crystals are likely to be isotopically heterogeneous.

Late Mesozoic volcanism of the eastern flank of Mongol-Okhotsky orogenic belt (Russia)

I.M. DERBEKO
Institute of Geology and Nature Management FEB RAS, Blagoveshchensk, (derbeko@mail.ru)

In the end of Mesozoic in frames of Eastern flank of Mongol-Okhotsky orogenic belt the volcanic zones were formed. Morinskaya zone of late Jurassic – early Cretaceous (800 km²) is made by volcanites of basic-acid composition. The age of the rocks is stated by floral remains (Agaphonenko, 2001) and geochronological data by U-Pb method: 120±5 Ma. Selitkanskaya zone of early Cretaceous (6000 km²) is made by volcanites of basic-acid composition. We defined an age of the rocks of the zone (U-Pb) - 101 ± 2 Ma, and by the data (Agaphonenko, 2001) (U-Pb) - 105 ± 2 Ma. Ezop-Yamalinskaya zone of late Cretaceous (2000 km²) is made by tuffs, ignimbrites, lavas of asid composition. Age of the rocks is 95.2±0.7 Ma (Rb-Sr) [1]. The period of the formation of the zones is pretty wide, but their geochemical characteristics are comparable (Fig. 1). They are impoverished by Nb, Ta, Zr, Hf, Sr and enriched with Rb, Ba, K, Th. According to diagrams that are used to state geodynamical situations it turns out that this rocks are the most close to the formations of edge-continental associations, The rocks are characterized by La/Yb=10-32, La/Ta=20-37.

Figure 1. Rocks of volcanic zones: Morinskaya (1), Selitkanskaya (2), Ezop-Yamalinskaya (3).

Conclusions
The geochemical characteristics of volcanites of Eastern flank of Mongol-Okhotsky belt show the presence of the subductional situation under conditions of an activ continental edge during late Jurassic – beginning of late Cretaceous. And the presence of Sr minimum (many authors connect with this a process of the subduction extinguishing) is characterized for the volcanites of the zones and it’s enlargement in the rocks to the beginning of late Cretaceous, may show the slowly coming subductional processes, that extinguish in the beginning of late Cretaceous.

Ge/Si fractionation by higher plants: mechanisms and applications to biogeochemical cycles

LOUIS A. DERRY, JED P. SPARKS AND SUBASH CHANDRA
Cornell University, Earth & Atmospheric Sciences, Ithaca, NY, USA (lad9@cornell.edu, jps66@cornell.edu, sc40@cornell.edu)

In the near surface environment, silica is under both mineralogical and biological control. In order to better understand the sources and cycling of silica in the critical zone we use the ratio of germanium to silicon as a tracer. Uptake by higher plants discriminates against Ge, and plant phytoliths have low Ge/Si ratios. We find consistently low Ge/Si ratios (< 0.5 µmol/mol) in biogenic silica separated from a wide variety of plant groups, including grasses, deciduous and coniferous trees, and ferns. The apparently ubiquitous occurrence of strong discrimination against Ge during uptake of silica from soil solution suggests a fundamental mechanism common to many higher plants. Preliminary SIMS data suggest that control on Ge and Si uptake is exerted along the Casparian strip in the roots of higher plants. These data are consistent with a proposed Si transport mechanism involving aquaporin family proteins across the Casparian strip (Ma et al., 2005). These proteins are known to control transport of small neutral molecules such as glycerol and water, and conformational effects could account for Ge-Si fractionation. The low Ge/Si of biogenic silica can be used to show that labile silica in shallow soils is dominated by biogenic sources. Ge/Si data from tropical sites indicate rapid and extensive cycling of silica through biomass. We find that Si is also strongly cycled seasonally in a NE USA sugar maple forest, with strong net uptake in spring and early summer coupled to transpiration, and release from litter during snowmelt season. Mass balance calculations suggest that a substantial fraction of “labile” Si in forested watersheds in tropical and temperate systems passes through the plant pool prior to export in stream water.

The mode of mantle convection: Exploring the model space and comparing with probabilistic tomography

F. DESCHAMPS AND P.J. TACKLEY
Federal Institute of Technology, Zurich, Switzerland (deschamps@erdw.ethz.ch)

A growing number of seismological observations indicate that strong compositional variations are present in the Earth’s mantle. Meanwhile, considerable progresses in numerical modelling of convection have been achieved in the past decade. These include thermo-chemical convection, compressibility, and spherical geometry. Still, the mode of convection of the Earth’s mantle is not well constrained. Important efforts have been made to estimate values of the controlling parameters for the Earth’s mantle by testing various models against available seismological information. Linking convection models and seismological data is a delicate step that requires careful modelling of the thermo-chemical properties of the mantle aggregate. Statistical approaches, which account for all reported sources of uncertainties in thermo-chemical data and modelling, provide the possible ranges of thermo-chemical structure predicted by seismology. Here, we explore the model space of thermo-chemical convection. We run new 3D models of thermo-chemical convection (Figure 1) in which we vary important parameters and properties, including the buoyancy ratio and the volume of dense material, the mode of heating, the spherical geometry, and the presence of a phase transition at the bottom of the fluid. We then test snapshots of these models at different time against existing models of probabilistic tomography (Figure 2).

Figure 1. An example of thermo-chemical convection model. Iso-surfaces represent the fraction of dense particles (green C=0.5) and the non-dimensional temperature (red and blue, contour levels T=0.0375 and T=0.0375, respectively).

Figure 2. Comparison between spherical harmonic degrees 2, 4 and 6 of chemical density anomalies at the bottom of the mantle (2000<z<2891 km) predicted by thermo-chemical convection. (B=0.2, X=10%) and probabilistic tomography as a function of time.
Evidence for stable strontium isotope fractionation during chemical weathering

G.F. DE SOUZA, B.C. REYNOLDS AND B. BOURDON
ETH Zurich, Institute of Isotope Geology and Mineral Resources, Switzerland (gdesouza@student.ethz.ch; reynolds@erdw.ethz.ch; bernard.bourdon@erdw.ethz.ch)

The use of a sample–standard bracketing protocol during multicollector inductively-coupled mass spectrometry (MC-ICPMS) enables us to determine the stable isotopic composition of Sr in a variety of materials (rocks & minerals, soils, and water). These variations are reported relative to the standard NBS 987 in the standard delta notation ($\delta^{88/86}$Sr) with an external reproducibility of $\pm 0.06\%$.

We have measured $\delta^{88/86}$Sr and $^{87}\text{Sr}/^{86}\text{Sr}$ of soil parent material (rock, mineral separates) and soils forming a ~150yr chronosequence in the forefield of the Damma Glacier in Central Switzerland. Minerals in the Hercynian granitoid rocks analysed show significant differences (0.3%) in $\delta^{88/86}$Sr, leading to whole-rock $\delta^{88/86}$Sr variations. Such differences are most likely due to postmagmatic events such as the subsolidus unmixing of alkali feldspars, or element remobilisation during a hydrothermal event or during Alpine metamorphism in the presence of fluids.

The $\delta^{88/86}$Sr of surface water tends toward lower values than average watershed lithology and is lower than that of seawater (Fietzke and Eisenhauer, 2006). Temporal variations of ~0.1% are observed and are most likely related to changes in discharge, either due to variations in subglacial water-rock interaction time or in the relative contribution of deep flowpaths to discharge.

The $\delta^{88/86}$Sr values of total soil digestions show a systematic trend from rock-like values (~0.2%) in the youngest soils to higher values (~0.5%) in the oldest. Unlike total soil $^{87}\text{Sr}/^{86}\text{Sr}$, these values cannot be explained by mixing between lithological endmembers, and thus require a preferential loss of isotopically light Sr during weathering, also indicated by the lower $\delta^{88/86}$Sr values observed in surface water. We propose that fractionation during dissolution of feldspars, during precipitation of secondary weathering phases and during biological utilisation are three possible mechanisms for the loss of isotopically light Sr.

This variation in total soil $\delta^{88/86}$Sr, together with heterogeneity in $\delta^{88/86}$Sr of the three main Sr-bearing minerals (plagioclase, K-feldspar, biotite) in granitoid rocks, has implications for studies of relative mineral weathering rates in granitic catchments. The combination of $\delta^{88/86}$Sr and $^{87}\text{Sr}/^{86}\text{Sr}$ data provides a unique solution for three-component mixing, thus obviating the need for simplifying assumptions that are necessary when only radiogenic Sr isotope variations are discussed.

Modeling the effect of aging on Deccan Traps weathering and CO₂ consumption

CELINE DESSERT¹, YVES GODDERIS² JACQUES SCHOTT² AND BERNARD DUPRE²

¹IPGP, Paris, France, (dessert@ipgp.jussieu.fr)
²LMTG, CNRS, Observatoire Midi-Pyrénées, Toulouse, France, (godderis@lmtg.obs-mip.fr)

Basalts weathering account for 30 % of the CO₂ consumption through continental silicate weathering, and may have played a major role in past climatic crises. Since basalts weather rapidly with the subsequent formation of thick soils, the question of the effect aging on weathering rate is crucial. Indeed, in the absence of efficient physical erosion, it can be expected that basalt weathering slows down rapidly with time, thus reducing its impact on the climatic evolution. Here we present the results of a numerical model describing the effect of aging of the rate of weathering of Deccan Traps. The model design is a 20 box-model, based on the structure of the WITCH model. Fresh primary minerals are supplied to the bottom layer through bedrock dissolution, and to top layers as the “numerical” column goes down into the bedrock following chemical dissolution. At each time step, the chemical composition of the downward water flux is calculated within each box, as well as the dissolution of primary minerals and the accumulation of secondary minerals representing the « soil » formation. Both precipitation and dissolution rates are calculated within the framework of Transition State Theory using the best available data issued from laboratory experiments. The model is run for 1 million years until a steady-state is achieved, corresponding to a constant mineralogical composition in each layer and a constant chemical composition of the percolating waters. Calculated elemental ratios in solution are compared to the field measurements, as well as absolute concentrations.

Perturbations are then applied to the model, through the prescribed removal of several boxes at the top of the soil pile, in order to simulate enhanced physical erosion due to external factors, such as anthropic activities. The response of the CO₂ consumption rate to these perturbations is quantified.
The interplay between volcanism, tectonics and hydrothermalism on the Mid-Atlantic Ridge 4-11°S and globally

C.W. DEVEY AND K. LACKSCHEWITZ
Leibniz Institut für Meereswissenschaften (IFM-GEOMAR), Wischhofstr. 1-3, D-24148 Kiel

Hydrothermalism on the slow-spreading Mid-Atlantic Ridge occurs either on-axis in places where excess volcanism has led to the construction of prominent axial highs (Menez Gwen, Lucky Strike, Turtle Pits, Lilliput) or off-axis in other regions (e.g. TAG, Rainbow, Logatchev, Saldanha). Both on- and off-axis systems appear, however, to draw their heat from similar, magmatic sources.

We present a model to explain the distribution of hydrothermalism on mid-ocean ridges, relating the frequency of volcanic events to the depth of the heat source and to the off-axis distance of the hydrothermal systems. Frequent eruptions produce hot crust and a shallow heat-source – fluids heated by this source exit close to its summit, i.e. on-axis (this is the dominant situation on the EPR, for example, where active off-axis hydrothermalism is almost unknown) and off-axis faults serve as recharge channels. When eruptions are less frequent, the shallow crust cools and hydrothermal circulation is only tapped by deeper-reaching faults related to the axial valley walls; hydrothermal venting migrates off-axis. The cooler the crust (and hence the deeper the isotherms), the farther off-axis venting will occur.

This model has predictive qualities: In areas with no bathymetric or side-scan evidence for abundant, recent volcanism, hydrothermal systems will be located exclusively off-axis. In areas dominated by tectonic spreading, not only will the hydrothermal systems be far off-axis, they will also be separated by large distances along axis due to aspect-ratio constraints. Satellite-based predicted bathymetry can, on the other hand, be used to identify on-axis highs with good hydrothermal potential.

Chemical weathering processes in sub-Saharan Africa: Evaluating controls at different spatial and temporal scales

S. DE VILLIERS1, R. ROSSOUW2 AND N. FISH3

1Department of Geology, University of Stellenbosch, South Africa, (steph@sun.ac.za)
2Central Analytical Facilities, University of Stellenbosch, South Africa, (rossouw@sun.ac.za)
3Department of Geology, University of Stellenbosch, South Africa, (nfish@sun.ac.za)

New insights into chemical weathering processes across a wide range of different climatic regimes were obtained from a combination of different methods: (i) long-term (> 50 years), high temporal resolution (monthly) records of river water geochemistry at more than 30 different sites and river systems with catchment scales varying from 625 to 650,000 km², (ii) analysis of river bedload material representing contrasting catchment lithologies, for geochemical proxies of chemical weathering intensity and catchment-to-coast geochemical transformations, (iii) geochemical characterization of surface soil samples, collected at ~ 900 km² sampling resolution within the catchments of river systems with ancillary river bedload and river dissolved load data records.

Chemical weathering rates as a function of different controls was evaluated in the context of both long-term and seasonal variations in river geochemistry. The data demonstrates the potential pitfalls associated with deducing weathering rates from once-off sampling surveys and provides important insights into which part of the hydrograph is most advantageous for such sampling strategies. Additionally, comparison with the chemical weathering potential of catchment lithologies and soils was made possible with the analysis of a large number of soil samples, with a new laser ablation q-ICP-MS method applied to powder briquettes, in conjunction with selective leaching experiments. The importance of consideration of the geochemical composition of catchment soils, in addition to that of unweathered bedrock lithologies, when evaluating lithology as a control on chemical weathering characteristics is demonstrated.
Factor analysis interpretation of Geochemical Atlas of Europe data

W. De Vos1, M.J. Batista2, A. Demetriadess3, S. Pirc4, S. Albane5e, B. De Vivo7, M. Bidovec4 and L. Martins2

1Geological Survey of Belgium, Jennerstreet 13, B-1000 Brussels, Belgium, wdevos@naturalsciences.be
2Geological Survey of Portugal
3Hellenic Institute of Geology and Mineral Exploration
4Geological Survey of Slovenia
5University of Naples

Factor analysis was performed on the analytical results of different sample media of the FOREGS-EuroGeoSurveys “Geochemical Atlas of Europe” baseline project (http://www.gtk.fi/publ/foregsatlas/). It was found that the element associations for solid media (subsoil, topsoil, stream sediment and floodplain sediment) are very similar, whereas the pattern for stream water is completely different. This reflects differences in the mode of geochemical dispersion. In each case, the factor structure is little affected by the statistical procedure, indicating that the factors are rather robust.

In the solid media, over 60 determinands are reduced to 7 factors. Straightforward geological explanations can be given for factor 1 (rare earth and alkaline elements), factor 2 (ultramafic and ultramafic rocks), factor 4 (elements of felsic rocks), factor 5 (carbonate versus clastic silicate rocks), and factor 7 (siliciclastics and especially zircon). Factor 3 is related to grain size and inversely to sodium, with Fennoscandia standing out as a region with Na2O rich rocks. Factor 6 groups sulphur, phosphate, total organic carbon and several chalcophile elements typical of human pollution, such as Cd, Hg and Pb. The relative importance of these factors varies, and some interesting differences are apparent between the different solid media. Factors 1, 2 and 4 account for the largest part of the variance and show the most stable patterns.

The factor analysis interpretation of stream water data shows a completely different picture. Factor 2 is related to the general mineralisation of stream water, i.e. all major ions (Cl, SO4, HCO3, Na, K, Mg, Ca, Sr, etc.) have high loadings. Factor 1 is related, among others, to REE, Al, Fe, Zr and dissolved organic carbon, and inversely to pH; it groups acidic samples of low mineralisation, especially well represented in Fennoscandia. Factor 3 groups chalcophile elements such as Pb, Zn, Cd and Cu, and seems to be related to anthropic contamination. Influence of geological substrate is apparent in factors 4 (alkaline rock elements), 5 (W and Mo), and 6 (ultramafic versus felsic elements). Factor 7 is related to Mn, Fe and dissolved organic carbon, and factor 8 to elements such as As, Br, Na and Cl, influenced by salinisation through sea water, saline aquifers, or in the case of the southern Iberian Peninsula, deficient drainage in an arid climate. Factors 1 and 2 carry most of the total variance.

Dust and aerosol pollution from stationary man-caused sources in Novosibirsk city: Geochemical aperiodicities and numerical models

A.Y. Devyatova1, S.B. Bortnikova1 and V.F. Raputa2

1Institute of Geology and Mineralogy SB RAS
2Institute of Computational Mathematics and Mathematical Geophysics SB RAS

The main sources of the air pollution in Novosibirsk besides transport are thermal power stations and plant facilities. In the winter time dust which they supplied are accumulated in blanket of snow. In that case, study and estimation aerosol pollution can base on snow survey data.

Snow sample was taken in the regions with man-caused pollution sources and in the regions without it for estimation of background. The level of pollution from each specific anthropogenic source was evaluated by ration average element concentration to average background value of this element. Thus for each element of considering man-caused source pollution level coefficients were calculate.

Concentrations of all analyzed elements in suspended part of snow samples in regions of Novosibirsk thermal power stations № 2 and №3 exceed background values at least at three times. The top concentrations in this region observed for Sb, Ge, Sn, Br, Cd, they are in 10-40 times more then background ones. In the region of Novosibirsk thermal power station № 5 in suspended part of snow samples predominate Br, Se, Mo, I, Sb, Sr. The list pollution level coefficients has Cr and Pb. Differences in emissions chemical composition enplanes various fuel types, thermal power stations № 2 and №3 used Kuznetsk bituminous coal, but heat power plant № 5 used mainly mazut, that verify high Br concentration in it emission.

In suspended part of snow samples in regions of Novosibirsk tin plant observed huge amount of Sn, it concentration in 255 times more then background ones, As - 166 times, Se – 68 times, Cd - 54 times, Sb – 12 times.

Solving inverse task of aerosol transport estimation was applied for forecasting pollution distribution from stationary source. It’s allow to aggregate parameters which can’t be measured (turbulence, particles deposition velocity and est.) and estimate they using natural measuring of pollution concentration in snow blanket.
Sensitivity analysis for a multisurface geochemical modelling approach

MARIA DIAZ1, JON PETTER GUSTAFSSON2, LAKHWINDER S. HUNDAL3 AND DEFNE S. APUL1
1Department of Civil and Environmental Engineering, The University of Toledo (maria.diaz@utoledo.edu)
2Department of Land and Water Resources Engineering, KTH (Royal Institute of Technology)
3Metropolitan Water Reclamation District of Greater Chicago

Geochemical models such as surface complexation have been used to successfully describe the leaching of trace metals from different waste matrices. As the model complexity increases different tools need to be used to understand the effect a given input parameter has on the model output. This work extended the multisurface geochemical modelling approach to predict trace metals leaching behaviour in sewage sludge. The NICA-Donnan model was used to incorporate organic matter as a sorbent. The generalized two layer model was used to incorporate iron, aluminium and manganese oxides. Selective chemical extractions were conducted to determine the concentration of available surface sites. The model was tested against pH dependent leaching experiments and isotherm studies.

A sensitivity analysis was conducted to rank the relevance the different input parameters have on the model outcome, as well as to test the model robustness and reliability. The sensitivity analysis was carried out by defining uniform distributions for the input parameters. New sets of input parameters were randomly obtained by sampling the input distributions with a Monte Carlo method; and the model was evaluated. The uncertainty of the outcome was assessed by comparing the median, 5th, 25th, 75th and 95th percentiles from the output with the experimental values. There are different ways to evaluate the effects of the input parameters on the model outcome. One of them is to define best and worst sets of inputs by comparing the output to the experimental value. The best and worst input sets were described in terms of probability distributions and the two probabilities were compared using the Kolmogorov-Smirnov test to determine how likely they are to be the same distribution. This sensitivity analysis shows that the most relevant parameters in this model are solid and dissolved organic matter concentrations, concentration of iron oxides available for sorption, amount of metal available for sorption. Background analytes have different levels of relevance.

Toward calculation of the thermodynamic stabilities of proteins in the deep biosphere

J.M. DICK AND H.C. HELGESON
Department of Earth & Planetary Science, 307 McConell Hall, University of California, Berkeley, CA 94720, USA (jedick@berkeley.edu; brogie@berkeley.edu)

Microbes that thrive in the deep subsurface and other extreme environments depend for their survival on proteins and other biomacromolecules that are chemically distinct from their counterparts in organisms on Earth's surface. Among the variables that characterize different geochemical environments are oxidation state, hydration state, temperature, pressure, and pH. Although the advantages of a chemical thermodynamic assessment of the relative stabilities of inorganic species as a function of physical chemical variables have long been recognized, such an approach generally has not been used to study systems of proteins and other biomacromolecules. Assessment of the relative metastabilities of proteins as a function of these variables can now be performed, owing to 1) generation of group additivity equations of state parameters for calculating the standard molal thermodynamic properties of ionized proteins at high temperatures and pressures, and 2) the development of a computer software package for calculating the chemical affinities of biomacromolecular formation reactions and displaying predominance diagrams consistent with metastability constraints in systems of biomacromolecules. In this communication we present the results of calculations of the relative metastabilities of orthologous proteins from organisms adapted to different geochemical environments. For example, diagrams representing the relative metastabilities of surface-layer proteins from mesophilic, thermophilic, and hyperthermophilic species of Methanococcus have been generated as a function of oxygen fugacity, temperature, pressure, and pH. The locations of the predominance fields of the proteins correspond with the temperature and other geochemical characteristics of the environments inhabited by these organisms. These findings support the notion that energy minimization in systems of representative proteins provides a thermodynamic driving force for the evolution of biological species, and also provide evidence that a thermodynamic assessment of the relative metastabilities of proteins can be used to predict the physical chemical limits on their occurrence in different environments. Because the current approach takes account of the relative metastabilities of different proteins, it permits explicit assessment of relations between different proteins and the physical chemical characteristics of geochemical environments. Hence, we also discuss calculations of the effects on protein metastability of potential biogeochemical oxidation-reduction buffers which may be composed of mineral or organic species, or both. Continued development of the thermodynamic calculations and integration with experimental observations may contribute significantly to our understanding of the fundamental forces involved in the interaction between microbes and their environments.
Fe isotope fractionation induced by aqueous Fe-siderophore complexes

K. DIDERIKSEN¹, J. A. BAKER²,³, M. BIZZARRO¹ AND S.L.S. STIPP¹

¹NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark; knudd@geol.ku.dk, stipp@geol.ku.dk
²Danish Lithosphere Centre, Øster Voldgade 10, DK-1350 Copenhagen, Denmark
³School of Earth Sciences, Victoria University of Wellington, P.O. Box 600 Wellington, New Zealand

The equilibrium Fe isotope fractionation induced by organic ligands was determined by experiments with pH 2 solutions that had coexisting inorganic Fe(III) species (Fe₅⁶) and siderophore complexes, Fe-desferrioxamine B (FeDFOB).

In the experiments, the two differently complexed Fe pools were separated by addition of Na₂CO₃, a method previously applied to separate aqueous Fe(II) and Fe(III) [e.g. 1]. Tests showed that the addition of Na₂CO₃ scavenged the inorganic Fe quickly and effectively, without causing significant dissociation of FeDFOB.

Preliminary experiments using enriched ⁵⁷Fe tracer indicate that isotope equilibration between the ⁵⁷Fe-labelled inorganic species and the isotopically “normal” Fe of the organic species was minor during the 1 s precipitation induced by Na₂CO₃ addition. Although Fe isotope fractionation during precipitation may cause some changes in the isotope composition of the Fe₅⁶, the results suggest that only negligible isotope re-equilibration occurs within the time of the separation, meaning that precipitated Fe faithfully records the Fe isotope composition of Fe₅⁶ and the remaining FeDFOB.

In experiments with starting solutions having δ⁶⁶Fe = 0.76 ‰, desferrioxamine-complexed Fe has δ⁶⁶Fe ~ 1 ‰, whereas inorganic Fe has lighter δ⁶⁶Fe ~ 0.5 ‰. This indicates that co-existing Fe-desferrioxamine B and inorganic Fe complexes have an equilibrium Fe isotope fractionation of 0.5‰ at a temperature of 25 °C. This value is comparable to the kinetic Fe isotope fractionation induced by desferrioxamine-promoted dissolution of hornblende [e.g. 2], suggesting that equilibrium Fe isotope fractionation induced by strongly coordinating organic ligands may fractionate Fe isotopes strongly in seawater, where above 99 ‰ of aqueous Fe is bonded by such ligands.

Ocean crust formed from E-MORB overlying an ultra-depleted mantle on Macquarie Island: Implications for mantle heterogeneity

ARJAN H. DIJKSTRA¹ AND PETER A. CAWOOD²

¹Institut de Géologie, Université de Neuchâtel, Switzerland (arjan.dijkstra@unine.ch)
²School of Earth and Geographical Sciences, University of Western Australia, Perth, Australia

Macquarie Island (Southern Ocean) is a fragment of young (Miocene) ocean crust and upper mantle uplifted and exposed above sea-level in an entirely intra-oceanic setting, without being obducted onto a continental margin. As such, it is unique in the world and it is generally considered as an important type-locality of oceanic crust and mantle and as a key link between oceanic basement and ophiolites. Several workers have pointed out the similarity between the crustal section on the island and the 'classical' ophiolite sequence. Recent work has, however, shown that the formation history of the island is more complex than originally envisaged.

There is evidence form field relations that the volcanics, dykes and gabbrics were formed during different magmatic episodes and it seems unlikely that the main crustal units are co-magmatic. We have dated the formation of the gabbrics at 9.0-8.6 Ma (U-Pb zircon SHRIMP ages). Secondly, the volcanic rocks on the island are unusual: there are few N-MORB and the majority of the volcanics are strongly incompatible element enriched E-MORB (La/Sm<8). Moreover, our new geochemical data show that the dykes, evolved gabbrics and cumulate rocks on the island are derived from parental melts that range from slightly depleted to enriched MORB, but that they were significantly less enriched (La/Sm<5) than the volcanic rocks on the island, ruling out a co-magmatic origin. Nd isotope data confirm that there is little compositional overlap between the parental melts of the gabbroic rocks (εNd(9Ma)=-7.8-9.3) and the volcanics (εNd(9Ma)=+7.2-8.3).

In addition, we will show that the mantle harzburgites on the island are much more depleted (residue of >20‰ near-fractional melting) than expected from the tectonic setting and slow spreading rate of the Macquarie paleo-ridge system. Their ultra-depleted character is also inconsistent with the thin magmatic crust (<3 km), and with the highly enriched character of the volcanics. This means that these mantle rocks are not the source residue of the magmatic rocks and that their depleted character is the result of an earlier melting episode.

We will attempt to tie these disparate observations into one model for the formation of the oceanic basement section on Macquarie Island. The parental magmas that formed the crust were probably derived from enriched and isotopically distinct lithological heterogeneities within the mantle, with a limited contribution from depleted mantle. Over a short time interval (~1 My), the input of enriched melts increased dramatically due to changes in the magma plumbing system, in the spreading geometry, or in the nature of the mantle material entering the base of the melting domain underneath the ridge system.
Neoproterozoic (~ 850 Ma) subducting in the Jiangnan orogen: New SHRIMP age of the Fuchuan SSZ-ophiolite, South Anhui, China

B.H. DING1,2, R.D. SHI*, L. ZHENG, L. CHEN AND X.C. ZHI 1

CAS Key Lab. of C-M Materials and Environments, School of Earth and Space Sciences, USTC, Hefei 230026, China (*shird@ustc.edu.cn/shirendeng@sohu.com)

The Jiangnan orogen separated the Yangtze continental terrane in the northwest and Cathaysia continental terrane in the southeast of the South China plate, the northeastern boundary of which is marked by the Fuchuan belt, the largest ophiolite block in South China. The Fuchuan ophiolite is represented by two tectonically distinct ophiolitic units: (1) the mantle peridotite unit, mainly composed of massive harzburgites; (2) the lava unit, including pillow lavas and cumulated rocks (dunite – whelrite – gabbro). Massive harzburgites are medium to heavily serpentinized, the high Cr2O3 (0.9-1.3 wt%) abundances of clinopyroxene in about 35% partial melting of a primordial mantle source. The Fuchuan harzburgites formed in the suprasubduction zone (SSZ), and thought as a residue after the subduction of the Jiangnan Ocean started before ~850 Ma. We infer that the Yangtze continental terrane and the Cathaysian continental terrane started to weld together at least before 827–849 Ma, which is consistent with the conclusion described early by Zhao and Cawood [5].

Silicon isotope compositions of the underground water, limestone and soil from Karst caves in Guilin City, Guangxi, China

T. DING1,2, S. TIAN1,2 AND J. GAO1

1Institute of Mineral Resources, CAGS, Beijing 100037, China (tding@cags.net.cn)
2Key Laboratory on Isotope Geology, CAGS, Beijing, China

Silicon isotope variation in hydrosphere catches more attention of geochemists recently. Several studies have been done on silicon isotope compositions of oceanic and riverine water [1,2]. Significant variation of silicon isotopes is discovered in these environments, indicating fine prospects of using silicon isotope to study hydrological processes and silicon circulation. We know that underground water is an important part of hydrosphere. However, no results on its silicon isotope composition have been reported by now.

A silicon isotope study on underground water has been carried out. Some results on silicon isotope compositions of the underground water, limestone and soil from the karst caves are reported here. All samples were collected from Panlongdong and Xiaoyandong karst caves in Guilin city, Guangxi, China.

The δ30Si values of underground water in these two caves vary from 1.4‰ to 1.9‰, with average value of 1.65‰. The δ30Si values of trace silicon in limestone from two caves vary from -0.2‰ to 0.3‰, with average value of 0.05‰. The δ30Si values of soils from these caves vary from -0.5‰ to -0.2‰, with average value of -0.4‰. No silicon isotope datum has been obtained for stalagmite, for its silicon content is too low. These results indicate that in the weathering process of limestone in the karst area, the produced soil tends to be enriched in 28Si and the dissolved silicon in underground water tends to be enriched in 30Si. These observations provide useful information for silicon transportation in continental environment.

Different mobility of Nb and Ta along a thermal gradient

X. Ding1,3, W.D. Sun1, F. Huang2, C. Lundstrom3 AND J. Li3

3Graduate University of the Chinese Academy of Sciences, Beijing 100049, P.R.China

Niobium and Ta have long been regarded as “identical twins” because of similar geochemical behaviors during processes linked to the evolution of the Earth’s mantle. A recent study indicates major Nb/Ta fractionation in subducted slab setting, which was used to interpret the systematically lower Nb/Ta in the continental crust compared to the mantle (Xiao et al., 2006). Here we report an experiment which shows that Ta and Nb are mobile and can fractionate from each other during migration in a temperature gradient.

A homogeneous andesitic powder (AGV-1) along with 4 wt% H2O was sealed in a 20 mm long double capsule, compressed to 0.5 GPa and run in a temperature gradient ranging from 950-350 ºC for 66 days. The run product was analyzed using JEOL 8100 electron microprobe and laser-ablation inductively-coupled-plasma mass spectrometry for major and trace elements, respectively.

The results show large variations in Nb and Ta concentrations as well as Nb/Ta along the temperature gradient. In the matrix of the low-temperature section that contains no melt, the Nb/Ta ranges between 7.5 and 24.8, with supra-chondritic value near the low temperature end and sub-chondritic value at adjacent higher temperature region. More specifically, the highest Ta concentration is observed close to the section where amphibole is present. As the temperature decreases further, the Ta concentration drops quickly to considerably lower than that of the starting material, indicating net transportation of Ta from both low and high temperature ends towards the intermediate temperature region. By contrast, the highest Nb concentration is observed in the lower temperature end, ~3 mm away from the Ta peak. The different migration patterns of Nb and Ta result in the large fractionation of Nb/Ta in the amphibole absent section.

We interpret that variations in Nb and Ta concentration and Nb/Ta to reflect a thermal migration process during which Nb and Ta partition between supercritical fluid and different minerals, likely driven by chemical mobility difference between Nb and Ta. Different thermal migration provides a feasible mechanism to produce lower Nb/Ta in the lower continental crust compared to the upper continental crust.

Formation history of Archaean TTG gneisses in the Taihua complex, Lushan area, central China: in situ U-Pb age and Hf-isotope analysis of zircons

Chun-Rong Di Wu1, Yong Sun1, Cui-Luan Lin1, Hai-Ping Li2, Liang Chen1 AND Xiao-Ming Liu1

1State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi’an 710069, China
2Geological survey of Shanxi province, Xi’an 710069, China (diwuchunrong@163.com)

The Taihua complex is discontinuously exposed along the southwest margin of the North China Carton (NCC). It can be divided into two main rock units, naming quartzofeldspathic gneisses and supracrustal rocks. Among these rock units, tonalite–trondhjemite–granodiorite (TTG) gneiss is the dominant rock type, making up 80% of the total exposure of the Late Archaean basement (Zhang et al., 1985). Zircon grains of TTG gneiss are euhedral, and have oscillatory zones with high Th/U ratios (0.20-1.49), indicating their igneous origin. The LA-ICP-MS zircon U-Pb dating yields age population at 2.8 Ga, representing the TTG magma emplaced at 2.8 Ga. Zircons from gneiss have variable Hf isotopic compositions with 176Hf/177Hf ratios from 0.281021 to 0.281189 and εHf(t) values from +0.68 to +7.09, with a weighted mean of 2.2±0.8. It is suggested that the protoliths of the gneisses were mainly derived from depleted mantle, Correspondingly, their Hf model ages are 2924–3059 Ma (TDM1), with a weighted mean of 2966 Ma. TDM1 model ages, which are calculated using the measured 176Hf/177Hf of the zircon, can only give a minimum age for the source material of the magma from which the zircon crystallized. Therefore zircon Hf isotopic data reveal that crustal component older than 3.0 Ga may exist in Lushan area, and zircon debris of this age have been found.

Trace element fractionation during exsolution of garnet from clinopyroxene in an eclogite xenolith from Obnazhennaya (Siberia)

G. DOBOSI, G. KURAT, F. WALL AND T. JEFFRIES

1Hungarian Academy of Sciences, Institute for Geochemical Research (dobosi@geochem.hu)
2Naturhistorisches Museum, Wien (gero.kurat@univie.ac.at)
3Natural History Museum London

A large (3 cm) Al-rich clinopyroxene megacryst from a bimineralic eclogite xenolith from Obnazhennaya kimberlite pipe contains 3 sets of garnet exsolution lamellae crystallized in sequence apparently as a result of slow cooling at depth. Thick lamellae (up to 1500 µm, Py38Alm30Gross22) crystallized first and were followed by medium-sized ones (up to 500 µm, Py40Alm27Gross33) and thin ones (50-100 µm, Py34Alm26Gross40). LAM-ICP-MS analysis of the different generations of garnet lamellae indicates the progressive depletion of trace elements compatible with garnet (HREE, Y and Sc) during the course of exsolution (see figure below):

Variation of trace elements in the garnet lamellae and their host clinopyroxene suggests a diffusion-controlled trace element fractionation during cooling and garnet exsolution. The preservation of the fractionated trace element patterns in the exsolved garnets, as well as the diffusion gradients in the host clinopyroxene indicate that cooling and exsolution occurred shortly before the xenolith was entrained by the kimberlite melt.

The differentiation of first planetary bodies at the metamorphism-partial melting transition, in the inner solar system, is an important petrological process that can help to understand the first stages of the Earth. This study is based on mineralogical, petrological, major and trace elements, melting models, and microstructural relationships. Mineralogical and modal composition of Lodran display that experienced high temperature (1150-1200°C) and extensive partial melting of silicates (30-35% for melt fraction), metal and sulfides. The silicate melts display dacitic compositions related to the breakdown of Na-Ca plagioclase, clinopyroxene and spinel. Using H or CR chondrites and Acapulco as precursor for Lodranite, melting models can’t explain low-Ca pyroxene abundance. On the other hand, the systematic occurrence of “Fe-rich” olivine (Fa17) as inclusion in low-Ca pyroxene in contrast with large tabular crystal of magnesian olivine (Fa0) support the idea of a reaction between silicate melt with Fe-richest olivine to produce orthopyroxene associated with a reduction process before/during melt extraction. The heat source that initiated the melting was probably the short-lived radionuclides such as 26Al. If we consider the extraction of dacitic melt from Lodranites precursor then it can lead to a heterogeneous thermal evolution of these small bodies. To understand the melt extraction process, we analyse the lattice-preferred orientation (LPO) of silicates, sulfides and metal by EBSD technique. Indeed, mechanical processes must induced deformation and LPO. The result is that any LPO was observed except in troïlite. We can conclude that silicate melt migrate at grain boundaries using surface tension and sulfide melt was interconnected. During cooling, formation of a single troïlite crystal occurs and post-magmatic recrystallisation can explain the preservation of the high LPO in troïlite.
Experimental determination of Ca-Sr distribution between zoisite-fluid and lawsonite-fluid

G. DOERSAM1, A. LIEBSCHER1, B. WUNDER2, M. GOTTSCHALK2 AND G. FRANZ1

1Institut für Angewandte Geowissenschaften, ACK 9, Ackerstrasse 71-76, D-13355 Berlin
2GeoForschungsZentrum Potsdam, Telegraphenberg, D-14473 Potsdam

The distribution of Sr between a 1 molar (Ca,Sr)Cl2 solution, (Ca,Sr)-zoisite and (Ca,Sr)-lawsonite was determined at 600°C, 2 and 4 GPa. The synthesized crystals of (Ca,Sr)-zoisite and (Ca,Sr)-lawsonite are homogeneous in electron microprobe analysis. The results indicate that Ca2+ can be replaced completely by Sr2+ at the M1 and M2-site in zoisite and at the M1-site in lawsonite. However, Rietveld refinement of the solid run products with site occupation refinement show that the larger M2 site in zoisite is preferred by Sr in the range X_{Sr}^{Zo} 0 – 0.40. Powder diffraction data show a phase transition in the lawsonite solid solution at X_{Sr}^{Law} ≈ 0.24 with a change of the space group from Cmcm to P21/m.

The compositions of the product fluid were analyzed by inductively coupled plasma emission spectrometry. In both the (Ca,Sr)-zoisite-fluid and (Ca,Sr)-lawsonite-fluid systems, Sr fractionates preferentially into the fluid, similarly as at low pressure for Ca-Sr-margarite, anorthite and carbonate (1).

The mixing energies of the solids were calculated using a regular solution model. In the (Ca,Sr)-lawsonite-(Ca,Sr)Cl2 system, ∆µ0 is 4.1 kJ and WlawCaSr = 9.3 kJ. In the system (Ca,Sr)-zoisite-(Ca,Sr)Cl2 the mixing energies for the M2 site were calculated and ∆µ0 is 11.0 kJ and WzoCaSr is –5.1 kJ.

The high ∆µ0 values and, to a much lesser extent, the W_{CaSr} values cause the preferred fractionation of Sr into the fluid. The observed lawsonite and zoisite structures within the solid solution series as well as the moderate values for W_{CaSr} strongly suggest that complete solid solution series exists for (Ca,Sr)-lawsonite and (Ca,Sr)-zoisite.

Petrology and geochemistry of Cemilköy Ignimbrite, Cappadocia, Turkey

G.D. DOĞAN1, A. TEMEL1 AND A. GOURGAUD2

1Hacettepe University, Dept. of Geol. Engineering, 06800, Beytepe-Ankara, Turkey (gdeniz@hacettepe.edu.tr; atemel@hacettepe.edu.tr)
2Université Blaise Pascal, OPGC, Laboratoire CNRS "Magmas et Volcans" 5 rue Kessler-63038, Clermont-Ferrand Cedex, France (gourgaud@opgc.univbpclermont.fr)

In this study, petrological and geochemical characteristics of the Cemilköy ignimbrite, in the Cappadocia region, located in the Central Anatolian Volcanic Province were identified by more detailed examination. The Cemilköy ignimbrite is composed of ash-size volcanic material, normally graded pumices and inversely graded lithic (volcanic and ophiolitic) clasts. Pumices are distinguished from other ignimbrites in the region by a slaty fabric. Mineralogical and petrographical studies show that pumices consist of plagioclases, biotite, quartz, amphiboles and oxide phenocrysts and microcrysts. Predominantly, vitrophyric-porphyrctic fabric is observed in the pumices. Plagioclase phenocrysts are identified as bytownite- oligoclase (An47-19) in composition and they are normally zoned. As a result of geochemical examinations, it has been determined that the Cemilköy ignimbrite is rhyolitic in composition and shows calcalkaline characteristics. The effect of fractional crystallisation process in the formation of the Cemilköy ignimbrite is observed from major and trace element versus SiO2 diagrams. The Cemilköy ignimbrite is enriched with LILE and LREE contents, indicating that not only fractional crystallization process but also subduction and/or crustal contamination processes were effective. A negative anomaly trend of Nb and Ta elements in spider diagrams, the ratio of Ba/Nb>28 (56-77) and the location of all samples in subduction-related volcanic arc granites area in a Rb-Y+Nb discrimination diagram point to the effect of subduction process. As a consequence, Cemilköy ignimbrites appear to have been produced from the magma that derived by partial melting of OIB-like mantle which was enriched by subduction process and also assimilation–fractional crystallization (AFC) process was effected on evolution of these ignimbrites.
Modeling of dehydrogenation of olivine during magma ascent

RALF DOHMEN¹ AND FIDEL COSTA²

¹ Institut für Geologie, Mineralogie, und Geophysik, Ruhr-Universität Bochum, 44780 Bochum, Germany, (ralf.dohmen@rub.de)
² CSIC, Institut de Ciències de la Terra 'Jaume Almera'.c/ Lluís Solé i Sabarís s/n, 08028 Barcelona, Spain. (fcosta@ija.csic.es)

Despite the recognised crucial role of H in affecting so many processes and rates of the deep Earth, the actual amount of H contained in Nominally Anhydrous Minerals (NAMs) in the mantle remains unclear. The H content in olivine from mantle xenoliths or megacrysts transported by magmas in different tectonic settings is highly variable from about <1 ppm to ca. 400 ppm H₂O (e.g., Beran and Libowitzky, 2006). This could reflect variable local water contents in the mantle, different transport histories of the olivines and host magma, or a combination of the two. The possibility of H loss from the olivines during magma transport is supported by the experimentally determined H diffusion rates in olivine (e.g., Mackwell and Kohlstedt, 1990) and by the H gradients in natural crystals (e.g., Demouchy et al., 2006). However, much uncertainty remains as to the significance of both, the maximum water contents, and the H profiles, since the effect of the ascent paths and conditions have not been considered, e.g. water saturated vs. undersaturated or multi-stage histories.

Here we present results of a dehydrogenation diffusion model of olivine that clarifies under which conditions of transport times, crystal sizes, and magma decompression paths the H content measured from naturally occurring olivine may reflect the original water content of the upper mantle. We find that even for a grain size of 2 cm, magma ascent rates of > 10 m/s are required to preserve at least most (e.g., 90 %) of the initial water content of an olivine orginated from the mantle. The simulations also show that (i) homogeneous H distribution within naturally occurring NAMs may indicate extensive diffusive loss of H rather than being representative of upper mantle H concentrations as is commonly assumed, (ii) a short stage of a few days in an intermediate magma reservoir prior to eruption completely re-equilibrates the water content with the new low pressure environment, even for crystals several cm in size. The fast rates of ascent required to preserve the highest water contents suggest that the H contents of natural crystals reflect the transport path of their magma rather than their mantle sources.

Thermodynamic model for the simultaneous exsolution of two fluids from silicic magmas

D. DOLEJS
Bayernisches Geoinstitut, University of Bayreuth, D-95440 Bayreuth, Germany, (david.dolejs@uni-bayreuth.de)

Chlorine is the predominant constituent in magmatic and hydrothermal fluids. From intrusive to shallow epithermal settings the salinity and composition of hydrothermal fluids changes dramatically and this is partly due to the subcritical phase separation in the H₂O-NaCl system. It is still unclear (1) what is the salinity of exsolving magmatic fluids, (2) whether one or two fluid phases simultaneously separate from the magmas, and (3) how analytical data from melt inclusions can be linked to fluid chemistry or be used to monitor the devolatilization paths. We propose a new thermodynamic model for chlorine in silica-rich melts that is based on Darken’s formalism for solute in a multicomponent solvent. Thermodynamic properties of NaCl are related to the molten-salt standard state via the increment, I_{NaCl} (kJ) = 11 + 0.03 T(K) - 1.33 p(kbar), which was calibrated by experimental data on the chlorine solubility in granite melts. Interaction between NaCl and H₂O in the melt structure is defined by the regular solution parameter, W_{NaCl,H2O} (kJ) = -53 + 0.04 T(K) + 2.67 p(kbar). Properties of the H₂O-NaCl-KCl fluids are described by the Kosinski-Anderko-Pitzer equation of state. Phase equilibrium computations in the granite-H₂O-C12O3 space reveal existence of a temperature minimum at 5.4 wt. % H₂O and 0.13 wt. % Cl in the melt (at 200 MPa) where very small changes in the melt Cl/H₂O ratio produce large variations in the fluid salinity. At subcritical conditions, the thermal minimum becomes an invariant point (Cl/H₂O = 0.037 at 100 MPa) where all differentiation paths of chlorine-bearing granitic magmas terminate by simultaneous saturation with the vapor and brine. Here the Cl and H₂O concentrations in the melt remain invariantly buffered despite the fact that the largest amount of fluids is produced at this stage. The thermodynamic model demonstrates that: (1) experimental data require only minor deviations from mixing of halide and aqueous components in the melt, i.e., the trends of chlorine and water solubilities are largely related to non-ideal activity-composition relationships in the aqueous fluid, (2) natural silicic magmas with Cl/H₂O < 0.04 first saturate with a low-density aqueous vapor and subsequently exsolvoc concentrated brines at the solids; decompression favors vapor saturation whereas crystallization promotes brine separation, and (3) realistic predictions of metal to hydrothermal fluids must consider both the melt-brine and melt-vapor partitioning. It remains to be understood whether the “vapor-then-brine” mechanism of fluid saturation in the shallow-level magma bodies promotes the vapor-mediated metal transport or it leads to metal enrichment in the melt up to high degrees of fractionation, followed by partitioning to late-stage brines. The new thermodynamic model offers the missing link between the melt and fluid chemistry in crustal magmatic reservoirs and it can be used in quantitative modeling and interpretation of devolatilization and ore-forming processes.
Dissolved quartz in supercritical water: Insights from ab initio molecular dynamics simulations

N.L. DOLTSINIS1, W.V. MARESCH2, M. BURCHARD3, and T. FOCKENBERG2

1Lehrstuhl für Theoretische Chemie, Ruhr-Universität Bochum, D-44780 Bochum, Germany (nikos.doltsinis@rub.de)
2Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität Bochum, D-44780 Bochum, Germany (walter.maresch@rub.de, thomas.fockenberg@rub)
3Mineralogisches Institut, Universität Heidelberg, D-69120 Heidelberg, Germany (burchard@min.uni-heidelberg.de)

We have carried out ab initio molecular dynamics (AIMD) simulations of \(\text{SiO}_2\) in supercritical water at temperatures of 900 K and 1200 K and a pressure of 1.5 GPa at concentrations of 5 and 16 wt% [1]. The different polymeric forms monomer (\(\text{SiO}_4\text{H}_4\)), dimer (\(\text{Si}_2\text{O}_7\text{H}_6\)), and trimer (\(\text{Si}_3\text{O}_{10}\text{H}_8\)) are found to be stable during the 10 ps time span of the simulations. A Raman spectrum recorded of the \(\text{SiO}_2/\text{H}_2\text{O}\) fluid in a diamond-anvil cell, comparable to spectra presented in the literature [2-4], has been compared to the vibrational spectra obtained from the AIMD simulations by Fourier transform of the velocity autocorrelation function. Determination of relative monomer and dimer concentrations from the relative intensities of the Raman bands is found to be problematic as both species contribute to the most intense band [1]. The mechanism of dimerisation and the associated free energy profile along the reaction coordinate have been obtained using coordination-constrained AIMD together with thermodynamic integration [5-7]. The calculated relative free energies of monomer and dimer suggest that both species should coexist at high P, T conditions.

Characterization of carbon materials in metasediment hosted gold deposits (NW Portugal) by micro-Raman spectroscopy

A. DÓRIA, A. GUEDES AND M.A. RIBEIRO
GIMEF, Centro de Geologia, Dep. Geologia, Fac. Ciências, Univ. Porto, Rua do Campo Alegre 687, 4169-007 Porto, Portugal (adoria@fc.up.pt)

Introduction
Micro-Raman spectroscopy (MRS) is a powerful technique used for the characterization of dispersed carbon materials (DCM) in metasediments, giving information about their evolution during metamorphic process (graphitization).

The aim of this study is to characterise the DCM by MRS in order to estimate the maximum P-T conditions reached during regional metamorphism.

Results
Using a Labram Dilor-Jobin Yvon spectrometer attached to an Olympus microscope and an excitation of 633 nm lines of a He-Ne laser, MRS analyses were performed on samples from metasedimentary rocks of borehole cores obtained during an exploration survey at Três-Minas roman open-pits. The criterion of sample selection was the presence of non-outcropping black-carbonate lithologies. Four samples were studied and ten Raman spectra were recorded for each sample.

The first-order Raman spectrum of DCM exhibit a graphite G band at around 1580 cm\(^{-1}\) and defect bands D2 around 1616 cm\(^{-1}\) and D1 around 1332 cm\(^{-1}\). For the second-order spectrum a symmetric S1 band and a broad S2 band appear near 1700 cm\(^{-1}\) and 1900 cm\(^{-1}\), respectively (Fig.1).

Figure 1: Representative Raman spectra obtained for DCM at Três-Minas.

After the calculation of the Raman parameters for the different first-order Raman spectrum and using Beyssac et al. (2002) graphite geothermometer in order to estimate the peak temperature of metamorphism the obtained temperatures are in the range of 360 to 490 °C.

This data will be further compared and constraint with others geothermometers, fluid inclusion and mineral assemblages.

Specific gas composition of the adsorbed form in impactites of the diamond-bearing Mongolian astropipes

D. DORJNAMJAA1, L.S. KONDRAKOV2, D.M. VOINKOV2, AND TS. AMARSAIKHAN1

1Paleontological Center, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia; (ddorj2001@yahoo.com)
2VNIIGeosystem, Warsaw highway, 8, Moscow, Russia (dvoinkov@nline.ru)

The new methodics
At present scrutiny of the adsorbed form of gas in rocks of diamondiferous provinces is new acknowledgement of an elaboration and sampling of the intraditional prospecting methodics.

The new results
According to Dorjnamjaa et al. (1) the Agit Khangay, Khuree Mandal Tsenkher, and Bayan Khuree diamond-bearing ring impact astropipe structures are established for the first time in Mongolia. These astropipes are wonderfully-preserved from erosion and active denudation, and characterized by both well natural exposures and diversity of different impact-derived and shocked magmatic rocks and minerals. The Agit Khangay astropipe is the most detailed studying meteorite structure.

The Agit Khangay astropipe in western Mongolia was formed at the Permian granite massive. The crater’s total diameter is about 10 km and filled with shattered and shocked granite (agizit). Most panned samples and hand specimens contain microdiamond of octahedron habit, gold, platinum, moissanite, pyrope, rhenium, coesite, khamarabaevite (TiC), graphite-2H, etc.

Conclusions
The adsorbed form of gas in the Mongolian astropipe impactites (Agit Khangay-sample 32/99, Khuree Mandal-sample 58/03, Bayan Khuree-sample 17/03) has been compared with gases of analogous form in volcanic rocks of modern (Volcano Gorelii, Kamchatka) and ancient (Maikhant-sample 25/04 and Zuun Busluur-sample 36/04., volcanoes, Dariganga plateau, Mongolia) eruption and kimberlite pipes (Victory-1, Shandun province, China).

Detailed geological and gas-geochemical investigations shows diamondgenesis is the expression of the collision of the lithospheric mantle with meteor impact collsaps explosion process. The essence of the phenomenon is mantle manifestation and plume of the combined nuclear-magma-palingenesis interaction.

Statistical determination of geochemical data to evaluate Oelberg-basalt as a geochemical reference material

SIGRID DORNDORF 1,2, ANTJE WITTENBERG2, SIMONE RÖHLING2 AND GEROLD GERWIG3

1Leibniz Universität Hannover, Callinstr. 3, 30167 Hannover, sigrid.dorndorf@web.de
2Bundesanstalt für Geowissenschaften und Rohstoffe (BGR), Stilleweg 2, 30655 Hannover
3Basalt-Actien-Gesellschaft, Nordostdeutsche Hartsteinwerke, Basaltwerk Oelberg, 37235 Hessisch Lichtenau/Quentel

Modern geochemistry allows very accurate and precise measurements, however the critical part is still the sampling. On the basis of statistical observations unaltered-tertiary basalt in the Northern Hessian Depression, Germany from a quarry of the German Basalt – Corporation are analysed. The aim of this study is to evaluate this alkali-olivine basalt from the Oelberg/Hessisch Lichtenau for its potential as being geochemical reference material. Hence, the samples are taken systematically by hand over a 500 m long profile in a distance of 5 to 10 m and of 5 kg each. Furthermore, from the operatingresher of the quarry of different fractions are taken as well for random sampling.

Besides macroscopically and microscopically petrographical investigations of each sample selected phases (xenoliths, crystalline and glassy matrix) are studied in detail by EMP. In addition to phase analyses by EDX on selected mineral separates some bulk analyses were performed. For the bulk rock chemistry the samples were crushed in steel crushers and milled down to fine powder of <125µm in an agate mill. After each step the sample are controlled for impurity, stepwise minimized and homogenised. All samples are analysed for major and minor element concentrations by XRF using smelting tablets. Minor and trace elements are studied by ICP-OES and ICP-MS. The measurements are performed as repeat determination. To control the accuracies and precision of the measurements reference material were analyses in addition (BHVO-1 and BB). The BB is an in-house reference basalt from the University of Göttingen (BB) from the Northern Hessian Depression.
Thermal stability of soil organic matter pools under elevated CO₂ and their turnover times calculated by δ¹³C and δ¹⁵N values

MAXIM DORODNIKOV¹,², ANDREAS FANGMEIER² AND YAKOV KUZYAKOV¹
¹Department of agroecosystem research, University of Bayreuth, Germany, 95440 Bayreuth;
(maxim.dorodnikov@uni-bayreuth.de; kuzyakov@uni-bayreuth.de).
²Institute of Landscape and Plant Ecology (320), University of Hohenheim, Germany, August-v.-Hartmann-Str. 3, 70599, Stuttgart; (afangm@uni-hohenheim.de)

Various SOM fractionation approaches (density, particle size, chemical extractability etc.) have been applied to estimate C and N turnover rates in SOM pools. The thermal stability of SOM coupled with C and N isotopic analyses has never been studied in experiments with FACE. We tested the hypothesis that the mean residence time (MRT) of SOM pools is inversely proportional to their thermal stability. Soil samples from FACE plots under ambient (380 ppm) and elevated CO₂ (540 ppm; for 3 years) treatments were analyzed by thermogravimetry (TG) coupled with differential scanning calorimetry (DSC). Based on TG, five SOM pools were distinguished. Soil samples were heated up to the respective temperatures and the remaining soil was analyzed for δ¹³C and δ¹⁵N by IRMS. Energy consumption and mass losses in the temperature range 20-200°C were mainly connected with water volatilization. The maximum weight losses occurred from 200-310°C. δ¹³C values of SOM pools under elevated CO₂ treatment showed an increase from -34.3‰ (20-200°C) to -18.1‰ (>480°C). The incorporation of new C and N into SOM pools was not inversely proportional to their thermal stability. SOM pools decomposed at 20-200 and 200-310°C had 2% and 3% of new C, with a MRT of about 60 years. The pool decomposed between 310-400°C had 22% of new C, with a MRT of 12 years. The amount of fertilizer-derived N decomposed at 20-200°C had 22% of new C, with a MRT of 149 years. In contrast, the pool decomposed above 480°C had only 0.5% of new N, with a MRT of more than 400 years in soils under both treatments. Thus, the separation of SOM based on their thermal stability was not sufficient to reveal pools with contrast turnover rates of C and N.

The timescale of sediment transport in a small tropical watershed

ANTHONY DOSSETO¹, SIMON P. TURNER¹, HEATHER L. BUSS² AND FRANÇOIS CHABAUX³
¹GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Sydney, Australia. (adosseto@els.mq.edu.au; sturner@els.mq.edu.au)
²USGS, Menlo Park, CA, USA. (hlbuss@usgs.gov)
³CGS-EOST, Université de Strasbourg, Strasbourg, France. (fchabaux@illite.u-strasbg.fr)

How fast are sediments produced, stored and transported in a watershed? This question has important implications for understanding the transfer of carbon, nutrients and pollutants from their continental sources to the oceans. Sediment transport times can be inferred indirectly through the measurement of erosion rates, however uranium-series isotopes have the great advantage of providing a direct measurement of the residence time of sediments in a catchment. Most previous studies have focused on large basins (e.g. Amazon [1,2], Mackenzie [3]), yielding important insights on timescales of sediment transport and chemical weathering. However, the provenance and path of sampled sediments are not well-constrained. In this study, we chose to focus on small catchments (less than a few km²) to quantify how much time sediments reside in a tropical watershed where landslides are the dominant agent of physical denudation.

The study area is located in the rainforest of the Luquillo Mountains, Puerto Rico. River suspended and bedload sediments have been analyzed for ²³⁸U-²³⁴U-²³⁰Th and ²²⁶Ra isotopes. Assuming that sediments have followed a single, continuous weathering evolution since their production from the bedrock, we inferred that the time elapsed between the onset of bedrock weathering and export of sediments out of the catchment is 100 – 200 years. This constrasts with previous estimates for rivers around the world (1,000 – 500,000 years [1-4]) and is best explained by the landslide-dominated nature of erosion in this region, which delivers to the river weakly weathered soil particles.

Soil profiles will also be studied in order to understand the rate of development of the weathering profile in this region and how physical erosion and sediment transport relate to weathering profile evolution.

Samples collected during the PACANTARCTIC 2 (PAC2) cruise fill a sampling gap from 53° to 41° S on the Pacific Antarctic Ridge (PAR). Therefore it becomes possible to have a picture of the geochemical variations along the PAR from 65°S to the Juan Fernandez microplate.

PAC 2 data together with a compilation of published Sr, Nd, Pb, Hf and He isotopic analyses show geochemical variations related to first order tectonic discontinuities. One example occurs at the Eltanin fracture zone. Another example is within the PAC2 study area at 50°S where a major transform fault, Menard TF, marks the boundary between two geochemical domains. To the south of Menard TF, trace element and isotope ratios are depleted and more variable than to the north where the variations are more subdued and the geochemical parameters indicate a more enriched source. These geochemical variations reveal large-scale chemical and morphological divisions of the Pacific mantle.

At a smaller scale, the regular sampling of the different segments, limited by overlapping spreading centers along the 53–41°S ridge section, shows regular variations in geochemical parameters. Most of the 100–260 km long segments are depleted with \( \text{Nb/Zr}_N < 1 \). The centers of the segments have higher \( \text{Nb/Zr}_N \) and more radiogenic Sr isotope ratios than the segment ends where the ridge becomes less robust. This small-scale geochemical segmentation together with observed variations of geophysical parameters suggests small-scale mantle flow below the ridge. However, this regular small-scale variation is locally affected by the presence of nearby off-axis volcanoes which define a pseudomicroplate. The consequences at the ridge axis are both morphological and geochemical. They are revealed by a slight change in the ridge axis direction associated with atypical geochemical signatures of the ridge basalts. Kinematic reorganization of the Pacific Antarctic plate boundary is likely responsible for these features.

Isotope evidences for the origin of Cape Verde oceanic carbonatites

R. DOUCELANC1, J. MATA2, M. MOREIRA3 AND L.C. SILVA4

1Laboratoire Magmas et Volcans (UMR 6524 CNRS), Observatoire de physique du Globe de Clermont-Ferrand, Université Blaise Pascal, 5 rue Kessler, 63036 Clermont-Ferrand cedex, France. (doucelance@opgc.univ-bpclermont.fr)

4Instituto de Investigação Científica Tropical, CeGUL, Portugal

Carbonatite rocks are found on every continents, except Antarctica. However, their occurrence in an oceanic setting is very rare and oceanic carbonatites have been reported only at the Cape Verde and Canary archipelagos. More precisely, they have been found on five out of ten islands of the Cape Verde archipelago, and on only one (Fuerteventura) amongst seven islands of the Canaries.

Geochemical studies based on stable, radiogenic and noble gas isotope systematics have led to the general consensus that parental magmas to continental carbonatites originate in the mantle. For oceanic carbonatites, their mantle origin is not debated either. They have been associated with the mantle plumes at the origin of the Cape Verde and Canary archipelagos (Hoernle et al., 2002; De Ignacio et al., 2006).

Here, we report new Sr-Nd isotope data, as well as major- and trace-element contents measured on 15 Cape Verde carbonatites (whole-rock samples and separate phases) collected on the islands of Brava, Fogo, Santiago and São Vicente. We discuss the relationship that exists between isotope data and the geographical location of carbonatites in the Cape Verde archipelago. That way we determine the best representative isotopic composition of the carbonatites parental magmas (pristine melts) and focus on the comparison between distributions of (i) carbonatite chemical compositions and (ii) basaltic rocks of the Cape Verdes. Finally, we discuss two alternative models for the origin of carbonatites: (1) partial melting of a HIMU-like Cape Verde plume component; and (2) plume-induced melt generation within carbonatitic metasomatized oceanic lithosphere domains.

This is a contribution of the FEDER/FCT project PLINT (POCTI/CTA/45802/2002)

Geochemical interactions between nitroaromatic (TNT) and nitramine (RDX and HMX) explosives and sediments

T. DOUGLAS1, M. WALSH2, L. JOHNSON1, C. MCGRATH3, C. WEISS4 AND C. COLLINS1

1Cold Regions Research and Engineering Laboratory: P.O. Box 35170 Fort Wainwright, Alaska 99703 USA (Thomas.A.Douglas@erdc.usace.army.mil)
2Cold Regions Research and Engineering Laboratory: 72 Lyme Road Hanover, New Hampshire 03755 USA
3Environmental Laboratory: 3909 Halls Ferry Road Vicksburg, Mississippi 39180 USA
4Geotechnical and Structures Laboratory: 3909 Halls Ferry Road Vicksburg, Mississippi 39180 USA

Training with artillery, mortars, hand grenades and small arms containing nitroaromatic (e.g., TNT) and nitramine (e.g., RDX and HMX) explosives is common at military training installations worldwide. Adsorption and transformation reactions of explosives are sensitive to the composition and geochemical conditions in the soils and sediments onto which they are deposited. Thus the geochemical relationships between training range sediments and explosives affect range sustainability, environmental stewardship and site remediation options. Our work addressed fundamental relationships between soil and water geochemistry and explosives degradation through two laboratory experiments.

First, we quantified the breakdown of TNT, RDX and HMX in surface waters containing different concentrations of sediment and dissolved organic carbon. Samples spiked with 10 different explosives and explosives breakdown products were sampled over 85 days and the explosives and breakdown products were measured. We found that the presence of either dissolved organic carbon or fresh mineral surfaces promoted the breakdown of nitroaromatics TNT, 1,3,5-trinitrobenzene and tetryl. RDX and HMX concentrations remained stable in all samples as expected. Concentrations of all explosives phases remained constant in 18Mohm-cm control water throughout the exposure period suggesting that either an organic substrate or a mineral surface is required to facilitate explosives transformation or breakdown.

In a second aspect of the study we investigated the interaction between explosives and freshly fractured mineral surfaces to assess the effects of detonation shock on the interactions between explosives species and sediments. Three different surface sediment samples were crushed with a 50,000 psi steel plate to simulate blast fracturing. Uncrushed “pristine” sediments were sieved using size fractions similar to the crushed samples. Column and batch experiments using waters spiked with TNT, HMX and RDX were applied toward investigating the reactive transport of explosives through the crushed versus pristine sediments. Grain surface morphology was examined by scanning electron microscopy. TNT in some of the columns comprised of fractured sediment showed greater retardation compared to the columns with pristine sediment suggesting that TNT is adsorbed or preferentially transformed on fresh mineral surfaces.

Electrolyte-promoted demineralization of biogenic, vitreous, and crystalline silica: A density functional investigation

P.M DOVE, A.F. WALLACE, Y. HE AND G.V. GIBBS

Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (dove@vt.edu, afw@vt.edu, gvgibbs@vt.edu)

The dissolution of amorphous and crystalline varieties of SiO2 is an integral part of the global biogeochemical cycle of silicon. Nanoparticulate biogenic silica produced by marine phytoplankton and terrestrial plants are of particular interest because their enhanced reactivity and abundance make them important sources and sinks of dissolved silicon in natural environments. Low concentrations of major solutes have been shown to enhance the rate of silica dissolution by up to a hundred times. Recent experimental results on Q3-terminated (100) surfaces of quartz, show that the presence of dissolved electrolytes triggers a crossover in the dominant dissolution mechanism from defect assisted dissolution and simple step retreat, to nucleation of vacancy islands. However, the underlying reaction mechanism remains poorly understood (Dove et al., 2005).

The specific effects of group II metal cations (Mg2+, Ca2+, Sr2+, Ba2+) on the energetics of Si-O bond hydrolysis have been investigated with density functional methods (B3LYP) and a relatively large neutral silica cluster (H13Si6O16). Reactant, product, and transition states for Q3 to Q2 hydrolysis in the presence and absence of the afore-mentioned cations have been determined with all electron (6-31G(d)) and effective core potential (SDDALL) Gaussian basis sets. The free energy of activation for Q3 to Q2 Si-O bond hydrolysis was determined to be approximately 5 kJ/mol lower for Ca2+ than Mg2+ at the 6-31G(d) level. Similar calculations for Ca2+, Sr2+ and Ba2+ using the SDDALL basis set yielded similar molecular geometries to the all-electron results, and free energies of activation for Sr2+ and Ba2+ that are ~10 kJ/mol and ~15 kJ/mol lower than for Ca2+ respectively. These results are consistent with experimental results which show that these cations increase the maximum rate of silica dissolution in the order Mg2+ << Ca2+ << Sr2+ << Ba2+. Although these calculations successfully reproduce the relative rates observed in the presence of these cations, they also predict that the rate of Si-O bond hydrolysis should be faster in the absence of electrolyte, which is contrary to experiment. To address this issue, supplemental calculations are being performed to determine how the incorporation of surface charge into the model will affect the energy landscape and mechanism of Si-O bond hydrolysis.

³University of Pretoria, Department of Plant and Soil Sciences (catherine.dowding@durham.ac.uk; Johan.vanderwaals@up.ac.za)

Introduction
The Kalahari Manganese Field, situated in the Northern Cape province of South Africa, represents the largest body of Mn ore in the world holding up to 80% of the world’s Mn reserves. As a result of ore extraction processes, large quantities of fine, relatively pure Mn oxide tailings are generated. Despite being classified as a ‘waste’ the tailings material could be a valuable source of ‘slow-release’ oxidising capacity for the treatment of organically contaminated soils. Manganese oxides are one of the most powerful oxidants in terrestrial geochemical systems. They are involved in redox cycles in soils and waters, which are essential to nutrient cycling, humification, contaminant fate and mobility.

Polycyclic Aromatic Hydrocarbons (PAHs) are ubiquitous contaminants which are not easily biodegraded, largely as a result of their very low water solubility (Zhang et al., 1995), and thus persist in soils and waters. There have only been limited studies conducted on the oxidation and degradation of PAHs by Mn oxides (Mihelcic and Luthy, 1988). In the present study the Mn oxide tailings materials were reacted with anthracene, one of 16 PAHs appearing on the USEPA priority contaminant list.

Discussion and conclusions
The results obtained using UV-visible spectrometry and gas chromatography mass spectrometry show anthracene is being oxidised to anthraquinone on the surface of the Mn tailings materials under certain environmental conditions. This is thought to be one of the few reported cases of anthracene oxidation by natural minerals.

Processes in early planetesimals: evidence from ureilite meteorites

H Downes¹ and DW Mittelfeldt²

¹School of Earth Sciences, Birkbeck, University of Londond, Malet St. London, WC1E 7HX, UK (h.downes@ucl.ac.uk)
²NASA/Johnson Space Centre, 2101 NASA Road 1, Mail code SR, Houston, Texas 77058, USA (david.w.mittlefehldt@nasa.gov)

Ureilites are primitive ultramafic achondrites composed largely of olivine and pigeonite, with minor augite, carbon, sulphide and metal. They represent very early material in the history of the Solar System and form a bridge between undifferentiated chondrites and fully differentiated asteroids. They show a mixture of chemical characteristics, some of which are considered to be nebula-derived (e.g. a negative correlation between Mg/Fe and Δ¹⁷O that resembles that of the ordinary chondrites but at lower Δ¹⁷O values) whereas others have been imposed by asteroidal differentiation. Carbon isotope data show a striking negative correlation of δ¹³C values with mg# in olivine. δ¹³C also correlates positively with Δ¹⁷O, and therefore this isotopic variation was probably also nebula-derived. Thus, oxygen and carbon isotope compositions and Fe-Mg systematics of each monomict ureilite were established before differentiation processes began.

Heated by decay of short-lived radioactive isotopes, the ureilite asteroid started to melt. Metal and sulphide would have melted first, forming a Fe-S eutectic liquid, which removed chalcophile elements and incompatible siderophile elements, and basaltic melts that removed Al, Ca and the LREE. Several elements show different abundances and/or correlations with Fo content in olivine, e.g. carbon shows a positive correlation in ferroan ureilites, and a weak or even negative correlation in more magnesian compositions. HSE such as Os and Ir also show different distributions, i.e. ureilites with Fo < 82 have very scattered Os and Ir concentrations, which reach high values, whereas ureilites with Fo > 82 tend to have much less scattered and overall lower Os and Ir abundances. A similar change in elemental behaviour is shown by the Fe-Mn relations in ureilite olivines: those with Fo contents < 85 show a good negative correlation, whereas those with Fo > 85 show much greater scatter.

This suggests that a major change affected the parent body at a time when melting had reached relatively magnesian bulk compositions. We consider that this event may have been a “hit and run” collision in which the ureilite parent body collided with a larger object. During the collision, the ureilite mantle broke up catastrophically but re-accreted in a jumbled state around the still-intact core. Mg-rich basaltic melts that were in the process of being formed at the time of break-up were retained in part as melt clasts that re-accreted to the regolith and are found in polymict ureilites.
Introduction
Recently, a new group of P-rich Fe-Ni sulfides has been reported from CM2 chondrites (e.g. Devouard and Buseck 1997, Nazarov et al. 1999, 2001). Lauretta et al. (1998) reported in run products of sulfidation of kamacite also a P-rich phase, in addition to the mixture of barringerite monosulfide solid solution with pentlandite. P-rich sulfides are very fine-grained and their reliable phase description is very difficult. Therefore, we opted for a study of phase relations in the ternary system Fe−P−S using the evacuated silica tube method. Reaction products were examined by X-ray powder diffraction, reflected-light microscopy and by electron microprobe.

Results and discussion
From the phase diagram in Figure 1 it is obvious that in the metal-rich portion of the system at 800°C, the following univariant assemblages are stable: Fe + FeS + Fe3P, FeS + Fe3P + Fe2P and FeS2 + FeS + Fe2P.

Figure 1: Phase relations in the metal-rich part of the Fe-P-S system at 800 °C.

The results of sulfidation and phosphidation experiments in the Fe-P-S system are displayed in Figure 1. Fe3P sulfidates through Fe2P+FeS to FeS +FeS2 +Fe3P (1) and FeS phosphidates to FeS2 +FeP (2). The P content in pyrrhotite from the univariant assemblage FeS2 + FeS + Fe2P at 800°C is in the range 0.01-0.02 wt.%. On the contrary, P content in natural phosphorite Fe-Ni sulfides is higher and ranges between 1.1 and 7.2 wt.%. (Nazarov et al. 1998 and 2001). Clearly, additional experiments and crystal-chemical analyses are needed to explain this discrepancy. Barringerite occurring in association with P-rich Fe-Ni sulfides could likewise be a product of phosphidation or sulfidation.

Element transfer through the Kurile convergent margin

B.M. DREYER¹, J.D. MORRIS¹, J.B. GILL² AND D.L. TOLLSTRUP²

¹Washington University, St Louis, USA
²University of California, Santa Cruz, USA

dreyer@levee.wustl.edu

We have recently conducted a detailed geochemical investigation (including selected trace elements and Sr-Nd-Pb-Hf- and Be-isotope ratios) of the incoming crust (sediments and AOB) and across the wide (volcanoes ~115-200km above slab depth), active Kurile arc in the NW Pacific to address 1) the changing nature of the slab component with depth and 2) element cycling via the subduction “factory.” Initial results indicate the pre-subduction mantle is a mixture of Pacific and Philippine Sea Plate types and melting processes largely explain systematics of immobile, incompatible trace elements in VF and BVF lavas. The behaviour of highly fluid-mobile trace elements is contradictory and is better explained by multistage processes operating beneath the arc.

The agent of mass transfer appears to change from aqueous fluid beneath the volcanic front to melt-like and solute-rich fluid beneath the deeper regions of the arc, which is demonstrated by: 1) the strong VF→BVF decline in highly soluble fluid mobile elements when melting effects are minimized (e.g., B/Be, B/Nb, Cs/Th, Pb/Ce), 2) these ratios are often higher in the VF than the bulk incoming crust, and 3) enrichments in sediment-derived cosmogenic ¹⁰Be (t₁/₂=1.5My) in BVF lavas that are equal to those in the VF-despite longer transit times. ¹⁰Be recycling (flux out / flux in) is estimated at ~17%, to which additional elements are compared. Cross-arc trends coupled with previously well-characterized Wadati-Benioff zone and mineral stability studies allow inferences about the pressure and temperature conditions at the slab-surface (e.g., exploiting the contrasting fluid and melt partitioning behaviours of Be and B in primary sedimentary host white mica) with extensions to thermal and geodynamic models. Geochemical flux estimates clarify longer-term evolution of the crust-mantle system.

Fluid properties at high P and T – What are they good for?

THOMAS DRIESNER

Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, 8092 Zurich, Switzerland
(thomas.driesner@erdw.ethz.ch)

The knowledge of accurate physical and chemical fluid properties at high pressures and temperatures is the key to a quantitative understanding of many geochemical processes. Recent simulation studies have demonstrated that the physical evolution of hydrothermal systems is largely controlled by the non-linear dependence of fluid properties such as viscosity, density and heat capacity on temperature, pressure, and composition. Using simplified fluid properties in a simulation will obscure and sometimes completely suppress important phenomena observed in natural systems. Typical examples from mid-ocean ridge type hydrothermal systems and ore-forming magmatic-hydrothermal systems will be discussed.

A major problem for understanding the geochemical evolution of these systems is the lack of accurate, experimentally determined thermodynamic data for many geochemically important fluid systems at high temperatures and pressures. Moreover, for the near-critical region as well as for phase-separating complex fluids, no thermodynamic formalism is currently available that allows the accurate description or even prediction of thermochemical properties. Current models for standard (infinite dilution) thermodynamic properties such as HKF/Superc fail in this region as do Gibbs Free Energy-based activity models for solutions with finite concentrations. To overcome these limitations, geochemists have more recently moved into theoretical and experimental fields that have little to do with a traditional view of geochemistry including combined quantum chemical calculations and mass spectrometric stability determinations of cluster ions, combined molecular dynamics simulations and EXAFS determinations of ion solvation, and theoretical studies linking these molecular-scale determinations to macroscopic thermodynamic fluid properties. The presentation reviews a few of these recent studies and gives an outlook how these approaches may eventually lead to a quantitative formalism for fluid properties at high temperatures and pressures.
Linkage between Hg(II) pore water speciation and MeHg production in contaminated sediments

ANDREAS DROTT1 AND ULF SKYLLBERG2

1Swedish University of Agricultural Sciences, S-901 83 Umeå, Sweden (Andreas.Drott@sek.slu.se)
2Swedish University of Agricultural Sciences, S-901 83 Umeå, Sweden (Ulf.Skyllberg@sek.slu.se)

Introduction
The formation of toxic and biomagnifying mono methyl mercury (MeHg) in sediments has been proposed to be largely controlled by a passive uptake of dissolved, neutral Hg-sulfides in sulphate reducing bacteria. We have studied relationships between the concentration of dissolved neutral Hg-sulfides, modeled by equilibrium speciation calculations, and specific methylation rate constants (Km. day⁻¹), as well as concentrations of MeHg (µg kg⁻¹), in sediments contaminated by Hg from the pulp and paper industry.

Materials and Methods
Sediments were sampled at seven sites in Sweden, covering a range of environments differing in salinity, total Hg concentration, annual air temperature sum, and organic matter content and quality. The potential methylation rate was determined by addition of isotopically enriched ²⁰¹Hg(II) followed by incubation at 23° C under N₂(g) for 48 h. Pore water Hg(II) speciation was modeled using measured concentrations of pore water Hg(II), pH, inorganic sulphides, halides and dissolved organic matter. Formation of HgS(s) and mixed Hg/FeS(s) was considered independently by Hg EXAFS and S XANES.

Results and Discussion
The sum of dissolved neutral Hg-sulfide species [Hg₃(SH)₂]²⁻(aq)] + [HgS₂⁻(aq)] was significantly, positively (p<0.001, n=20) correlated to Kₘ at depths of 5-100 cm in brackish water sediments. In contrast, total Hg, total Hg-sulfides or Hg(SR)₂ (aq) in pore water gave no significant relationships with Kₘ. In two sets of freshwater sediments, both neutral Hg-sulfides and total Hg (because of an autocorrelation) gave significant relationships with Kₘ. Furthermore, the sum of neutral Hg-sulfides in pore water was significantly, positively correlated to total sediment MeHg (µg kg⁻¹) in brackish waters (p<0.001, n=23), in southern, high-productivity freshwaters (p<0.001, n=20) as well as in northern, low-productivity freshwaters (p=0.048, n=6). Our results confirm findings from laboratory experiments that concentrations of dissolved neutral inorganic Hg-sulfide species largely control Hg methylation rates, as well as accumulated MeHg concentrations, in contaminated sediments.

Archean granites from the Rum Jungle Complex, Australia

KIRSTEN DRÜPPEL1, ALISTAIR MC CREDAY2 AND EUGEN STUMPFL

1TU Berlin, Sekr. ACK9, Ackerstr. 71-76, 13355 Berlin, (kirsten.drupeppel@tu-berlin.de)
2Saskatchewan Research Council, 125 - 15 Innovation Blvd., Saskatoon, Saskatchewan, Canada, S7N 2X8

The 2.55 Ga Rum Jungle Complex (RJC), N Australia, comprises two Archean basement cores, the Rum Jungle and the Waterhouse domes that are surrounded by ortho- and paragneisses of the Palaeoproterozoic Pine Creek Orogen (PCO). The RJC predominantly comprises granite, syenite, quartz-monzonite, and quartz-monzodiorite intruding earlier schists and BIFs. A large number of uranium and base metal deposits have been discovered in black pelites of the PCO neighbouring the granitoid bodies.

Perthitic K-feldspar and quartz are the main minerals present in the granitoids, accompanied by variable amounts of plagioclase (An₀₂₃), magnetite, relict biotite, and accessories such as zircon, monazite, titanite, allanite, apatite, and ilmenite. Most of the samples underwent major post-emplacement mineralogical changes, e.g., formation of white mica at the expense of feldspar, replacement of titanite by rutile, and formation of biotite rims (X_Mg: 0.45-0.53) around magnetite. A pervasive alteration is characterised by sulphide mineralisation, chloritization of biotite and white mica, marlization of magnetite, formation of tourmaline, muscovite, and thoro-silicates along micro-shear zones.

The major element data of the granites show well-defined fractionation trends, involving a negative correlation of Si with Ti, Fe, Mg, Ca and P, whereas K increases in the same direction. The granitoids are metaluminous to peraluminous and alkalic to alkali-calcic in composition, the X_Mg is 0.45-0.53, suggesting that they were derived from the same parental magma. Remarkably, they have conspicuously high Th (8.6-123.3 ppm) and U (2.9-39.9 ppm) compared to the average Upper Crust. All samples, except three highly altered granitoids, can be defined as I-type granites (ASI 0.9-1.1).

Post-emplacement deformation and alteration are associated with secondary, low-salinity (0-14 wt.% NaCl equiv.) to high-salinity fluid inclusions (15-38 wt.% NaCl equiv.) in magmatic quartz that display generally moderate homogenisation temperatures (107-384°C and 81-392°C, respectively). High-salinity inclusions also comprise minor gas-rich mixed H₂O-CO₂ inclusions. All fluid inclusions contain a variable number of presumably accidentally trapped solid inclusions. The fluids are suggested to have been derived by de-wetting of metasediments of the PCO and to be modified by fluid-rock interactions during transport and metamorphism of the RJC and PCO at c. 1.8 Ga. This process might also be responsible for the formation of U and ore deposits in the vicinity of the RJC.
The geochemical characteristics of molybdenum ore deposits in east Qinling orogenic belt, north China

X.W. DU¹, X.Y. YANG¹*, M.L. LI² AND X.X. LU²

¹CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University Science and Technology of China, Hefei 230026, China (*xxyang@ustc.edu.cn)
²Institute of Geology, Henan Provincial Bureau of Land and Mineral Resources, Zhengzhou, 410000, China

Introduction
The molybdenum mineralization district in east Qinling orogenic belt is tectonically located in the south edge of north China Craton, where a series of molybdenum ore deposits are discovered. These ore deposits retain the largest capacity of molybdenum in China. The most important mineralization of these molybdenum ores is porphyry type genetically forming with the Yanshan granites (Mesozoic) in Qinling orogenic belt. In this study, both the granitic samples and molybdenum ore samples are collected for detailed geochemical analyses to focus on the genesis of these molybdenum ore deposits.

Experiment and Results
Major elements, trace elements and REE are determined by XRF, ICP-AES and ICP-MS, respectively. The major elements that the samples are alkali granite and syenite-granite, which are formed in an anorogenic, syn-collisional or postorogenic environment. The chondrite normalized spider diagram and the MORB normalized diagram for the trace elements of the samples are both similar to that of the upper continent crust. The total REE amount is 32.1-251.4ppm, with an average 113.3ppm. The highest δEu anomaly is 1.7, while most of samples are less than 1 (with an average value of 0.67). The Re-Os ages of molybdenum ore give 144.8 ~ 132.40 Ma (Li et al, 2005), resembling the same period of massive Yanshanian granitic intrusives, indicating that the metallogenesis of these molybdenum deposits are relevant to the Mesozoic magmatic activities in east Qinling orogenic belt. In fact these ore deposits are associated with the small medium-sized acidic intrusives.

Acknowledgments
This study is supported by Chinese National Key Research and Development Program (2003CB214607) and Project by Henan Pro vincial Bureau of Land and Mineral Resources.

The geochemical characteristics and its tectonic backgrounds of the Lower Silurian flysch sandstones in North Qilian orogenic belt

YUANSHENG DU, JIANGHAI YANG, JIE ZHU AND XU YAJUN

China University of Geosciences, Wuhan, Key Laboratory of Biogeology and Environment Geology of Education Ministry of China, Wuhan, 430074 (dxyyz@cug.edu.cn)

The North Qilian orogenic belt is an elongated unit situated between the North China plate in north and Qaidam plate in the south. The lower Silurian Angzanggou Formation is distributed in Zhenglu, Cuijiadun sections in the eastern sector of the orogenic belt. Angzanggou Formation is dominated by clastic deposits, which is typical turbidite deposit of flysch facies. Sandstones collected from Zhenglu section consist of SiO2 ranging from 61.83% to 69.90% and Fe₂O₃*+MgO(3.83—4.98), Al₂O₃/SiO₂(0.13—0.17), K₂O/Na₂O (0.89—1.35), Al₂O₃/( CaO+Na₂O ) (0.81—2.76). The provenance analyses and tectonic setting distrimination indicate that the terrigenous materials come from the active continental margin and orogenic belts. Sandstones collected from lower part of Cuijiadun section consist of Fe₂O₃*+MgO(5.03—5.11), Al₂O₃/SiO₂(0.12—0.14), K₂O/Na₂O(0.43—1.26), Al₂O₃/( CaO+Na₂O ) (2.21—3.53). The upper part of Cuijiadun section consist of Fe₂O₃*+MgO(15.6—17.63), Al₂O₃/SiO₂(0.24—0.28), K₂O/Na₂O(0.25—0.85), Al₂O₃/( CaO+Na₂O ) (0.98—1.42). The provenance analyses indicate that the lower part of the turbidite is mainly derived from a mixed provenance between ancient orogenic belt of Alashan Plate to the north and active continental margin to the south.The upper part come from the eroded mid-basic igneous rocks implying an environment of back-arc basin.

Lead(II) desorption from goethite mediated by hydroxamate ligands

W.E. DUBBIN1 AND E.L. ANDER2

1Department of Mineralogy, The Natural History Museum, London SW7 5BD, UK; (B.Dubbin@nhm.ac.uk)
2British Geological Survey, Keyworth, Nottingham NG12 5GG, UK; (ELAnder@bgs.ac.uk)

Introduction

Siderophores are low molecular weight organic molecules secreted by plants and micro-organisms in response to Fe stress. More than 400 siderophores have been isolated, the majority of which possess either catecholate or hydroxamate functional groups. With stability constants commonly exceeding 10^{30}, siderophores are considered to have higher affinities for Fe(III) than for any other major or trace element dissolved in soil solution. Despite the abundance, ubiquity and structural diversity of siderophores in both terrestrial and aquatic ecosystems, their possible role in Pb mobilisation has received only brief attention. Here we show that three hydroxamate siderophores solubilise lead(II) chemisorbed to an iron(III) oxide adsorbent, significantly increasing the bioavailability of this toxin.

Methods

Goethite [α-FeOOH], prepared by standard methods and identified by X-ray diffraction, gave a specific surface of 36 m² g⁻¹ as determined by N₂ multipoint BET analysis. Adsorption experiments were performed aseptically using a batch method with a goethite concentration of 1.0 g l⁻¹ and an ionic strength of 0.01 M NaClO₄. Soluble Pb and Fe were measured between pH 3 and 8 by first adding Pb (10 µM) and then siderophore (10, 20, or 40 µM) to the goethite suspension. Following 20 h reaction, Pb and Fe in solution were measured by ICP-MS (Pb detection limit ≈ 0.1 ng g⁻¹) and ICP-AES, respectively.

Results

The efficacy of Pb desorption varied with siderophore type and generally increased with pH and siderophore/Pb molar ratio. A trihydroxamate siderophore, at pH 6.5 and a siderophore/Pb molar ratio of 4, solubilised nearly 25% of the total sorbed Pb. In the presence of 10 µM ferrichrome, Pb adsorption largely mimicked that for the siderophore-free system, whereas significant amounts of Pb were desorbed with 20 µM ferrichrome at pH > 5.5. Rhodotorulic acid was the least effective Pb chelator, requiring 20 µM to desorb detectable amounts of Pb.

Isotopic tracing of water filtration in oxidizing, fractured porous media

E.O. DUBININA, V.A. PETROV AND V.N. GOLUBEV

119017, Staromonetnyi per., 35, Moscow, Russia, IGEM RAS (delta@igem.ru)

The Krasnokamensk area, SE Siberia, Russia is known for its rich ore deposits. The Tulukuevskoe U deposit is hosted in Mesozoic (135 Ma) welded tuffs that are characterized by tectonic faulting, hydrothermal-metasomatic alteration, and oxidizing transformation. Further to environmental impacts caused by open pit mining, the migration of U from the ore body into the wall rocks and to the underlying aquifers is of particular interest for nuclear waste management purposes. Using the Tulukuevskoe open pit as a natural analogue, the conditions under which U can be mobilized, transported and precipitated are being investigated.

In this context the dynamics of isotope (¹⁸O, D) composition of meteoric water filtering through the fractured-porous media was studied. We monitored 9 water locations for 7 years.

Figure 1: δD for meteoric water filtering through fractured-porous media of the Tulukuevskoe U deposit

We also studied the ⁸⁷Sr/⁸⁶Sr and chemical composition of waters. The same type of analysis was performed for rain and snow precipitation. To explain the results obtained, the integration of water isotope parameters inside the fractured-porous media was modeled for many-years type of monitoring. The model calculations show that the mean extent of water filtration is from 2 to 3.5 years for the various watersampling locations.

The model calculations based on δD behavior gave more realistic results, than those based on δ¹⁸O behavior. The oxygen isotope composition of infiltrating water obviously could be altered by oxidation and carbonatization of the media. ⁸⁷Sr/⁸⁶Sr data supported this interpretation.
Searching for the perfectly removable, ultrabasic and dense lower crust

MIHAI DUCEA
University of Arizona, Tucson, AZ 85721, USA

The two main lines of thinking concerning lower crustal recycling into the mantle are mass balance-related; one is “mechanical”, and comes from shortening estimates in compressional orogens, the other is “chemical”, and is driven by the realization that the continental crust is too silicic to be produced directly by mantle melting. The first line of reasoning can be directly applied to specific mobile belts on Earth, whereas the second remains plagued by our inability to decipher the rate of continental growth through time and thus is difficult to connect to specific orogenic styles. The discourse on tectonic recycling of lower crustal crust into the mantle is plagued by the misconception that “founding of dense, eclogitic material (that is) produced during continental orogenesis … at the base of the crust”, as stated even in the overview for this session. The statement does vaguely imply that solid-state, metamorphic processes in overthickened orogenic crust lead to eclogite facies formation and potentially to subsequent convective removal. However, there is no reason why thickening-related eclogitization (although perfectly plausible) would segregate a felsic upper crust from a mafic-ultramafic lower crust. Instead, subduction-related arc environments are the only realistic settings in which felsic crust can be segregated, because magmatic differentiation operates in corroboration with shortening. Unfortunately, the most cited paper addressing removal of the deepest arc petrologic crust deals primarily with the architecture of ISLAND arcs (mafic rocks, garnet-free pyroxenite residues). Lower crustal delamination in island arcs has neither any significance on continental formation nor any relevance to mechanical mass balance issues mentioned above. Instead, I will argue that transitional or continental arcs are the perfect environments for differentiating felsic crust from a garnet-rich residue that is likely to be recycled in the mantle.

Uncertainty of Hf isotope analysis in zircon using LA-MC-ICPMS techniques: Full disclosure

S.A. DUFRAINE, J.D. VERVOORT AND G.L. HART
Washington State University, School of Earth & Environmental Sciences, Pullman, WA 99164
(dufraine@wsu.edu; vervoort@wsu.edu; ghart@wsu.edu)

In-situ Hf isotope measurements of zircon by laser ablation (LA) MC-ICPMS coupled with in-situ U-Pb geochronology by SHRIMP or LA-ICPMS is a potentially powerful technique because both tracer and age information can be determined from small zircon domains. The uncertainties inherent in zircon LA-Hf isotope analysis, however, can be considerable and all must be accounted for in order to assess these data in the context of Hf isotope data determined on chemically purified solutions.

In order to assess precision and accuracy associated with LA-MC-ICPMS zircon Hf analysis we analyzed 7 zircon standards (91500, QGNG, Temora, Peixe, R33, FC-1, and 94-35) during separate analytical sessions. Hf isotope measurements were made using a ThermoFinnigan Neptune MC-ICPMS with a New Wave 213nm Nd-YAG laser. A large source of analytical uncertainty in LA-Hf isotope analysis comes from the interference corrections on mass 176, principally from $^{176}$Yb. Mass bias for Yb was exponentially corrected assuming: (1) $\beta_{\text{Yb}} = \beta_{\text{Hf}}$ and (2) $\beta_{\text{Yb}} = x \beta_{\text{Hf}}$, where $x$ is determined by normalizing to a standard and subsequently applied to the “unknowns”.

Internal precision for individual analyses averaged $\sim 1 \, \varepsilon_{\text{Hf}}$ unit (2$\sigma$, SE). External precision of each standard during an analytical session ranged from 0.4-1.1 $\varepsilon_{\text{Hf}}$ units (2$\sigma$, SD, n=6). Between analytical sessions, however, the spread of the session means range over 1.5 $\varepsilon_{\text{Hf}}$ units, with one Yb rich zircon sample (R33) varying by $> 4 \, \varepsilon_{\text{Hf}}$ units. Accuracy of the LA Hf analyses (compared with solution Hf analyses) varied depending on the Yb correction method. For method 1, session averages for 5 samples were accurate within $\sim 1$ $\varepsilon_{\text{Hf}}$ units, but Peixe was several $\varepsilon_{\text{Hf}}$ units low and R33 was $\sim 3 \, \varepsilon_{\text{Hf}}$ units high. Method 2 improved accuracy for R33 (high Yb/Hf) but had little affect on accuracy of Peixe (low Yb/Hf).

Potential sources for variations in precision and accuracy for LA Hf isotope analysis include matrix effects and oxide interferences from Dy or Gd. For initial $^{176}\text{Hf}^{177}\text{Hf}$ ratios a large source of potential error comes from uncertainty in the age, particularly for old zircons. This is not due to the radiogenic correction of the initial $^{177}\text{Hf}^{177}\text{Hf}$ ratio, which is quite small, but in the CHUR reference, which varies by over 2 $\varepsilon_{\text{Hf}}$ units/100 m.y. Regardless of their sources, all uncertainties associated with LA-MC-ICPMS zircon analyses need to be incorporated into the errors reported on $^{176}\text{Hf}^{177}\text{Hf}$ ratios. These several $\varepsilon_{\text{Hf}}$ unit uncertainties may not be an issue where large variations in $^{176}\text{Hf}^{177}\text{Hf}$ are expected (e.g., detrital zircons), but they put limitations on applications where small variations in $^{176}\text{Hf}^{177}\text{Hf}$ are significant (e.g., constraining crust-mantle evolution).
Molecular and compound-specific stable C isotope investigation of the fate of dung C in a temperate grassland soil

J.A.J. DUNGAIT1, R. BOL2 AND R.P. EVERSHED1

1Organic Geochemistry Unit, Bristol Biogeochemistry Research Centre, School of Chemistry, University of Bristol, Cantock’s Close, Bristol, BS8 1TS, UK. (r.p.evershed@bristol.ac.uk)
2Soil, Environmental and Ecological Science Department, Institute of Grassland and Environmental Research-North Wyke Research Station, Okehampton, Devon, EX20 2SB, UK. (roland.bol@bbsrc.ac.uk)

Establishing the potential of soils to sequester C and elucidating the mechanisms whereby this is achieved is vital in order to understand the capacity of terrestrial ecosystems to act as sinks for anthropogenic C. Significant quantities of cattle dung are applied to temperate grassland annually and traditional long-term use of manures as soil improvers has been proven to increase SOM (Haynes and Naidu, 1998). This project applied molecular and compound-specific stable C isotope methods to investigate the fate of cow dung in a temperate grassland soil, utilising the Δ13C(con-trt) values of compounds from natural abundance 13C-labelled C4 dung (δ13C = -12.6‰) and C3 soil (δ13C = -30.3‰). The 0-5 cm horizon of dung-treated soils were sampled at 0, 7, 14, 28, 56, 112, 224 and 372 d. Bulk δ13C values estimated that a maximum of 12% dung C was incorporated at 56 d (Dungait et al., 2005) with compound-specific determinations estimating that 19% dung C was incorporated at this time. Differences between degradation rates of major organic components of C4 dung were revealed. C4 dung comprised 80% carbohydrate, 5% lignin and <1% lipid. Percentage incorporation of xylose accounted for 10% dung C at 56 d, compared with 3% for glucose; significant concentrations of dung carbohydrates remained in the soil at the end of the experiment. Dung-derived lignin 4-hydroxyphenols displayed a range of degradation rates in the soil, but appeared to be more labile than expected and did not contribute significantly to dung-derived C later in the experiment. Faecal biomarker 5β-stanols and free fatty acids suggested that concepts of recalcitrance might not rely on individual chemistry but on the potential of certain compound classes to escape degradation or leaching; very long chain fatty acids were appeared to be the most resistant dung compound class.

Investigation of the ‘Trigger Molecule Response’ using 13C stable isotope probing of microbial membrane fatty acids

J.A.J. DUNGAIT1, S.J. KEMMITT2, L. MICHALLON2, C.V. LANYON4, R.P. EVERSHED1, A.G. O’DONNELL3 AND P.C. BROOKES2

1Organic Geochemistry Unit, Bristol Biogeochemistry Research Centre, School of Chemistry, University of Bristol, Cantock’s Close, Bristol, BS8 1TS, UK. (r.p.evershed@bristol.ac.uk)
2Soil Microbial Biomass Research Group, Agriculture and Environment Division, Rothamsted Research, Harpenden, Herts., AL5 2JQ, UK. (philip.brookes@bbsrc.ac.uk)
3Institute for Research on Environment and Sustainability, Devonshire Building, University of Newcastle, Newcastle-upon-Tyne, NE1 7RU, UK. (tony.o’donnell@ncl.ac.uk)

The ‘Trigger Molecule Response’ is a hitherto unrecognised mechanism in soil microorganisms that provides a strategy for survival in a relatively substrate-poor environment. Previous respiration experiments have shown that the additions of ‘trigger molecule’ concentrations of low molecular-weight compounds to soils induce two- to five-fold greater expenditure of energy by the soil microbial biomass than that provided by the added substrate (De Nobili et al., 2001). Thus, we investigated the hypothesis that soil microorganisms maintain metabolic alertness in anticipation of a food event through application of 13C-labelled substrates at ‘trigger molecule’ concentrations, using compound-specific 13C isotope analysis of microbial biomarker PLFAs (Evershed et al., 2006). This paper presents results from recent experiments with soils from Rothamsted Classical Experiments that show: a) significant increases in the δ13C values of individual PLFAs without significant increases in abundance at four concentrations (0, 25, 83 and 416 µ 13C g-1 soil) after 120 h, and, b) differential uptake of 13C over a 240 h time course in individual microbial PLFAs extracted from soils treated with 15 µ 13C g-1 soil. Additional evidence for the ‘Trigger Molecule Response’ from concurrent experiments using CO2 respiration, nucleic acid and RNA-SIP methodologies will also be discussed. The significance of these findings in the context of the role of the soil microbial biomass in C cycling in soils will be considered.

References
The Dolomites of the eastern Southern Alps were formed from the Permo-Triassic sedimentary cover of the South Alpine unit that was slightly deformed in the Tertiary. The different parts of the Dolomites have suffered Alpine deformation two times, and the shortening process is actually still active along the southernmost thrusts. The direct dating of the deformation is possible only in the southern zones, where sediments are involved in the thrusts, whereas in the northern areas no or rather scarce geological evidences on the timing of structural evolution exist. The isotope geochronological dating is difficult due to lithology of the sedimentary successions, areas no or rather scarce geological evidences on the timing of shortening process is actually still active along the southernmost thrusts.

In order to constrain structural evolution of the area, we applied low temperature thermochronology [apatite fission track (AFT) and apatite (U-Th)/He (AHe) dating methods] on the Triassic volcanic dikes and tuff horizons. The AFT ages are ranging between 210 and 6 Ma. The oldest ages indicate the presence of slightly reset areas and date the exhumation of some structural blocks to be Late Miocene. The AHe ages are younger than the AFT ages in each sample. In the western Dolomites, where the Neogene thermal reset is not detected by the AFT thermochronometer, the AHe ages show Late Miocene reset due to the lower closure temperature of the later method. Inferring from the significant contrast between the AFT and AHe ages we conclude that the dated stratigraphic horizons were deeper than the total reset depth of AHe method but shallower than the reset depth of the AFT method between the Late Triassic and Late Miocene. We suppose that beyond the general Miocene uplift of the Dolomites mainly the displacements along the Stava line and Schio-Vicenza fault or Bassano thrust are responsible for the exhumation of Passo Feudo and Recoaro area, respectively.

Data handling, outlier rejection and calculation of isotope concentrations from laser ICP-MS analyses by PEPITA software

I. DUNKL, T. MIKES, K. SIMON AND H. VON EYNATTEN

Geoscience Center, University of Göttingen, Germany

The raw output data of laser ICP-MS analyses are composed of high number of ion counts registered in time. The handling of these huge matrices and the expression of trends, isotope ratios and finally the concentrations is a rather time consuming procedure. We have created a data handling system and an evaluation software (for Windows) that stores the necessary background information, and performs several outlier tests and the computations for the concentrations.

The composition of the standards, measurements on standards and the used dwell-times are stored in different files. The blank counts can be extracted from the data files or from separate 'blank files'. The computation starts with the selection of internal standard isotopes. Then PEPITA investigates the compatibility of the files and warns if one or more isotopes are not present in all kind of input files. The preferred time slices for the calculation of the isotope concentrations can be extracted graphically from a time/cps plot. The raw data or the cps values normed by the counts of the internal standard can be tested for outliers.

The time slices show always some fluctuation of the cps values, and the experiments frequently contains spikes, which appear only in single time slices. These individual data can seriously bias the average count, especially when the count rate is low. PEPITA offers three methods to visualize and/or reject the extreme values. (1) The minimum and maximum values detected by the record of an isotope can be highlighted. (2) The Grubbs outlier test indicate the probability that the highest or lowest value belongs to the rest of the population. (3) The user can specify how many relative standard deviation can be tolerated for the individual data points. The extreme values (e.g. having more than 4 rel. std. dev., which is rather probably a 'technical outlier') can be rejected and this procedure can be consequently repeated for all processed files.

The software exports into files or pastes to the clipboard the results in the following order: (a) list of files, time slices used, rejection algorithm and criterion, (b) average concentrations, limit of detection and other statistical parameters, (c) concentrations and errors in time slices (d) warning in case of incompatible files.

PEPITA is freeware, downloadable from:

Isotopic zonation in zircon as a recorder of progressive metamorphism

D. J. DUNKLEY
National Institute of Polar Research, Tokyo, Japan
(danield@nipr.ac.jp)

Zircon and garnet share some common traits: both are typical metamorphic phases in granulites; both are important sinks for heavy REEs; and both tend to preserve complex compositional zoning that reflects growth behaviour during high-temperature metamorphism. Whereas growth stages recorded in garnet porphyroblasts are widely used to characterize stages along a metamorphic P-T path, zircon tends to be treated as a single stage mineral, with growth (and consequently age estimates from U-Pb isotopic dating) tied to a poorly defined thermal maximum. This is in contradiction to the complex zoning commonly seen in metamorphic zircon grains, especially those in metapelitic migmatites. Such zoning can be understood through the same methods by which garnet is studied; i.e. compositional mapping and micropetrographic relationships. Zircon grains from metapelite samples of the granulite-grade Lützow-Holm Complex of east Antarctica show a complex range of textures and ages. Whereas previous SHRIMP ages from zircon grain separates concentrate around 530-550Ma, and were interpreted as timing peak metamorphism, further detailed analysis yields a spread of age estimates from 500 to 630Ma. In-situ analyses of zircon inclusions in garnet porphyroblasts reveal a stage of U-rich zircon growth at c.600Ma, with flat HREE-MREE profiles indicating prograde growth in the presence of garnet. Zircon preserved in a garnet megacryst from felsic pegmatite that fills boudin necks in a metapelitic layer show multiple stages of growth (Fig.), with c.600Ma flat H-MREE (garnet-equilibrated) cores, c.570Ma rims with outward steep to flat H-MREE growth zoning, and resorption prior to incorporation in the garnet megacryst and crystallization of the felsic pegmatite at c.550Ma. Although the 100Ma spread of zircon ages could be interpreted as recording separate metamorphic events, the textural and chemical associations between zircon, garnet and felsic melt suggests that zircon growth was progressive through a prolonged metamorphic event, and that a large proportion of zircon growth at 530-550Ma occurred during retrograde rather than peak metamorphism.

A bacterial model for studying interactions between microorganisms and CO₂ injected in the subsurface

S. DUPRAZ¹, M. PARMENTIER¹, B. MENEZ², P GOUZE², R. LEPROVOST² AND F. GUYOT¹

¹Institut de Physique du Globe de Paris, Centre de Recherches de Stockage Géologique du CO₂ (IPGP/TOTAL/SCHLUMBERGER), Paris, France (dupraz@ipgp.jussieu.fr)
²Géosciences Montpellier, UMR 5243, Université Montpellier

Geological storage of CO₂ in the subsurface will likely become an important industrial process since it is an option envisaged to mitigate the increase of atmospheric CO₂ in the coming decades. The potentialities of some subsurface microorganisms to induce CO₂ mineralization into carbonates could strongly enhance the stability of the CO₂ containment or could also have adverse effects on the injectivity. In order to study this process, we have carried out experiments of biotransformation of CO₂ into solid carbonates using Bacillus pasteurii, an ureolytic model strain. The strain was inoculated in an artificial ground water based on the composition of actual deep groundwaters from the basin of Paris, France. Experiments were performed in a specially designed circulation cell. The complex pH evolution, induced by the strain in the artificial groundwater, could be modelled using the geochemical software Chess 3.6, from Ecole des Mines de Paris, including enzymatic kinetics of ureolysis, kinetics of gas-solution transfer, and rate of calcite precipitation. Alkalization due to the enzymatic hydrolysis of urea, part of which was shown to occur by extracellular processes, reached a plateau once a dynamical equilibrium was established with the rate of CO₂ transfer into the aqueous solution. Calcite precipitation induced a decrease in pH as well as a strong cellular mortality due to nucleation of carbonates on bacteria followed by the embedding of cells within the carbonate crystals, as evidenced by SEM, X-ray synchrotron imaging and TEM studies. The implications of this model for CO₂ biomineralization in subsurface environments are finally discussed in the light of subsurface metabolisms, which might often imply local pH increases (e.g. dissimilatory sulphate reduction).
FT-IR spectroscopic study in plants from contaminated mining sites

NUNO DURÃES¹, IULIU BOBOS¹ AND EDUARDO FERREIRA DA SILVA²

¹GIMEF – Center of Geology, University of Porto, Rua do Campo Alegre, 687 4169-007 Porto, Portugal (nunodurães@fc.up.pt)
²ELMAS – Department of Geosciences, University of Aveiro, Campus de Santiago, 3810-193 Aveiro, Portugal

The roots and above ground parts of three different plants species (Cistus Ladanifer, Juncus efusus and Scirpus holoschoenus) collected in contaminated mining sites of Iberian Pyrite Belt were chemical analysed. Concentrations of toxic metals (Cu, Pb, Zn) were found higher in both Juncus efusus and Scirpus holoschoenus especies than Cistus Ladanifer. The concentration values of toxic metals determined in roots in the firsts plants species are: Cu 352 -519 mg.kg⁻¹, Pb 169 – 568 mg.kg⁻¹, Zn 212-563 mg.kg⁻¹. Both Fe and Mn concentrations increase, as toxic metals concentrations increase.

FT-IR technique was used for evaluation of the type of organic and inorganic complexes in plants. The analyses were carried out on drying and low ashing temperature material of different parts of each plant.

Slightly differences regarding to organic complexes were observed in FT-IR patterns. Strong stretching bands attributed to C–H (2923; 2850 cm⁻¹) and C=O (2360; 2340 cm⁻¹) were found for each part of studied plant. Salts and fatty acids are observed at 1620 cm⁻¹, 1536 cm⁻¹ and strong saturated fatty acids occur at 1700 cm⁻¹. A slight broadening band at 3400 cm⁻¹ is attributed to OH⁻ stretching band. Bands associated with H₂O (1630 cm-¹ bands) are more expressive in the roots and stems. No H₂O bands were identified in the upper part of plants.

However, strong differences in inorganic complexes were observed between the roots and above ground parts of plants species analysed. Molecular vibrations associated with inorganic complexes were related to the stretching modes of the S–O bonds show characteristic absorption bands at 1250 – 1000 cm⁻¹. Probably, these bands are characteristics for sulfate adsorption on Fe-oxyhydroxides. The presence of S–O bonds suggests that some mechanisms of detoxification of metals in plants consist in the precipitation of metals as sulfates. A strong band at 669 cm⁻¹ attributed to anhidrite occur mainly in leaves and stems.

The organics acids and S–O complexes may act as chelating agents in the transporte of metals in plants allowing the accumulation of metals in plants.

Distribution and speciation of mercury in the Curuai floodplain lakes and role of the water exchanges with the Amazon River, Brazil

³Ifremer, BP 21105 44311 Nantes, France (Daniel.Cossa@ifremer.fr)
⁴UFF, Programa de Geoquimica, Outeiro São João Batista, 24020- 007 Nitéroí, Brazil (marcelaaperez@hotmail.com, pturcq@geoq.uff.br)

The role of the channel-floodplain interactions in the biogeochemical cycle of mercury in the Amazon basin is still poorly documented. It appears that floodplains can act as an important sink of sediments and Hg associated with fine particles. The main objective of this work is to study the distribution and the speciation of Hg in the Curuai floodplain lakes system (3800 km²) in the Middle Amazon.

The sediment inputs in these floodplain lakes occurs during the rising stage of the Amazon R., from January to May. In most of these lakes, the maximum Filtered-Hg and F-CH₃Hg concentrations are observed during the rising water stage, varying from 27.6 to 51.6 pM and 0.12 to 1.66 pM respectively, that coincides with the F-Hg input of the Amazon R. The dry season, when most of the lakes are isolated from the mainstream, is characterized by low F-Hg concentrations. This can be explained by the formation of Hg° from Hg ²⁺ reduction and its volatilisation induced by wind waves. On the contrary, the highest P-Hg concentrations are observed during the dry season (47 to 478 pM) due to the elevated TSS content associated to the re-suspension by the wind of the bottom sediments in shallow water lakes (~50cm) and by the fish and invertebrates bioturbation. The negative correlation between the partition coefficient of Hg (Kₐₐ) and the TSS content confirms the Hg complexation on OM-fine particles during its transfer in the floodplain system. The water and sediment storage in the floodplain lakes favors biogeochemical processes, like reduction, volatilization, adsorption and re-suspension of Hg in surface waters.
Provenance and fates of the REEs and heavy metals in the suspended particulate matter off Luzon shelf in the South China Sea

JOSELITO P. DUYANEN1 AND MARTIN WIESNER2

1National Institute of Geological Sciences, University of the Philippines, Diliman, Quezon City, Philippines (jpduyanen@yahoo.com)
2Institute of Biogeochemistry and Marine Chemistry, University of Hamburg, Germany

The study establishes the provenance of the suspended particulate matter (SPM), collected in the upwelling area at a water depth of 1,200 m off Luzon shelf using sediment traps during eleven sampling periods. The shale-normalized REE patterns of the SPM correlate with those of the volcanoclastic sediments of the Amburayan and Abra Rivers in NW Luzon, establishing their mutual provenance. These river systems drain Cu mine areas.

Knowing their mutual sourcing, we tried to correlate the REEs and heavy metals with the host matrices to ascertain their fates. The REEs, known to be chiefly geogenic, do not correlate with the heavy metals, such as Zn ($R^2 = 0.002$), Pb ($R^2 = 0.020$), and Cd ($R^2 = 0.085$), which are mine-derived. Cu, on the other hand, correlates fairly with the REEs, but not with the other heavy metals.

Cd is hosted by the Mn oxides, whereas, Zn and Pb have strong affinity with the clay minerals, especially smectite. These heavy metals take on soluble form when released from their sources and favor matrices that bond them as adsorbed or exchangeable cations. In contrast, the REEs are associated with the lithogenics and the organic matter. The same association is exhibited by Cu with the lithogenics, which is largely controlled by the presence of chlorites.

Though mutually sourced, the above geochemical scenarios for the REEs and the heavy metals establish that they share only the same provenance but not geochemical behavior once they are released from their source rocks. When released anthropogenically by mine activities or, geogenically, by weathering, the heavy metals become significantly more available for uptake, whereas, the REEs are more strongly bound by their particulate hosts.

The reactivity of raw and incinerated mammalian bone in the presence of aqueous metals

A.D. DYBOWSKA1, E. VALSAMI-JONES1 AND D.A.C. MANNING2

1Department of Mineralogy, Natural History Museum, London, UK (a.dybowska@nhm.ac.uk)
2School of Civil Engineering & Geosciences, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

The production of meat generates a range of by-products including meat and bone meal, the use of which, in applications such as animal feeds, has become severely restricted, due to possible contamination by pathogens (e.g. BSE). The material has to be incinerated and then disposed of in landfills, unless other applications are found.

Raw bonemeal has been previously used in the remediation of metal contaminated soils [1]. Thermal treatment of this material to remove the organic matrix has been suggested in order to increase its reactivity and eliminate pathogens. The purpose of the work presented here was to investigate metal removal capacity of both incinerated and raw bonemeal with a view of a potential application of this waste by-product in wastewater/acid mine water remediation.

Raw and incinerated bonemeal at temperatures ranging from 725-850ºC (as supplied by industry – PDM Group) were reacted with 1000 mg/L solutions of Pb, Zn and Cu. Synthetic HAP was used as a control. Metals in solution were measured using ICP-AES while the solid residues were characterised using analytical SEM, FT-IR and XRD.

Synthetic HAP outperformed both raw and incinerated bonemeal in the removal of all metals except for Pb. HAP removed 95% Pb, 86% Cu and 80% Zn. Both raw and incinerated bonemeal removed 99% of Pb. However, Zn and Cu were only eliminated from solution by 60% by the raw bonemeal and by 18% for Cu and below 10% for Zn by the incinerated bonemeal. Metal phosphates formed as a result of Pb, Cu and Zn reaction with HAP, as indicated by SEM analysis. In samples of raw and incinerated bonemeal only phosphates of Pb were found.

Incineration of bonemeal at high temperatures (700-850ºC) reduces its removal capacity for Zn and Cu, indicating a different removal mechanism to that of Pb, which appears to be always by precipitation of Pb phosphates. Incinerated bone has a strong pH buffering capacity and thus may prove effective in remediation of acid mine waters – leaching columns tests are now carried out to investigate this further.

Variscan potassic-alkaline magmatism in Stara planina, Bulgaria – Composition, source and geodynamic significance

M. Dyulgerov1, B. Platevoet2 and U. Schaltegger3

1Sofia University “St. Kliment Ohridski”, Fac. Geology & Geography, Sofia, Bulgaria (momchil@gea.uni-sofia.bg)
2Université Paris-XI, Dept. Sciences de la Terre, Orsay, France (platvoet@geol.u-psud.fr)
3Université de Genève, Section Sciences de la Terre, Geneva, Switzerland (Urs.Schaltegger@terre.unige.ch)

Three Variscan potassic-alkaline plutons: Svidnya, Buhovo-Seslavtzi and Shipka outcrop in Western and Central Stara planina, Bulgaria. The rocks intrude Silurian, Ordovician and Devonian metasediments. The existing isotopic data indicate an emplacement age between 340-320 Ma for Svidnya, the first TIMS results on zircons for Buhovo-Seslavtzi yield 352±22 Ma.

The plutons have essentially intermediate monzonite - syenite composition, with minour amounts of granite. The metaluminous intrusive varieties predominate, but in the three plutons magmatic activity terminates with the separation of strongly peralkaline dyke residue. The peralkaline dyke rocks are of quartz syenitic and granitic composition and contain sodic-calcic and sodic pyroxenes and amphiboles. The rocks have pronounced potassic character, with K2O in the range 5.49 – 11.04 wt.%, and very high LILE and Th – U contents. Synchronous with the peralkaline tendency the contents of HFSE and REE increase.

Preliminary isotopic results show that the rocks have isotopic signature plotting in the enriched quadrant of Sr-Nd isotope systematics. 87Sr/86Sr and 143Nd/144Nd for Svidnya pluton are 0.709 – 0.712 and 0.51192 – 0.51194 respectively. For Buhovo-Seslavtzi 87Sr/86Sr is 0.709 and 143Nd/144Nd is 0.51191 – 0.51188, coupled with εHf from -3.8 to -5.2. Concordant with the moderate enrichment in incompatible elements Shipka pluton shows less enriched composition: 87Sr/86Sr is 0.705 and 143Nd/144Nd is between 0.51215 and 0.51217.

The rocks present fractionated trend of distribution of REE with La/LuN: 23 (Svidnya) and 17 (Buhovo-Seslavtzi), which features are consistent with the presence of residual garnet in the source. The rocks from Shipka have less fractionated trend with La/LuN: 10 which implies on the presence of residual spinel in the source. Low rate melting of enriched mantle is the probable mechanism for the magma generation of this Variscan association.

The very high K2O and the dominance of LILE, Th and U over HFSE indicate significant crust – mantle interactions and involvement of crustal materials into the mantle. The potassic rocks asssociate with S and I type granitoids and this fact is in favor of the orogenic character of the whole Variscan magmatism in Stara planina, Bulgaria. The rocks have isotopic fabrics and are formed after the main orogenic events.

Controls on major and trace element zoning in hydrothermal garnet

A. Dziggel, K. Wulff, J. Kolb and F.M. Meyer

Institute of Mineralogy and Economic Geology, RWTH Aachen, Wueellnerstrasse 2, 52062 Aachen, Germany; adziggel@iml.rwth-aachen.de

Garnet from the Navachab gold deposit, Namibia, records complex zoning profiles that reflect the alteration history during mineralization. The deposit is situated in the Southern Central Zone of the Damara Orogen, a typical low-P metamorphic terrane. It is hosted by late Proterozoic shelf sediments that are dominated by marbles and calcisilicate rocks, consisting of highly variable proportions of Cal, Cpx, Kfs, An and Qtz. The P-T conditions of formation have been estimated at c. 550-600°C and 2-3 kbars, consistent with the low-P regional metamorphism in the Damara belt.

The garnets investigated in this study are from a massive “replacement-style” sulfide lens and associated alteration zone. Hydrothermal alteration was mainly driven by an increase in bulk rock Mn, Si, and Fe. Two types of alteration can be distinguished that are interpreted to have formed contemporaneously: one dominated by Gt-Cpx-Kfs-Qtz, the other one mainly consisting of Gt and Bt. Textural analysis, coupled with detailed mineral-chemical investigations reveal two distinct garnet generations, and a two-stage growth history.

Stage I garnet usually forms the cores of individual porphyroblasts, and is highly enriched in spessartine. It commonly records a classic bell-shaped zoning profile, in which the XMn progressively decreases from core to rim. This type of zoning profile formed during pervasive hydrothermal alteration, leading to the progressive depletion of Mn in the fluid.

Stage II garnet overgrows the early garnet, and is best-developed in zones of intense fluid-rock interaction. Most of the major and trace elements (including the REE) were mobile at this stage. Stage II garnet is Ca-rich, and records variable zoning patterns that are controlled by the permeability in the different alteration zones. In the Gt-Bt alteration, stage II garnet is characterized by µm-scale oscillations. The oscillations document the episodic supply of fluid in zones of strongly reduced permeabilities. In high-permeability zones, such as the massive sulfide lens, the compositional variations are more progressive, suggesting a rather constant fluid supply in these units.

The garnet zoning pattern are related to different stages during the development of the hydrothermal system. They document the complete history of initial fluid-rock interaction during the onset of pervasive hydrothermal alteration, subsequent fluid pressure built up towards critical values, and final hydraulic fracturing in zones of high fluid pressures. There is no evidence for changing P-T conditions during garnet growth.
Low-Ca pyroxene relics in drilled basalts from EPR crust (IODP Site 1256D)

W. DZIONY, J. KOEPE AND F. HOLTZ
Institut für Mineralogie, Leibniz Universität Hannover, Germany (w.dziony@mineralogie.uni-hannover.de)

It is well-accepted that under fast-spreading ridges the differentiation of primitive MORB into the upper volcanic, and the lower plutonic crust proceeds in crustal magma chambers. Thus, it is to expect that those phases which are fractioned in the magma chamber should also be found as phenocrysts in the erupting melts, at least from time to time. This is general valid for olivine, plagioclase, and clinopyroxene, but not for orthopyroxene. This is expressed in the "orthopyroxene paradoxon" meaning that orthopyroxene is often present in the gabbroic rocks of the plutonic crust from fast-spreading ridges (e.g., from Hess Deep and Garrett Transform fault), but not in the corresponding basalts of the upper crust.

We studied basalts and gabbros from the IODP (Integrated Ocean Drilling Program) Site 1256D in the eastern Pacific where 15 Ma old crust was formed at the EPR (East Pacific Rise) under superfast conditions (Wilson et al., 2006). Here, the Expeditions 309 and 312 deepened Hole 1256D initiated by Leg 206, drilling through lavas, the underlying sheeted dike complex, and into gabbroic rocks, providing the first penetration of the dike-gabbro boundary in intact ocean crust. Many of the gabbros bear orthopyroxene both as poikilitic and as prismatic crystals implying that orthopyroxene saturation was reached during differentiation. However, up to now, orthopyroxene was not recorded as phenocryst or matrix mineral in the corresponding dikes, sheet flows and pillow basalts above the gabbro/dike transition. Therefore, the first observation of low-Ca pyroxene in the volcanic section of the 1256D drill core is of significance.

Low-Ca pyroxene was detected as relics in matrix clinopyroxenes in several samples from the uppermost sheet flows of Leg 206. They appear as strongly disrupted, often cloudy patches in intensely zoned matrix clinopyroxenes. Since they show relatively high CaO contents (4-5 wt%), these pyroxenes correspond in composition to typical pigeonites. Their Mg# (MgO/(MgO+FeO)*100; molar) vary between 75 and 82, and are generally slightly higher compared with the rimming matrix clinopyroxene. This implies that the magma which generated the low-Ca pyroxene was more primitive than the later one producing the matrix clinopyroxene, which contrasts with the general observation that orthopyroxene is more stabilized in evolved MORB systems than in primitive (at shallow pressures). The textural features of the low-Ca pyroxenes suggest that partial melting reactions proceeded instead of simple resorption by a later magma.

Individual particle analysis of urban aerosols in the Rhein-Main area

M. EBERT1, B.P. VESTER1, E. BARNERT1, K. KANDLER1, L. SCHÜTZ2 AND S. WEINBRUCH1

1Institute of Applied Geosciences, Darmstadt University of Technology, Germany (mebert@geo.tu-darmstadt.de)
2Institute for Physics of the Atmosphere, Johannes-Gutenberg-University, Mainz, Germany

Epidemiological studies have shown a correlation between aerosol concentration in the ambient air and mortality. Adverse health effects seem to be better correlated with the surface or the number as with the mass of aerosol particles inhaled. Therefore individual particle analysis techniques provide very valuable additional information to the conventional performed mass concentration measurements (Pm).

In the years 2003 and 2004, size-resolved aerosol particle samples in the size range 0.1 – 10 µm aerodynamic diameter were collected at an urban background station in Mainz, Germany. Size, morphology, chemical composition and mixing state of more than 5400 individual particles of seven selected sampling days were analyzed in detail by scanning electron microscopy and energy-dispersive X-ray microanalysis. In addition, transmission electron microscopy, aerosol mass spectrometry and atomic force microscopy were applied to obtain further information about the mixing state of the particles. The fine particle fraction (diameter < 1 µm) is always dominated by complex secondary aerosol particles (≥ 90 % by number) independent from air mass origin. These particles are complex internal mixtures of ammonium and sodium sulfates, nitrates, and organic material. Between 20 and 40 % of the complex secondary aerosol particles contain soot inclusions. The composition of the coarse particle fraction (> 1 µm diameter) is strongly dependent on air mass history with highly variable abundances of complex secondary aerosol particles, aged sea-salt, silicates, silicate-mixtures, calcium sulfates, calcium sulfate/carbonate mixtures, calcium nitrate/carbonate mixtures, biological particles, and external soot.

The dominance of complex secondary aerosol particles shows that reduction of the precursor gases has to be a major goal for successful reduction strategies for PM10. Additionally, because of the carcinogenic potential and the frequent occurrence of soot inclusions within secondary aerosol particles, the reduction of the soot component has to be an important goal.
Evaluation of oxidation state and potential for bio-signatures in Fe-bearing minerals in deep-sea minerals using spectroscopic approaches

X-ray absorption spectroscopy has proven to be a useful way of examining the chemical state of various elements in Earth materials. Iron is the most abundant redox-active element near the Earth’s surface, and is particularly abundant in oceanic rocks and minerals and biological mats that occur in hydrothermal systems. Basalt is the dominant extrusive rock that comprises the ocean crust, and is approximately 10 wt % FeO, principally as Fe(II). Hydration and oxidation of basalt during water rock reactions produces clay minerals and oxides of variable composition, crystallinity, and oxidation state on the surfaces of basalt. Sulfide minerals, such as pyrite (FeS₂) that precipitate at hydrothermal vents also undergo alteration reactions that produce Fe(III) minerals. We are using XANES (X-ray absorption near-edge spectroscopy) to examine Fe-bearing rocks and minerals from the deep sea. Our objectives are two-fold: 1) test our ability to discriminate Fe(II) from Fe(III) in rocks and minerals from the seafloor; to discriminate between Fe(II) and Fe(III) we are using a new method is proposed which is usable with only ordinary levels of energy resolution, signal/noise, and energy calibration accuracy. 2) Examine the range of natural Fe(III)-bearing minerals occurring in the deep sea in order to determine if biological activity produces a distinct signature in the short- and intermediate-range order.

The Loihi Seamount microbial observatory: An extremely common deep-sea habitat for Fe-oxidizing bacteria

K.J. Edwards¹, C.L. Moyer², C. Chan³, D. Emerson⁴ and G. Horn⁵

⁴David Emerson, American Type Culture Collection, (demerson@gmu.edu)
⁵University of Southern California, Department of Biological Sciences, (ghorn@usc.edu)

Loihi Seamount is a seismically active submarine volcano that represents an emerging Hawaiian island. Hydrothermal fluids are emitted at the summit, in vicinity to the pit craters, and at more diffuse sites long the flanks of the seamount, even down to the seamount base (5000 meters). Since discovery of this seamount a prominent microbial group that has been recognized and play prominent roles in biogeochemical cycles on the seamount are the neutrophilic iron oxidizing bacteria (FeOB). FeOB habitats include the hydrothermal vents, which range in temperature from ambient (~)°C) to about 55°C presently. The composition of the fluids at Loihi is largely dictated by magmatic degassing and consequently are enriched in carbon dioxide and Fe(II) and are depleted in sulfide by comparison to other deep-seam marine hydrothermal venting habitats. Previous studies have established that FeOB play a major role in Fe oxidation and Fe oxide deposition at the site; these processes may serve as modern analogues to past major Fe oxide depositional settings. Our ongoing studies are evaluating the communities mediating Fe oxidation, the physiology of FeOB, and the biomineralogy of Fe oxides formed by FeOB. Other habitats occupied by FeOB among other microbial groups include the bare rock of the volcano itself, theollitic basalt that undergoes hydration and oxidation reactions in the presence of oxidizing seawater, and rock that interacts with hydrothermal fluids that are being emitted. Ongoing studies are looking at the biogeochemical roles epilithic and endo-lithic microbial communities play in mediating water-rock alteration reactions on basalt surfaces.
**U(VI) and Eu(III) interaction with pyrite (FeS₂)**

N. EGLIZAUD¹*, M. DESCOSTES¹, M.L. SCHLEGEL², F. MISERQUE³ AND E. SIMONI⁴

¹CEA, DEN/DANS/DPC/SECR/Laboratory of Radionuclides Migration Measurements and Modelling, F-91191 Gif-sur-Yvette, France (michel.schlegel@cea.fr)
²CEA, DEN/DANS/DPC/SCP/Laboratory for the Reactivity of Surfaces and Interfaces, F-91191 Gif-sur-Yvette, France (frederic.miserque@cea.fr)
³CEA, DEN/DANS/DPC/SCP/Laboratory for the Reactivity of Surfaces and Interfaces, F-91191 Gif-sur-Yvette, France (michel.schlegel@cea.fr)
⁴Institut de Physique Nucléaire d’Orsay, Université Paris Sud, Bât. 100, F-91406 Orsay, France (simoni@ipno.in2p3.fr)

The mechanism of U(VI) and Eu(III) interaction with pyrite was studied by solution chemistry and X-Ray Photoelectron Spectroscopy (XPS). Pyrite dissolution under anoxic conditions leads to the production of sulphoxyanions and ferrous iron, which in turn is sorbed at the pyrite surface. This sorption was confirmed by isotopic dilution. U(VI) is in competition with Fe(II) for adsorption on sulfur sites. This sorption is maximum at pH ≥ 5.5. Co(II) and Eu(III) are also sorbed on pyrite surface at pH ≥ 5.5, confirming that sorption on pyrite does not necessarily result from a redox reaction.

When [U]₉₆h is below 4 10⁻⁹ mol g⁻¹, a redox reaction occurs at the pyrite surface and leads to the formation of reduced uranium and elementary sulphur. Iron remains at oxidation degree +II during the whole process. The formation of these solid products tends to passivate the pyrite surface as the redox reaction is no longer observed when the amount of sorbed U increases. The surface is saturated for [U]₉₆h = (3.4±0.8) 10⁻⁷ mol L⁻¹. The sorption at [U] > 10⁻⁹ mol L⁻¹ can be modelled by a Langmuir isotherm with a sorption constant equal to 8 10⁻⁷ L mol⁻¹.

At higher uranium (VI) concentration, a redox reaction between U(VI) and Fe(II) occurs. This reaction produces a U(IV)-U(IV) mixed (hydr)oxide, U₄O₉(s), and iron (III) (hydr)oxide, such as maghemite (γ-Fe₂O₃(s)), which can in turn participate to U(VI) adsorption.

**Comparison of estimates for Andean Plateau formation from thermochronology and stable isotope paleoaltimetry**

TODD A. EHLERS AND JASON B. BARNES

Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109 USA, (tehlers@umich.edu, barnesja@umich.edu)

Quantifying the timing and rates of central Andean mountain building and plateau formation have previously been limited by (1) sparsely available age constraints on the timing of deformation, and (2) a lack of constraints on the elevation history of the plateau. We address these limitations with 52 new low-temperature thermochronometer ages, and stable isotope paleoaltimetry results of Garzione et al (2005) and Ghosh et al. (2006). Thermochronometer samples were collected across two 200-300 km long transects in the northern (~15ºS) and southern (~19ºS) Bolivia thrust belt. We assess the consistency of interpretations of plateau formation from these two approaches.

We interpreted thermochronometer cooling ages along each transect to constrain the timing of deformation in different tectonic zones across the Andes. Results suggest a consistent chronology of deformation in northern and southern Bolivia. We find: (1) deformation initiated ~40 Ma along the plateau margin (Eastern Cordillera) with distributed exhumation across the entire thrust belt since about ~15 Ma, (2) deformation in the eastern part of the thrust belt (Subandean Zone) initiated by ~25-10 Ma, (3) shortening rates across each transect have been similar and decelerated over the last ~20 Ma, and (4) development of the Andean Plateau analogous to it’s modern width (but unknown elevation) occurred by ~20 Ma (Barnes et al., 2006).

In comparison, paleoaltimetry results suggest a 3.7 ± 0.4 km increase in plateau elevation between 10.3-6.7 Ma. Plateau rise is suggested to have increased deformation in the Subandean Zone over this time interval. The retention of a dense mantle root below the plateau could account for the plateau remaining at a low elevation for ~10 Ma after the thermochronometer data suggest its modern width formed. However, the steadiness of shortening rates across the thrust belt since ~20 Ma, as well as the initiation of Subandean deformation predating plateau rise by up to ~10 Ma draws into question the consistency of these two approaches. Work in progress is evaluating if temporal variations in atmospheric temperature and moisture source could account for the appearance of a low-elevation plateau prior to 10.3 Ma from stable isotope techniques.

Multilayer fixation of dissolved phosphate on natural calcites derived from sorption experiments

E. EICHE1, U. BERG2, T. NEUMANN3, R. NÜESCH3 and D. STÜBEN3

1Institut für Mineralogie und Geochemie, Universität Karlsruhe, 76131 Karlsruhe, Germany (elisabeth.eiche@img.uka.de)
2Institut für Technische Chemie, Forschungszentrum Karlsruhe, 76028 Karlsruhe, Germany

The predominance of different phosphate fixation mechanisms on natural calcite were studied in short-term batch experiments varying in hydrochemical conditions and physical properties of calcites. The fixation mechanism is crucial for the efficiency of sediment capping with calcite as an active material to reduce phosphate flux from anoxic sediments into the water column of eutrophic lakes.

Depending on the specific surface area of the applied calcite (SSA_Cc) as well as on the dissolved phosphate concentration different processes are indicated by sorption isotherms. Low P-concentrations (10 - 30 µmol L⁻¹) in the solution together with a small SSA_Cc (1 - 4.3 m² g⁻¹) lead to logarithmic shaped isotherms, indicating that adsorption processes are predominant. The same shape of isotherm can be achieved if both P-concentration (400 µmol L⁻¹) and SSA (67 m² g⁻¹) are high. Both cases result in a SSA_Cc/P-ratio of 0.1 to 0.2. Low P-concentrations (30 µmol L⁻¹) in connection with a large SSA_Cc (67 m² g⁻¹) as well as high P-concentrations (100 - 200 µmol L⁻¹) and low SSA_Cc (1 - 4.3 m² g⁻¹) result in sigmoidal shaped isotherms. The calculated SSA_Cc/P-ratio for both cases is > 1.8 and < 0.02, respectively. Depending on the residual P-concentration in solution, the sigmoidal shaped isotherms can be divided into three sections indicating different processes responsible for the P-fixation on calcite surfaces. Adsorption prevails in equilibrium with lowest residual P-concentrations. The inflection of the isotherm at moderate residual P-concentrations suggests that precipitation and transformation of Ca-P-compounds becomes dominant. This is supported by characteristic Ca/P-ratios for different Ca-P-compounds, e.g. β-Tri-Calcium-Phosphate, Octa-Calcium-Phosphate. The last section, with highest residual dissolved P-concentration, shows a logarithmic form, which can be attributed to adsorption onto the newly formed Ca-P-surface. Our results indicate that the P-fixation onto calcite is as multilayer process.

In addition, calcite saturation of the solution has an implication on the precipitation process. Subsaturation leads to partial dissolution of calcite followed by heterogeneous nucleation of Ca-P-compounds whereas supersaturation is followed by precipitation via solid solution formation.

Petrography, geochemistry and isotope characteristics of authigenic carbonates from the Mid-Atlantic Ridge

B. EICKMANN AND J. PECKMANN

DFG-Forschungszentrum Ozeanränder, Universität Bremen, D-28334 Bremen, (eickmann@uni-bremen.de, peckmann@uni-bremen.de)

Although much work focused on sulphide mineralogy of active hydrothermal systems hosted in ultramafic rocks, little is known about the genesis of authigenic carbonates found in these settings. Serpentinization of peridotites at mid-ocean ridges leads to the formation of carbonates. The hydrolysis of peridotite minerals results in an increase in pH. The high alkalinity favours the precipitation of calcium carbonate. Almost 20% of the ocean crust consists of ultramafic rocks. The formation of carbonates in ultramafic rocks may consequently represent a major CO₂ sink in the global carbon cycle. Yet, the geochemical parameters of carbonate formation in ultramafic systems are poorly understood.

We analyzed serpentinite-hosted carbonates, sulphide-hosted carbonates, and dolomite hosted in red jasper from the Logatchev hydrothermal field. The unusual dumbbell-shaped crystal aggregates of dolomite represent the first observation of dolomite in a hydrothermal environment. From the Gakkel Ridge serpentinite-hosted carbonates have been studied. Most serpentinite-hosted carbonates are isopachous and botryoidal aragonite. Occasionally, microcrystalline aragonite is predating these cements. The paragenetic sequence of the sulphide-hosted carbonates is represented by (1) micrite, (2) botryoidal and isopachous aragonite and (3) clotted micrite. Our observations reveal that carbonate formation is not a single event during late-stage seafloor alteration. δ¹⁸O values of the serpentinite-hosted carbonates range from −20.0 to +5.3‰, those of the sulphide-hosted carbonates range from +1.3 to +4.2‰. Dolomite in the red jasper exhibits δ¹³C values from −9.2 to −7.0‰. δ¹³C values of sulphide-hosted carbonates vary from +2.5 to +3.6‰, those of dolomite dumbbells range from +2.6 to +3.0‰. δ¹³C values of the serpentinite-hosted calcite that formed at high temperatures range from −5.8 to −5.5‰, reflecting a signal of mantle CO₂. The δ¹³C values of the serpentinite-hosted aragonite range from −1.6 to +2.7‰, which are typical for marine carbonates. We suggest that δ¹³C values of +3.0‰ and higher found for carbonates in serpentinites may reflect a partial contribution from methanogenesis. This hypothesis is supported by high Fe contents in these carbonates. Chondrite-normalized REE+Y patterns of the dolomite dumbbells are characterized by (1) a negative Ce anomaly, (2) a positive Eu anomaly, and (3) a slight enrichment of HREE. The negative Ce anomaly of the dolomite dumbbells indicates formation from oxic waters.
Denudation rates in NE-Iceland. Evolution of a steady state model of erosion

E. S. EIRIKSDOTTIR1, P. LOUVAT2 AND S. R. GISLASON1

1Institute of Earth Sciences, Reykjavík, Iceland
(ee@raunvis.hi.is; sigrg@raunvis.hi.is)
2IPGP, Université Paris VII, Paris, France
(louvat@ipgp.jussieu.fr)

This study critically assesses the temporal sensitivity of a steady state model of erosion that has been applied to various chemical and mechanical weathering studies worldwide. The model assumes a geochemical mass balance between the initially unweathered rock of a drainage basin and the weathering products (Gaillardet et al., 1995).

The model was applied on 89 samples of river dissolved and suspended matter collected during 1998-2002 from five basaltic glacial river catchments in NE-Iceland. The steady state model of erosion was sensitive to the seasonal changes of the dissolved constituents in the rivers. However, the measured and modelled results are within the error of the method. The modelled concentrations of the suspended inorganic matter were most consistent to the measured ones, when the average annual chemical composition of the dissolved- and the suspended matter was used in the modelling (figure 1).

These results validate the use of a steady state model of erosion in estimating the denudation rate at a catchment scale. Best results are gained when samples are collected at close to average dissolved loads of the rivers.

Dehydration processes determine fO2 of arc and intraplate magmas

MARLINA A. ELBURG1 AND VADIM S. KAMENETSKY2

1Department of Geology and Soil Sicence, Ghent University,
Krijgslaan 281 S8, 9000 Ghent, Belgium
(marlina.elburg@UGent.be)
2CODES and School of Earth Sciences, University of
Tasmania, Hobart, Tasmania 7001, Australia

Chromite inclusions within early-crystallised olivine phenocrysts (Fo>85 mol%) in most arc lavas have lower Fe2+/Fe3+ ratios than similar inclusions from MORB. This can be calculated to reflect a higher oxygen fugacity (ΔFMQ>+2) in the source region of arc magmas compared to the source of MORB (ΔFMQ <+1). This higher oxygen fugacity in arcs is likely related to the “subduction component” added to the asthenospheric, MOR-like mantle. Aqueous fluid by itself is a very inefficient medium to increase the mantle’s oxygen fugacity, so it has been proposed that Fe3+-bearing melts are involved (Frost and Ballhaus, 1998). However, not all arcs show influence of a slab-derived melt.

We propose that the observed higher oxygen fugacity in arcs is related to the dehydration of serpentinites, formed in either the downgoing slab or the forearc mantle. Serpentinisation involves the hydration and oxidation of olivine and pyroxene, and generation of serpentine, magnetite, ± brucite, H2 ± CH4 (Frost, 1985). Serpentinites release their water into the sub-arc mantle by formation of olivine and orthopyroxene at ~2-3 GPa and 700-750ºC. Olivine is always more iron-rich than its equilibrium serpentine (Evans, 2004) and neither olivine nor orthopyroxene can accomodate Fe3+, so ferric iron from magnetite needs to be reduced to be incorporated into these minerals. This reaction will liberate oxygen that is carried into the mantle wedge with the aqueous fluid, explaining the high oxidation state of the sub-arc mantle.

Dehydration of the similarly oxidised metabasaltic portion of the subducted slab leads to the formation of an eclogitic mineral (cpx-gt) assemblage, which does not discriminate against Fe3+ in the same manner as ol-opx. This material is subducted into the deep mantle, and recycled to form OIBs. This model agrees with the oxygen fugacity of OIBs being intermediate between that of MORBs and arcs.

**Biominerals, proxies, vital effects, and ocean palaeochemistry**

H. ELDERFIELD

The Godwin Laboratory for Palaeoclimate Research, Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK, (he101@esc.cam.ac.uk)

Successful reconstruction of the physics, chemistry and biology of past oceans from marine biominerals requires the fusion of several strands: understanding the physical basis of trace element and isotopic incorporation, modelling, empirical calibrations, analysis of natural systems, critical evaluation of the PCF, evidence by application, high resolution records, new developments. Focussing chiefly on O, C, Mg and B of planktonic and benthic foraminifera, recent work will be presented that gives insights into the biomineralisation process (vital effects), how conflicting results from proxies may be reconciled, and on changes in ocean temperature, carbonate ion saturation and hydrography over glacial-interglacial periods.

**High-pressure mineral inventory in the Ries crater, Germany: A window to phase transformation processes in planetary interiors**

A. EL GORESY1, PH. GILLET2 AND L. D. DUBROVINSKY3

1Bayerisches Geoinstitut, Universität Bayreuth, 95447 Bayreuth, Germany (ahmed.elgoresy@uni-baureuth.de)
2Ecole Normale Supérieure de Lyon, 69007 Lyon, France (directeur@ens-lyon.fr)
3Bayerisches Geoinstitut, Universität Bayreuth, 95447 Bayreuth, Germany (leonid.dubrovinsky@uni-bayreuth.de)

**High-pressure mineral inventory**

The impact event that created the Ries crater in the Swabian Alb 14.7 My ago induced high-pressure phase transformations in minerals in the crystalline basement. These inversions include quartz to coesite and stishovite, graphite to diamond (El Goresy et al., 2001a), rutile to two new dense and ultradense polymorphs of TiO2 (El Goresy et al., 2001b; El Goresy et al., 2001c). In situ study of these high-pressure polymorphs is a key method in uncovering critical parameters that promoted and controlled the high-pressure mechanisms of phase transitions, possible back transformations and in conducting a more realistic estimate of the equilibrium shock pressures in natural events.

**Results and discussion**

We successfully in situ localized quartz-coesite, graphite-diamond, and rutile to orthorhombic (space group Phen) and to the monoclinic polymorphs (space group P2/c) inversions. Quartz-coesite inversion is preferably localized at the grain boundaries to neighboring denser minerals. Raman mapping revealed the presence of coesite intergrown only with undeformed quartz thus indicating partial back inversion of coesite or plausibly complete back inversion of stishovite to quartz. Graphite/diamond inversion is never complete (<60%) and is localized exclusively at the graphite/garnet interface as a result of the high difference in shock impedance. The petrographic settings of the two new TiO2 dense and ultradense polymorphs with their parental rutile also indicate the crucial importance of phase boundary settings in accomplishing the phase transitions. Grafhite/diamond and rutile to the both dense orthorhombic and the ultradense monoclinic polymorphs are encountered in graphite-bearing garnet-cordierite-sillimanite gneisses and their coexistence allows to constrain the equilibrium shock pressures to be definitely < 28 GPa and the post-shock temperature < 200°C.

Trace element data and fluid regime during HP-LT metamorphism of basic rocks, Ile de Groix, France

A. EL KORH1, S. TH. SCHMIDT1 AND A. ULIANOVA2

1Department of Mineralogy, University of Geneva, Switzerland (Afife.ELKorh@terre.unige.ch, Susanne.Schmidt@terre.unige.ch)
2Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland (Alexey.Ulianov@unil.ch)

Trace element contents in whole-rock samples and minerals of the metamorphic rocks of the Ile de Groix - part of a Hercynian HP/LT metamorphic belt - were analyzed in massive and banded eclogites and blueschists. Geochemical data indicate that the protoliths of the massive lithologies represent MORB-type basalts. The banded lithologies are of volcano-sedimentary origin.

Trace elements contents for metamorphic assemblages were determined by LA-ICP-MS. GR03 is a banded blueschist containing an assemblage of grt-ep-Fe3+ rich gln-pheng-rt-mt-volcano-sedimentary origin.

The comparison of massive and banded rocks indicates that the massive rocks were less affected by the fluid/element transfer than the banded rocks. Epidote in massive eclogites is REE enriched compared to the bulk rock. The distribution of REE in epidote is highly variable in all rock types. This seems to be constrained by the local equilibria associated with the appearance and disappearance of new stable mineral phases (garnet, apatite or titanite) during the various stages of metamorphism. We suggest that the massive rocks were less rich in fluid components before the onset of high-P metamorphism, and that during fluid escape the REE mostly remained trapped in the newly forming mineral phases.

The cycling of Li at the Earth’s surface results in marked isotopic fractionations (~40%) that lead to the subduction of isotopically heavy Li. This scenario suggests that Li isotope ratios should provide a distinctive tracer of subducted components in oceanic basalts. Such promises are based on the tacit assumption of equilibrium, in which only low temperature processes can significantly fractionate stable isotopes. However, several recent experimental and observational studies have highlighted that Li isotopes are readily fractionated in magmatic processes by diffusion. In order to use Li isotopes as a tracer of recycled material it is thus critical to understand the role of diffusion on Li isotopes at different length scales.

We have examined Li isotopic profiles in phenocrysts of lava flows. Except in glassy samples, we commonly find zoned crystals. Such isotopic zoning appears to be the natural consequence of cooling, during which the partition coefficient of Li in phenocrysts increases. We have reproduced the forms of isotopic profiles in a self-consistent model driven only by cooling. Deriving absolute cooling rates depends on several parameters which are currently poorly constrained (e.g. the diffusivity of Li in olivine), but the data plausibly imply temperature drops of a few hundred degrees in hours.

The influence of diffusion on the Li isotopic composition of a whole lava flow, rather than its redistribution during final cooling, is more difficult to determine. The general over-lap of (unzoned) olivines from peridotite xenoliths with many mantle derived melts suggest that whole rock compositions are not ubiquitously fractionated by diffusion. As an empirical assessment of possible diffusively driven differences in bulk Li isotopic compositions, we have analysed a suite of samples from the East Pacific Rise (9-10°N). These samples show near homogeneity in long-lived radiogenic isotope tracers but contrasting U-series disequilibria, suggesting their derivation from different depths of the melting regime. This should give rise to differential chemical gradients between the melts and mantle through which they finally ascend, potentially driving different diffusional loss of Li. Although the sample suite shows a significant range in δ7Li related to disequilibrium, its magnitude is small (0.7‰), suggesting that the role of diffusion in influencing these lava compositions is minor.
Consideration of formation buffering potential and reactive mineral availability pertaining to geological storage of carbon dioxide

B.R. ELLIS,¹ K.M. BOWMAN,¹ C.A. PETERS,¹ AND M. BUSCHKUEHLE²

¹Department of Civil and Environmental Engineering, E-209A E-Quad, Princeton University, Princeton, NJ 08544 (cap@princeton.edu)
²Alberta Geological Survey, 4th Floor, Twin Atria Building, 4999-98 Avenue, Edmonton, Alberta, T6B 2X3 Canada

One promising strategy for decreasing CO₂ emissions to the atmosphere is carbon capture and storage in deep saline formations. Modelling efforts and the experimental measurements that support these efforts are critical to determining the fate of injected CO₂. The focus of this work is CO₂-water-rock interactions as they pertain to formation buffering potential and reactive mineral availability. In addressing formation buffering potential, PHREEQC was used to model pH evolution in siliciclastic and carbonate rocks. The initial mineral and formation water compositions were determined from analyses of core samples and brines from several formations in the Alberta sedimentary basin in western Canada. Simulation parameters correspond to injection conditions of 50°C, CO₂ pressure of 100 bar and high ionic strength. The aim of this modelling is to evaluate host formation mineralogy based on the ability to buffer the acid created by CO₂ injection.

Our second goal is to better define mineral abundance and availability in siliciclastic sedimentary rocks, to support the development of relationships for upscaling reactive transport. Energy dispersive X-ray spectroscopy and back-scattered electron microscopy were used to identify minerals and characterize the spatial distributions of potentially reactive minerals in thin sections from the Alberta Basin. Minerals of mean atomic mass greater than quartz, which include those that are reactive under acidic conditions, occur as entire grains in sandstones and shaly sandstones. Kaolinite is found to cement quartz grains and line pore spaces, decreasing primary porosity and obscuring contact between pore fluids and reactive minerals. There is less kaolinite in conglomerate sandstones but reactive minerals are sparse and typically found as inclusions, thus limiting their contact with pore fluids. The sandstone specimens have between 1% and ~5% reactive minerals, but these estimates of mineral abundance overestimate the percentages of reactive minerals accessible to pore fluids by as much as a factor of five. Incorporation of these results into reactive transport models will allow for more accurate representation of formation reactivity with injected CO₂.

Reactive transport and pore-size controlled solubility in porous rocks

SIMON EMMANUEL¹, JAY J. AGUE¹ AND BRIAN BERKOWITZ²

¹Department of Geology and Geophysics, Yale University, P.O. Box 208109, New Haven, CT 06520-8109 USA (simon.emmanuel@yale.edu; jay.ague@yale.edu)
²Department of Environmental Sciences and Energy Research, Weizmann Institute of Science, Rehovot 76100, Israel (brian.berkowitz@weizmann.ac.il)

Nano-scale pores in sediments and soil can modify the effective solubility of minerals, allowing highly supersaturated fluids to exist within the porous medium; this mechanism suggests that precipitation or dissolution can occur when fluid flows from small pores into larger ones, or vice versa. Pore-size controlled solubility (PCS) is a process which stems from the surface tension associated with crystals growing in rigid pores. In many ways analogous to the capillary pressure at a liquid-vapor interface within a pore, this surface tension gives rise to an excess pressure within the crystal, which can be related both to solubility and pore size. Here, we demonstrate how PCS can be incorporated into continuum equations for fluid transport and porosity evolution in simple porous media. Using numerical simulations, we demonstrate that the PCS mechanism can account for the filling of large pore spaces during transport through a heterogeneous rock matrix and represents an effective mechanism for fracture mineralization. In addition, evidence for PCS from scanning electron microscope (SEM) analyses of sedimentary rocks is also presented.
A micrometeoritic "volcanism" in the early thermosphere

C. ENGRAND AND M. MAURETTE
CSNSM CNRS-Univ Paris Sud, Bat.104, 91405 Orsay-Campus, France (maurette@csnsm.in2p3.fr; engrand@csnsm.in2p3.fr)

Our scenario, "EMMA" (Early Micrometeorite Accretion), describes the formation of the Earth's atmosphere through the destruction of volatile-rich micrometeorites during their frictional heating in the thermosphere [1]. We recently improved EMMA by taking into account: (i) measurements of the C, N and S contents of Antarctic micrometeorites (AMMs) [2, 3]; (ii) studies of the Wild 2 cometary grains showing that AMMs could have a cometary origin [e.g., 4]; and (iii) studies of unweathered AMMs recovered from ultra-clean snow in Central Antarctica [5].

About 99% of the AMMs are related to the volatile-rich hydrous-carbonaceous chondrites. The Earth's atmosphere has a "micrometeoritic-like" composition: the average values of D/H ratios and the Ne, N₂, H₂O and C contents of a few hundreds of AMMs are similar to that of the ~2 x 10^24 grams of the Earth's atmosphere that formed about 4.4 Ga ago. This micrometeoritic "purity" of the Earth's atmosphere can be most simply interpreted if the Moon forming impact blew off most of the complex pre-lunar atmosphere at a time when the young Earth was already mostly degassed.

This similarity also suggests that the composition of the micrometeorite flux was invariant with time since the formation of the Moon. This invariance yields a simple accretion formula to estimate the total amount, Mₘ, of any given species, A, deposited on the Earth by the degassing of AMMs during their atmospheric entry after formation of the Moon:

\[ Mₘ \sim \frac{[A(\%) / 100]}{\Phi} \times \Phiₘ \]

where, \( \Phiₘ \) is the integrated mass flux of micrometeorites since the formation of the Moon, and \( A(\%) \), the wt.% of specie A in AMMs. We derived three independent estimates of \( \Phiₘ \) by taking into account: (i) measurements of the C, N and S contents of Antarctic micrometeorites (AMMs) [2, 3]; (ii) studies of the Wild 2 cometary grains showing that AMMs could have a cometary origin [e.g., 4]; and (iii) studies of unweathered AMMs recovered from ultra-clean snow in Central Antarctica [5].

Characterization of the silicon isotopic composition of the terrestrial biogenic output from a boreal forest in Northern Sweden

E. ENGSTRÖM¹, I. RODUSHKIN¹,², D.C. BAXTER², J. INGRI¹ AND B. ÖHLANDER¹

¹Division of Applied Geology, Luleå University of Technology, Luleå, Sweden (emma.engstrom@ltu.se)
²ALS Analytica AB, Luleå, Sweden (iliarodushkin@alsglobal.com)

During the last decade, the potential plant impact on the biogeochemical cycle of Si via the large terrestrial biogenic Si reservoir formed by vegetation has attracted considerable interest. It has been concluded that the release of silicic acid from dissolution of soil phytoliths might exceed the Si mobilized by weathering of Si-containing primary minerals, which implies that the biogenic contribution to the total content of Si in the soil profile must be considered in weathering studies.

Information about Si isotopes can potentially be used for differentiation between relative contributions from biogenic and mineral sources in natural waters, soil solutions and plants. This would, however, require thorough characterization of the terrestrial biogenic Si reservoir, a task that received somewhat limited attention to date.

The aim of the present study was to characterize the Si isotopic composition of a boreal forest, with bedrock consisting of dolomitic limestone, in Northern Sweden. Representative biomass from the forest area exhibited a surprisingly homogenous Si isotopic composition, ranging from \( \delta^{29}\)Si (~0.14 ± 0.05)‰ (2σ) to (0.13 ± 0.04)‰. Further, a change in the Si isotopic composition of (+0.39 ± 0.04)‰ has been detected in Leymus arenarius, indicating predominant accumulation of heavier isotopes from spring to autumn.

Recent studies of Si isotopic composition in plants have focused on the root uptake of dissolved silicic acid as the only Si accumulation path. Results acquired during the present study provide compelling evidence to suggest that exogenous Si is also incorporated in the surface structure of the plant material. A surface contribution in excess of 5% of the total Si would introduce a significant shift in the bulk isotopic composition (~0.1‰) assuming that the exogenous material differed by 2‰ from the biogenic Si. This strongly suggests that the surface contribution must be carefully considered during in situ uptake studies.

Intragranular replacement of chlorapatite by hydroxyapatite during scapolitisation

A.K. ENGVIK1, U. GOLLA-SCHINDLER2, H. AUSTRHEIM3 AND A. PUTNIS2

1Geological Survey of Norway, 7491 Trondheim, Norway (ane.engvik@ngu.no)
2Institut für Mineralogie, 48149 Münster, Germany (golla@uni-muenster.de, putnis@uni-muenster.de)
3PGP, Universitetet i Oslo, 0316 Oslo, Norway (h.o.austrheim@geo.uio.no)

Intragranular replacement of chlorapatite by hydroxyapatite is studied in the Ødegården metagabbro, Bamble sector of south Norway. The Ødegården metagabbro is pervasively scapolitised in a 1.5 km long zone of 50-100 m thickness, forming a rock composed of Cl-rich scapolite + rutile + apatite ± edenite ± phlogopite ± enstatite ± diopside. The magmatic apatite is non-porous and homogenous in composition with a Cl-content of c. 2 wt%. Scapolitisation transforms apatite during multi-stage replacement reactions: I) The magmatic apatite was transformed to chlorapatite with Cl-content of 6.5 wt%. II) A secondary replacement reaction transforms the chlorapatite to porous hydroxapatite with only minor Cl (Fig. 1), and is correlated with a hydration of enstatite to talc. The observed compositional zoning in apatite is consistent with observations of apatite from pegmatites cutting the Ødegården metagabbro (Harlov et al. 2002). The observed changes in Cl-content of apatite is interpreted to reflect the fluid evolution and the propagation of metasomatic fronts through the gabbro. The reaction mechanism of chlorapatite to hydroxyapatite is studied by energy-filtered transmission electron microscopy (TEM). A TEM-specimen across the replacement interface was prepared using a focused ion beam apparatus (FIB). The diffraction pattern is similar in the chlor- and hydroxyapatite parts of the crystal. The results are consistent with replacement by a coupled dissolution-reprecipitation mechanism during metasomatism.

Figure 1: Chlorapatite (light grey) partly transformed to hydroxyapatite (dark grey).

Dissolution from a CO2 lake

LARS INGE ENSTAD1,2, PETER M. HAUGAN2 AND GUTTORM ALENDAL1,3

1Bergen Center for Computational Science, Thormøhlensgate 55, N-5008 Bergen, Norway, (lars.inge.enstad@bccs.uib.no)

3Mathematical Institute, University of Bergen, Johannes Bruns gate 12, N-5008, Bergen, Norway, (guttorm.alendal@math.uib.no)

If liquid CO2 is stored as a dense "lake" on the deep ocean floor, it is expected to dissolve in seawater. A similar situation may occur if CO2 is dissolved from a saturated benthic boundary layer caused by a potential leak of geological stored CO2. Due to ocean currents and turbulence the net rate of release may increase by several orders of magnitude compared to molecular diffusion. However, density stratification induced by dissolved CO2 will tend to reduce vertical mixing. This scenario has previously been modelled in two dimensional domain (e.g. Fer & Haugan, 2003; Haugan and Alendal, 2005). There has also been a three dimensional study (Enstad et al. 2006) using the MIT general circulation model (http://mitgcm.org). Recently the MITgcm model has been coupled with the General Ocean Turbulence Mode (http://gotm.net/), and this model is used to simulate the lake option. The new vertical turbulent mixing scheme takes into account density effects, and should give more realistic results for the CO2 plume than constant eddy diffusivity models. The introduction of a third direction gives qualitatively different results for the spreading of the CO2 plume than previous two dimensional results. Among the results we also show the hit rates of a passive tracer passing through the domain.

Development of the high precision measurement of mercury species isotopic ratios by GC-MC-ICP-MS and its validation with two other analytical approaches

V.N. EPOV1, P. RODRIGUEZ-GONZALEZ1, J. SONKE2, E. TESSIER1, D. AMOUROUX1, L. MAURICE BOURGOIN2, N. ESTRADE1,3, J. CARIGNAN1 and O.F.X. DONARD1

3CRPG-CNRS, 15 rue Notre-Dame des Pauvres, BP 20, Vandoeuvre-les-Nancy, 54501 France

Development of the novel technique
Mercury is transformed by microorganisms into organic forms, mainly CH$_3$Hg ($\text{MeHg}^+$) and (CH$_3$)$_2$Hg (di-MeHg), which are highly toxic and volatile. Hence, two most abundant Hg species in the environment are Hg$^{2+}$ and MeHg. Since gas-chromatography (GC) is one of the easiest approaches to separate this species on-line, with relatively simple sample preparation, we have estimated the suitability of the GC hyphenation with MC-ICP-MS for the precise isotopic analysis. A new protocol for the simultaneous measurement of isotopic ratios in Hg species was developed.

Validation of developed method versus other techniques
Two other analytical approaches cold-vapour generation (CVG) and continuous nebulization (CN) were chosen as reference techniques to validate the measurement of isotope ratios by GC-MC-ICP-MS. Analytical performances of these three techniques were compared, and precision for the different techniques are compared in the table below. Optimisation of the integration approach of the transient signal and GC parameters provide a suitable precision for the Hg isotopic analysis in environmental samples.

<table>

</tbody>
</table>

Conclusions
When analysing real-world samples for Hg species isotopic analysis, preliminary sample preparation for both CVG and CN are very time- and labour-consuming in comparison with GC, while GC has a higher precision of the measurements. The precision of the GC-MC-ICP-MS measurement can be improved if a preconcentration step is applied before injection into the GC.

Stress-induced redistribution of Y and HREE in garnet during high-grade polynmetamorphism

M. ERAMBERT, T.S. ROHR AND H. AUSTRHEIM

Physics of Geological Processes (PGP) and Department of Geosciences, University of Oslo, Norway
(m.m.l.ерambert@geo.uio.no, t.s.rohr@geo.uio.no, h.o.austrheim@geo.uio.no)

Almandine garnet (Alm$_{62.6}$Pyr$_{11.4}$Sp$_{8.4}$And$_{6.5}$Grs$_{4.0}$) exceptionally rich in Y$_2$O$_3$ (1.8-2.3 wt%), Sc$_2$O$_3$ (0.11-0.23 wt%), HREE$_2$O$_3$ (1.9-2.3 wt%) and Na$_2$O (~ 0.3 wt%) occurs in Precambrian quartzofeldspatic granulites ($T$ ~ 860 °C) on Hisarøya, Western Gneiss Region, Norway. The granulites were partially reequilibrated to eclogite- ($P$: 14.9 ± 1.3 kbar, $T$: 649 ± 67 °C) and amphibolite-facies assemblages during the Caledonian Orogeny. The high Y and HREE concentrations allowed quantitative analysis and imaging of element distribution at the spatial resolution of EMPA. The granulite-facies garnet is overgrown by Caledonian garnet with Y$_2$O$_3$ and HREE$_2$O$_3$ both below 0.1 wt%. The granulite-facies cores are reequilibrated to lower Y$_2$O$_3$ and HREE$_2$O$_3$ in an outer zone, typically ~ 4 µm thick, (both Y$_2$O$_3$ and HREE$_2$O$_3$ ~ 1.2 wt%), and along internal deformation structures including microfaults with horsetails, en-echelon bands and splaying features around the tip of fractures (Y$_2$O$_3$ and HREE$_2$O$_3$ ~ 1.8 wt%). Locally, the internal reequilibrated zones, typically 10-20 µm across, have shoulders with higher Y and HREE (~ 2.9 wt%) than in the original garnet, suggesting closed-system behaviour for these elements. In addition, the garnet locally displays a m-scale complex mesh-like pattern with high and low HREE and Y bands, possibly related to straining. All features indicate ineffective Y and HREE diffusion under the present P-T conditions. Two charge-balancing mechanisms account for Y and HREE incorporation: (1) the YAG substitution involving incorporation of Al into the tetrahedral site is dominant in the granulite-facies garnet, and (2) coupled substitution with Na into the dodecahedral site is increasingly important during high-P reequilibration. The internal closed system reequilibration of the granulite-facies garnet may be due to stress concentrations build up in relic garnet during the eclogite-facies event. Possible mechanisms for reequilibration are discussed.
Petrogenesis of the basic volcanism behind the volcanic front (Cinotepeque range, El Salvador)

V. ERBAN1,2, V. JANOUŠEK1,2 AND V. RAPPRICH1

1Czech Geological Survey, Klárov 3, Prague, Czech Republic (erb@ngu.cz)
2IPSG, Faculty of Science, Charles University, Albertov 6, Prague, Czech Republic

Most of Quaternary volcanic activity in El Salvador is concentrated to 5 major volcanic centres, forming part of the volcanic front (VF), directly related to the subduction of the Cocos Plate under the Caribbean Plate. A volcanologically distinct volcanic province is represented by diffuse clusters of subrecent cinder cones and small shield volcanoes behind the volcanic front (BVF). While geochemistry of the prominent BVF zone, situated in the Ipala transtensional Graben along the Guatemala–Salvadorian border, has attracted much attention, the minor Quaternary BVF field in the central El Salvador has been little studied so far. This zone of 30 individual volcanic bodies extends from the Boquerón Volcano (VF) c. 20 miles N, as far as the N–S trending horst of the Cinotepeque Range (Rapprich & Hradecký, 2005).

Compositional data available for the Cinotepeque area correspond to a suite of fairly fractionated subalkaline basalts and basaltic andesites (mg# < 55, Cr < 149 ppm and Ni < 56 ppm). Characteristic is steep increase in K2O with increasing differentiation (SiO2). Identical trend is observed in the lavas from Boquerón and, to some extent, the Ipala Graben (data of Carr, 2003). Similar behaviour may be demonstrated also for the other LILE. In the SiO2–FeOtot/MgO plot, the whole series falls within the Fe-rich, “tholeiitic” field. On the other hand, the K2O increase in lavas from the more remote VF edifices is much slower and their FeOtot/MgO significantly lower, typical of normal calc-alkaline rocks.

In spite of similarities of BVF and adjacent VF volcanoes, there are also differences. At the given SiO2, the BVF lavas have higher MgO, lack the negative Eu anomaly, and show lower LILE/HFSE ratios indicative of diminishing subduction fluid involvement (Ba/La > 43). Similar pattern was reported previously also from the Ipala area.

Compositional trends in main oxides of the Cinotepeque lavas can be modelled by up to 40% fractional crystallization (plg 40%, augite 35%, olivine 20% and magnetite 6%). The enrichment in incompatible elements requires comparable degrees of fractionation. The variation in silica contents in the BVF lavas is limited. Clearly the SiO2 content of the fractionating assemblage (43.6 %) was too similar to the most primitive lavas (49.7 %) to produce acid magmas.

Geochemistry of an actual Fe-sulfides formation from Acisu district, Karsanti, Adana, Turkey

YEŞİM ERCAN1 AND SEDAT TEMUR2

1Min. Res. and Expl. Directory of Turkey, 42042 Konya, Turkey, (yesimercan74@yahoo.com)
2Selcuk Univ. Dep. of Geol., 42075, Konya, Turkey, (stemur@selcuk.edu.tr)

The aim of this study is to elucidate the geochemical characteristics of the Acisu district actual Fe-sulfides (pyrite/marcasite) formation (Karsanti, Adana, Turkey). Around this mineralization, Upper Cretaceous ophiolite is cropped out and Paleozoic and Mesozoic aged sedimentary rocks are trusted over it. The Fe-sulfide occurrence is approximately 25 m length, 5 m width, and 3 m depth in diameter. The paragenesis comprises marcasite, chalcopyrite, quartz, hematite and calcite/dolomite. Approximately 0.5 l/s hydrothermal water (pH=4-6 and T=40-45°C) is going out to surface as a spring. Total sulfur concentration of the is 200-250 µM. It is known that Ti, Ni, Co, Mn, Zn, Pb, Ge, Cd, and As contents and Co:Ni ratio of the pyrite/marcasite are permit to distinguish them sedimentary, high and low temperature occurrences (Huston et al., 1995; Temur et al., 2006). Fe and Sb contents in the ore showed positive correlation, against to strong negative correlation of Fe and SiO2, Al2O3, CaO, MgO, Sr, U. Wide ranges in concentrations of Cd, Cr, and Zn characterize the mineralization. The samples contain low Ag (12 ppm), As (26 ppm), Ni (14 ppm), Sr (1.4 ppm), Y (0.25 ppm), versus high Cu (9600 ppm), Mo (23 ppm), Pb (120 ppm), Se (86 ppm). Based on cluster analysis, four main groups can be clearly distinguished. These are the main oxides group (SiO2, CaO, MgO, Al2O3, Sr and U) respecting enrichment of these element against to Fe; the iron-sulfide group (Fe, Sb, LOI and TOS) representing of the main marcasite mineralization; the chalcophile elements group (Zn, Cd, Hg, Ga, Ag and Cu) reflecting a mineral accumulations by sulfo-salt in solution; and the Co-Cr group (Co, Bi, Se, As, Cr, Y, and Au) representing contamination by ultramafic wall rock. On the triangular diagram of (Sr-Sb-Zn) and (Sr-Co-Zn), three mineralization types can be deviated from each other as: (1) pure marcasite; (2) marcasite which contains rich lattice stoichiometric substitutions; (3) marcasite which contains rich other sulfide minerals.

Calcification in hermatypic corals is based on direct seawater supply to the biomineralization site

J. EREZ AND A. BRAUN
Institute of Earth Sciences, The Hebrew University of Jerusalem, Israel 91904, (erez@vms.huji.ac.il)

Corals are major CaCO₃ producers the ocean and their skeletons contain a unique archive of paleo-environmental information based on their isotope and trace element composition. The physiological process of biomineralization in corals, however, is not well understood, thus limiting our ability to predict their resistance to global changes, and lowering the reliability of paleo-environmental reconstructions. We investigated the biomineralization processes in the hermatypic coral species *Pocillopora damicornis* and *Stylophora pistillata* using fluorescent dyes with laser confocal microscopy. Colonies growing flatly on glass Petri dishes and small colonies completely covered with tissue (microcolonies) allowed direct in vivo microscopic observations on the actively growing crystals at the calcification site. The fluorescent cell impermeable dyes Calcein and FITC-Dextran which were added to seawater were incorporated to the aragonite skeletons of micro-colonies during short incubations of several hours. This suggests direct seawater supply into the calcification site. The seawater probably passes through the calicoblastic epithelium in narrow paracellular pathways between cells. The size of these narrow pathways is probably between 20 nm and 1 µm based on the incorporation of fluorescent plastic spheres into the growing skeleton of micro-colonies. Previous studies demonstrated the involvement of membranal Ca²⁺ channel and Ca-ATPase in the calcification process of corals. We propose that in addition to the activity of these channels and pumps, Ca²⁺ and CO₃²⁻ ions are supplied to the calcification process directly with the seawater. The activity of Ca-ATPase may be very important to elevate the pH of the seawater at the calcification site, thus increasing the CO₃²⁻ and facilitating diffusion of inorganic and respiratory CO₂(aq) into the calcification site. Our findings explain both the high sensitivity of corals to ocean acidification and their high fidelity in recording paleo-environmental proxies of ocean chemistry.

Environmental pollution originated from open dumping of solid waste in the cities of Eastern Black Sea

H. ERSOY¹, A. FIRAT ERSOY¹, S. DAĞ² AND M. BERKÜN³

¹Karadeniz Technical University, Department of Geological Engineering, 61080, Trabzon, Turkey (ersoy@ktu.edu.tr)
²Karadeniz Technical University, Gümüshane Engineering Faculty, Department of Geological Engineering, Trabzon, Turkey
³Karadeniz Technical University, Department of Civil Engineering, 61080, Trabzon, Turkey

Almost all municipalities dispose and discharge their wastes and wastewaters into the shallow sea water and the coast, mostly without treatment and outfall systems in the countries on the Black Sea coast. About 450-500 tons solid waste is generated in a day and more than 70 percent of solid waste having high organic and inorganic strength is disposed to the open dumps, land, sea and the rivers in the coastal cities of the Eastern Black Sea Region, Turkey. In the coastal cities of Eastern Black Sea Region, collection and transportation stage of solid wastes are generally well organized, but not disposal of municipal, industrial and agricultural wastes. All municipalities and industrial factories have disposed their solid wastes with together hospital and hazardous wastes to the nearest lowlands and river valley or directly into the sea environment without any prior treatment. This solid waste management strategy applied for a long time has threatened environmental health. Due to these solid waste and wastewater management strategies, coastal cities of Eastern Black Sea are faced with serious environmental and administrative challenges in recent years. In this study, an overview of the current solid waste management situation in Eastern Black Sea Region and provides a brief discussion of the future challenges are analyzed, the environmental, technical, social goals are discussed.

Nanonuggets and their implication for core formation

W. ERTL AND D.B. DINGWELL
Ludwig Maximilian University Munich, Theresienstr. 41, 80333 Munich, Germany; (ertel-ingrisch@lmu.de)

The Platinum group elements (Ru, Os, Ir, Pd, and Pt) together with Au and Re are defining the geochemical group of the highly siderophile elements (HSE) based on their 1 atm extremely high metal/silicate partition coefficients ($D_{\text{metal}} > 10^5$). In consequence, these elements are present in very low absolute elemental concentrations in the Earth’s upper mantle ranging from 0.3 ppb for Re to 8 ppb for Pt.

However, two startling observations led to the “enigma of the overabundance of the HSE” in the Earth’s upper mantle [1]. First, according to their extremely high metal/silicate partition coefficients at 1 atm, all HSEs should have been stripped entirely into the Earth’s core by the Fe-rich liquid forming the Earth’s core, resulting in unmeasurable low concentrations left in the mantle. Second, their elemental abundances show interelement ratios which are similar to what is observed in CI chondritic material.

The development of new analytical techniques made accurate HSE concentration determinations in basaltic, ultramafic and synthetic samples possible, and in consequence, stimulating fundamental experimental investigations of their partition behavior between metal, silicate and sulfide phases.

LA-ICP-MS techniques revealed another exciting feature of the HSE geochemical behavior: the so-called Nanonugget formation problem, mostly observed at very low oxygen fugacity conditions. At present it is under debate whether these Nanonuggets are intrinsic features of HSE solubility in silicate melts [2], contaminants [3] and, therefore, non-representative for its natural equilibrium solubility, and/or simply quench products. Including or excluding Nanonuggets during the elemental concentration determination procedure alone can account already for two to 3 orders of magnitude regarding their metal/silicate partitioning behavior. The clarification whether Nanonuggets represent the true solubility of an element, or are contaminants which, in consequence, have to be excluded from the concentration determination needs fundamental investigation.

In this paper, we present the latest results on our study on the formation and existence of Nanonuggets in Re, Os, Pt, Rh, and Ir containing experiments and discuss their influence on metal/silicate partitioning during core formation scenarios.

Werner Schreyer's experiments on synthetic B-rich high-pressure tourmalines and micas

A. ERTL AND E. TILLMANNS
Institut für Mineralogie und Kristallographie, Geozentrum, Universität Wien, Austria (andreas.ertl@a1.net)

Recently Werner Schreyer worked on the synthesis of B-rich mica (boromuscovite) and Al-rich tourmaline (olenite). He published many interesting papers with his colleagues, resulting from high-pressure experiments in Bochum. Olenites, where [4]B substitutes for up to ~2 apfu Si, were synthesized at PT-conditions in the range 10-40 kbar/450-700°C [1]. Like excess-B in olenites, B in boromuscovite is favoured by high pressures and low temperatures. Schreyer was also involved in investigations on natural olenite with [4]B up to ~1 apfu, from Koralpe, Austria [2-3] and from Kola Peninsula, Russia [4]. The unique pegmatite in the Koralpe, which contains B-rich olenite and muscovite may also have formed at relatively high pressures and low temperatures [5-7]. Pure endmember boromuscovite was found to be stable only at 500°C, >5 kbar and at 750°C, >10 kbar, up to 50 kbar [8]. Experimental incorporation of [4]Al extends the high-pressure stability field of boromuscovite to lower pressures [9]. We suggest a similar situation for B-rich olenite: the amount of [4]B may be pressure dependent but the stability field may be extended to lower pressures when significant amounts of [4]Al are present, as in the olenite from Koralpe. Future search for boron in muscovites and in tourmalines should be focused in high-pressure environments. Werner Schreyer’s unique contributions in experimental metamorphic petrology and mineralogy together with his theoretical models should invite petrologists and mineralogists to conduct future work in this interesting field.

Molybdenum speciation in anoxic aquatic systems: HPLC-ICPMS determination of molybdate and thiomolybdates.

L. Esnauld, M. Pepe, D. Jezequel, A. Thiam and E. Viollier
Laboratoire de géochimie des eaux, université Paris Diderot and IPGP (esnault@ipgp.jussieu.fr)

Dissolved molybdenum in fresh and marine waters is essentially under molybdate form. Though adsorbed on manganese oxides or complexed by natural organic ligands in specific conditions, molybdate is not very reactive. In anoxic condition, molybdenum can be strongly associated with colloidal organic matter [1]. When sulphide is present, transformation of molybdate to thiomolybdates (MoO_xS_{4-x}) has been proposed to explain Mo precipitation in euxinic water column and sediment Mo enrichment. Such pathway is validated in laboratory [2] but thiomolydates are not yet detected in natural aquatic samples. Here we present a new method that will allow to fulfil this objective: HPLC-ICP-MS protocol is further discussed and apply to lake Pavin samples (a permanently anoxic, sulphide rich crater lake). Molybdate is separated from tetra-thiomolybdate within 15 minutes (fig 1) with optimal conditions.

Mass independent fractionation of Hg isotopes during evaporation and condensation processes

N. Estrade1,2, J. Carignan1, J. Sonke3 and O.F.X. Donard2
1CRPG-CNRS, BP 20, 54501 Vandoeuvre les Nancy, France, (nestrade@crpg.cnrs-nancy.fr)
2IPREM/ECABIE, HELIOPARC, 64053 Pau, France
3LMTG, 14 av. Edouard Belin, 31400 Toulouse, France

We measured mass independent isotope fractionation during experimental evaporation of liquid metal mercury. Recent revision of the theory of first-order mass dependent fractionation by Bigeleisen (1996) introduced nuclear field shift effects as the cause of mass independent fractionation. In equilibrium conditions, Schauble (2007) calculated the proportions of mass dependent and nuclear volume dependent isotope fractionation between several species of mercury relative to metal mercury vapour. We suggest that nuclear volume dependent isotopic fractionation can occur during evaporation and condensation of Hg.

Different sets of experiments were performed: 1) Hg liquid-vapour equilibrium between 0 and 25°C, and 2) evaporation of liquid Hg under vacuum conditions varying i- the fraction of liquid Hg evaporated at 22°C and ii- the temperature of evaporation (20°C to 100°C). Isotopic compositions were measured by generation of mercury vapour (SnCl2) coupled with an MC-ICP-MS. For the equilibrium experiment, we report \( \Delta^{202/198} \text{Hg}_{\text{liq/vap}} = 0.8 \pm 0.3\% \) on the range of temperature. Results from the vacuum experiments fit perfectly to a Rayleigh distillation system and indicate \( \alpha^{202/198} \text{Hg}_{\text{liq/vap}} = 6.5 \pm 0.3\% \) at 22°C, different from the kinetic theoretical value of 10.1%. Isotopic fractionation between liquid and vapour Hg decreases with temperature to reach close to 0% at 100°C. This suggests that both kinetic and equilibrium processes are involved.

The relationship between \( \delta^{202/198} \text{Hg} \) and \( \delta^{199/198} \text{Hg} \) of vapour Hg in equilibrium with liquid Hg indicates that more than 90% of the total fractionation is explained by nuclear volume processes, while only 15% is required for vacuum experiments at 22°C. This proportion increases exponentially with temperature, as the importance of equilibrium increases over kinetic processes. These results suggest that liquid-vapour equilibrium isotopic fractionation is mainly nuclear volume dependent, whereas kinetic fractionation is mass dependent.

Fly ashes from a waste combustor reflecting progressive Hg condensation (300°C-200°C) did not show mass independent isotope fractionation, suggesting a dominance of kinetic fractionation during Hg condensation.

Mineralogy and alteration of fly ash from secondary Pb metallurgy

V. ETTLER1, Z. JOHAN2, M. MIHALJEVIČ1, O. ŠEBEK1, P. BEZDIČKA3 AND M. KLEMENTOVÁ3

1Charles University of Prague, Czech Republic (ettler@natur.cuni.cz, mihal@natur.cuni.cz, sebek@natur.cuni.cz)
2BRGM, Orléans, France (zdenek.johan@free.fr)
3Institute of Inorganic Chemistry, Academy of Science of the Czech Republic, Řez u Prahy, Czech Republic (petrb@iic.cas.cz, klemari@iic.cas.cz)

The mineralogy and solubility of fly ash and air-pollution-control (APC) residues from a secondary lead (Pb) smelter have been studied on samples from the Příbram smelter, Czech Republic, recycling car batteries, with the emphasis on their potential environmental effect. The X-ray diffraction analysis, scanning and transmission electron microscopy and electron microprobe were used for this investigation. The presence of dominant anglesite (PbSO4) and laurionite (Pb(OH)Cl) was observed in a sintered residue from after-burning chambers (800-1000°C). Low temperature Pb-bearing phases, such as KCl·2PbCl2 and caracolite (Na3Pb2(SO4)3Cl), were detected in the major APC residue from bag-type fabric filters. The formation of anglesite, cotunnite (PbCl2), (Zn,Cd)2SnO4 and (Sb,As)2O3 was observed during the sintering of this APC residue at 500°C in rotary furnace (Ettler et al., 2005a).

The 720-hour leaching test on filter residues indicated rapid release of Pb and other contaminants. Caracolite and KCl·2PbCl2 are significantly dissolved and anglesite and cotunnite form the alteration products, as was confirmed by mineralogical analysis (XRD, TEM/EDS) and PHREEQC-2 modelling (Ettler et al., 2005a,b). The observed Pb-bearing chlorides have significantly higher solubility than anglesite and, following emission from the smelter stack, can readily dissolve, transferring Pb into the environmental milieu (soils, water, inhabited areas). As a result, only anglesite as an alteration product was detected by X-ray diffraction analysis in soil horizons highly contaminated by Pb smelter emissions (Ettler et al., 2005c).

Synchrotron studies of RbBr-bearing solutions ± CO2 in synthetic fluid inclusions

KATY EVANS1,3 AND JOHN MAVROGENES1,2

1Research School of Earth Sciences, the Australian National University, Canberra ACT 0200, Australia
2Department of Earth and Marine Sciences, the Australian National University, Canberra ACT 0200, Australia
3Department of Applied Geology, Curtin University of Technology, Perth, Western Australia

Salt- and CO2-bearing solutions are common in geological environments, yet the consequences of interactions between these components remain unclear. XAS studies of corundum-hosted synthetic fluid inclusions that contain RbBr -CO2-H2O solutions have shown that: 1) Br exhibits a strong pre-edge peak in CO2-bearing solutions at temperatures between 25 and 150°C. The pre-edge feature is similar to that shown by covalently bonded Br, but observed and calculated concentrations of covalent Br-bearing compounds (HBr, Br2, CH3Br) are vanishingly small. An alternative possibility is that CO2 contributes to a charge delocalisation on the solvated Br ion that confers some covalent character to bromine-solute interactions; and 2) Rb EXAFS at temperatures to 650°C and pressures to 0.6 GPa are consistent with a decrease in the number of waters of hydration and Rb-nearest neighbour distances with increasing temperature and pressure. This result is consistent with those of previous workers. The presence of CO2 in concentrations of up to X(CO2) of 0.1 is not observed to have a significant effect on either the number of nearest neighbours or ion-solute differences. However, the possibility that CO2 affects salt speciation by inducing an increase in ion association, cannot be eliminated. Simulations show that a significant increase in the number of Rb-anion nearest number pairs would be difficult to detect by this method.

Overall, the presence of CO2 is shown to affect the local environment of salts in solution, at least at low temperatures. Complementary methods are required to determine the magnitude and consequences of CO2-induced changes in fluids at higher temperatures and pressures.
Non-biological fractionation of Ca isotopes in soils of the Atacama Desert, Chile

STEPHANIE A. EWING1, WENBO YANG1, DONALD J. DEPAOLO1 AND RONALD AMUNDSON2

1Center for Isotope Geochemistry, Dept. of Earth and Planetary Sciences, University of California, Berkeley, CA 94720; (saewing@nature.berkeley.edu; wenbo@berkeley.edu; depaolo@eps.berkeley.edu)
2Ecosystem Sciences Division, ESPM, University of California, Berkeley, CA 94720; (earthy@nature.berkeley.edu)

Stable Ca isotopes hold great potential for weathering studies, but their successful interpretation will require improved understanding of processes that fractionate Ca isotopes in terrestrial surficial environments. It has been demonstrated that both biotic uptake and abiotic precipitation fractionate Ca isotopes. To consider abiotic effects in a natural context, we measured Ca stable isotope ratios ($\delta^{44/40}$Ca) in an ancient (2My), nearly abiotic, hyperarid soil in the Atacama Desert. The primary source of mobile Ca in this soil is atmospheric deposition, and the primary mechanism of isotopic fractionation appears to be precipitation of sulfate and carbonate minerals. Most of the accumulated Ca in the upper meter of this soil (2.9 kmol m$^{-2}$) is present as sulfates (2.5 kmol m$^{-2}$). Sulfate-associated $\delta^{44/40}$Ca$_E$ values (vs. bulk Earth) increase with depth (1.4 m) from a minimum of -1.91‰ to a maximum of +0.59‰. Linear correlation between sulfate-associated $\delta^{44/40}$Ca and sulfate-$\delta^{34}$S indicates a $\delta^{44/40}$Ca fractionation factor of -0.4‰ in CaSO$_4$. The overall depth trend in Ca isotopes is reproduced by a transport model that considers repeated small and infrequent rainfall events. The lowest Ca isotope values occur at shallow depths and are reproduced by a Rayleigh model, using measured soil Ca concentrations and the Ca fractionation factor predicted by the relationship with S isotopes. This indicates that the primary mechanism of fractionation in CaSO$_4$ is incremental and effectively irreversible precipitation with downward transport during repeated small rainfall events. This work demonstrates that significant inorganic Ca isotope fractionation in terrestrial settings can be a function of transient conditions of water supply, solution chemistry, and dissolved transport. These conditions are ubiquitous in weathering environments and should be considered in the interpretation of Ca isotope values.

Numerical modeling of continental plate retreating and crustal recycling

M. FACCEADA1, T.V. GERYA1, S. CHAKRABORTY2 AND M. GIORGIO3

1Institut of Geophysical, ETH Hoenggerberg, 8093 Zürich, Switzerland (facceada@erdw.ethz.ch);

(gminelli@unipg.it)

Numerical experiments of oceanic subduction followed by continental collision reveal continuous subduction of the downgoing plate. When the continental plate arrive to the trench, slab pull and ridge push forces drag it into the mantle. When slab pull overcomes plates coupling, the subducting plate detaches from the upper one and starts to retreat. Relatively buoyant mantle astenosphere wedges between the two plates facilitating the continental plate retreating process. The upper crust is scraped off by the astenosphere and thrust over the pro-foreland; on the other hand, the lower crust is dragged into the deep mantle with important consequences for crustal growth models. Models with a weak lower crust exhibit a complete delamination of the lithospheric mantle from the continental crust. At the surface, we have development of a system characterized by two different tectonic regimes: the pro-foreland is dominated by compressional tectonics, while backward crustal thinning is evidenced by very low depth astenospheric mantle. The Western Mediterranean formed from the Oligocene times with a mechanism supposedly analogous to our models. We try, therefore, to compare our results with an extensively studied belt of this area, the Appennines. The geological record and geophysical data show indeed interesting similarities with the models, supporting the idea that the Western Mediterranean is the result of a retreating oceanic and, ultimately, continental plate.
Mineralogy and Nd and Pb isotope signatures of clay-size fraction of northern North Atlantic sediments during the Holocene and Late Glacial: Implications for the inception of modern deep circulation pattern

N. FAGEL1, R. BRASSEUR1, N. MATTIELLI2, R. STEVENSON3 AND C. HILLAIRE-MARCEL3

1UR. Clay and Paleoclimate and Mare, University of Liege, B-4000 Liege, Belgium (nathalie.fagel@ulg.ac.be, roberbrasseur@skynet.be)
2DSTE, University of Brussels, Belgium, nmattiel@ulb.ac.be;
3GEOTOP, UQAM, Montreal, Canada (chm@uqam.ca, stevenson.ross@uqam.ca)

The production rate of North Atlantic Deep Water (NADW) is a critical component of the high-latitude ocean-climate system. Here we analyse the mineralogy and Sm/Nd and Pb isotope signatures of the clay-size fraction of four sediments cores collected in Labrador Sea and adjacent basins. Clay composition and their isotopic ratios bring information on the origin of particles driven by deep currents. Our aim is to monitor deep current variability through the Holocene and the Late Glacial.

The cores are located along gyres of NADW components in the NW North Atlantic. In the Iceland basin, cores MD99-2254 (2440 m deep, on the eastern side of the Bight Fracture Zone) and HU91-045-091 (3870 m deep on the western side of the Charlie Gibbs Fracture Zone) are used to document water outflow originating from the Norwegian Sea. In the Labrador and Irminger seas, cores MD99-2227 (3460 m deep, off Southern Greenland) and HU91-045-080 (3024 m deep, on the western side of the Charlie Gibbs Fracture Zone) illustrate conditions along the pathway of the Western Boundary UnderCurrent that carries NADW masses in their deep Labrador Sea gyre.

Based on sedimentary mixings of four regional end-members, our isotopic dataset emphasizes several main changes in the relative contribution of the two major components of North Atlantic Deep Water, i.e. the North East Atlantic Deep water (NEADW) and the Danmark Strait Overflow Water (DSOW) throughout the last 12 kyr, and especially during the Late Holocene.

An innovative tool for in situ monitoring of Fe and associated trace metal mobilization in soils

M. FAKIH, M. DAVRANCHE, A. DIA, P. PETITJEAN, X. CHATELLIER AND G. GRUAU

CNRS-UMR 6118 Géosciences Rennes, 35042 Rennes Cedex, France (mohamad.fakih@univ-rennes1.fr)

Iron (III) oxides are common mineral components of soils, sediments, aquifers and geological materials. Trace metals associate with Fe (III) oxides as adsorbed or co-precipitated species and, consequently the biogeochemical cycles of Fe and trace metals are closely linked. Therefore, the sorption and redox chemistry of Fe (III) oxides have been widely studied because of recognition that they control water chemistry and contaminant behaviour in near-surface geochemical systems. However, most previous experimental approaches, set up to study the in situ evolution of such oxides through redox alternations within soils, suffered from drawbacks related to the disturbance of the soil system during the recovery of the Fe oxides. The aim of this study was to design and test a new tool for the in situ monitoring of Fe and associated trace metal mobilization within soils and for tracking the potential changes of mineralogy of the Fe solid phases. Fe oxides characterized by various (i) mineralogical phases (ferrihydrite, lepidocrocite and goethite) and, (ii) associated co-precipitated trace metals (Cd or As) were directly precipitated on little (2-cm-side square) striated polymer supports. These plates were inserted both in laboratory soil columns under anaerobic conditions and, in three different soil horizons (organic-rich, albic and redoxic) belonging to a wetland located in the western part of France. The pedo-climatic setting and the hydrological and geochemical behaviour of this long-term surveyed wetland is well known. Reductive conditions allowing Fe oxides to dissolve when soils are waterlogged occur annually during the winter season.

The polymer supports were unaltered through time, suggesting that this technique can be safely used to study Fe oxide evolution. Fe amounts were quantified by XRF before and after incubation. The evolution of Fe oxides was also observed by SEM and characterized by XRD. Over a period of three months during the winter season, 69% of ferrihydrite and 15% of lepidocrocite were dissolved while the more crystallized goethite remains unaltered. SEM observation coupled with XRD showed that new iron sulphide and oxide phases precipitated on the polymer supports. Moreover, SEM observation showed that the supports were highly colonized by bacteria and biofilms suggesting that micro-organisms played a key role in the occurring mineralogical changes as well as in the Fe and associated trace metal release. Further studies dedicated to the identification of both the involved bacteria consortium and the secondary mineralogical phases as well as, kinetic study of metal release in solution will be undertaken.
Oxynitride glass-ceramic microstructures
L. K. L. Falk\(^1\), Y. Menke\(^2\), N. Schneider\(^2\) and S. Hampshire\(^2\)

\(^1\)Department of Applied Physics, Chalmers University of Technology, SE-412 96 Gothenburg, Sweden (lklfalk@fy.chalmers.se)
\(^2\)Materials and Surface Science Institute, University of Limerick, Limerick, Ireland (stuart.hampshire@ul.ie)

Oxynitride glass-ceramics attract an interest, not only because of their improved mechanical properties and refractoriness compared with oxide glass-ceramics, but also because of their presence as an intergranular microstructure in liquid phase sintered silicon nitride based ceramics. This intergranular microstructure is a result of the oxynitride liquid phase sintering medium required for densification. A tailored starting powder composition containing a combination of metal oxide and nitride additives that would form an oxynitride glass-ceramic may result in a liquid phase sintering medium that is readily crystallized after densification leaving a minimum of residual glass.

This presentation will focus on B-phase, which is a five-component phase, and its incorporation into the intergranular regions of silicon nitride ceramics. B-phase glass-ceramics may be fabricated through the nucleation and crystallization heat treatment of nitrogen rich parent sialon glasses with composition \((\text{e/o}) 35\text{R}:45\text{Si}:20\text{Al}:83\text{O}:17\text{N}\), where \(\text{R} = \text{Er, Yb, Y or a mixture of Y and Yb}\). The element \(\text{R}\) determines the degree of crystallization, and it has been shown that a virtually fully crystalline, single-phase, glass-ceramic may be obtained with \(\text{R} = \text{Y}\).

Water diffusion in trachyte and phonolite melts
S. Fanara\(^1\), H. Behrens\(^1\) and Y. Zhang\(^2\)

\(^1\)Institut für Mineralogie, Universität Hannover, Hannover, Germany (s.fanara@mineralogie.uni-hannover.de, h.behrens@mineralogie.uni-hannover.de)
\(^2\)Department of Geological Sciences, University of Michigan, Ann Arbor, Michigan, USA (youxue@umich.edu)

Knowledge on water diffusivity in silicate melts is required for modelling degassing of magmas and magma/fluid interaction. Water diffusion in trachytic and phonolitic melts was investigated in a piston cylinder apparatus at pressure from 5 to 25 kbar, at 1300°C and for durations of 0 to 300 s. As starting materials we have used synthetic analogues of potassium-rich trachyte from the Phlegeran Fields, Italy and potassium-rich phonolite from Laacher See, Germany. Hydrous glasses were produced by fusion of glass powder plus water for 20 h in AuPd capsules in an internally heated pressure vessel at 1200°C and 4 kbar. In diffusion couple experiments two cylindrical halves with different water contents (nominally dry to 5.5 wt%) were combined. Water concentration profiles were measured by Fourier transform infrared microspectroscopy using the peak heights of combination bands of OH and H\(_2\)O in the near-infrared. The obtained total water profiles are asymmetric, very steep in the half with low water content but more extended into the water-rich half. Water diffusion coefficients were calculated from the total water profiles by the Boltzmann-Matano analysis and/or numerical fitting. In case of phonolite melts fitting of the profiles indicate that the water diffusivity is proportional to the total water content.

In a first experiment at 1325°C, 15 kbar for 5 min combining phonolitic halves containing 0 and 5 wt% H\(_2\)O we determined a water diffusivity of \(7.7 \times 10^{-11}\) m\(^2\)/s at 1 wt% H\(_2\)O, similar as found by Freda \textit{et al.} [1] for trachytic melts at 10 kbar, but about 0.7 log units faster than in rhyolite (Zhang and Behrens 2000, [2]). Effects of pressure and temperature on water diffusion are discussed.

The role of Mn oxides on the geochimical cycle of chromium: a field study in New Caledonia

3Centre Européen de Recherche et d’Enseignement en Géosciences de l’Environnement (CEREGE), UMR CNRS 6635, Université Paul Cézanne – Université de Provence, 13545 Aix en Provence, France

Chromium is naturally released in the environment upon weathering of ultramafic rocks containing Cr3+-bearing minerals [chromite FeCr2O4, magnetite Fe3-xCrxO4, olivine (Mg,Fe)2-xCrxSiO4 or pyroxene (Ca,Mg,Fe)1-xCrxSiO3]. In surface conditions, chromium occurs under two main redox states (Cr3+ and Cr6+), the former being much less soluble, bioavailable and toxic than the latter (Anderson, 1989). Several laboratory studies have shown that Cr3+ ions could be oxidized to Cr6+ ions by Mn oxides (Fendorf and Zasoski, 1992; Silvester et al., 1995; Weaver and Hochella, 2003), which suggest that the concomitant occurrence of chromium and Mn oxides in soils could be hazardous. Although few field studies already addressed the question of the mobility and bioavailability of chromium in naturally Cr-enriched soils (Neel et al., 2007; Garnier et al., 2006; Becquer et al., 2003), only one (Cooper, 2002) focused on the role of Mn oxides on these geochemical parameters.

The present study, which is supported by the French ANR-ECCO program, aims at increasing our knowledge on the actual role of Mn oxides on the geochemical cycle of chromium in soils developed upon weathering of ultramafic rocks. To reach this goal, soil samples were collected along a 60 m core drilled across a weathering sequence in New Caledonia. Chemical and mineralogical analyses along this sequence indicate the occurrence of a saprolitic unit (ultramafic rocks more or less altered) at the bottom. This unit is overlaid by a first lateritic unit containing goethite, hematite and chrome and particularly enriched in Mn oxides (asbolan), which is itself overlaid by a second lateritic unit containing no Mn oxides. XANES analysis allowed detection of significant amounts of Cr6+ (up to 20 wt% of total chromium) in the unit containing Mn oxides whereas no oxidized chromium could be detected in the other units of the drilling core. These results strongly suggest that the reactivity of Cr3+ with Mn oxides observed in laboratory experiments is effective in soils and that these Mn oxides actually play a key role on the redox state of chromium, and in turn, on the geochemical cycle of this element in surface environments.

Constraining reaction rates in marine carbonate sediments using reactive transport modeling: Investigating the effects of diagenesis on Sr, Ca, and Mg

M.S. FANTLE1 AND D.J. DEPAOLO2

1Pennsylvania State Univ., Geosciences Dept., University Park, PA 16802; (mfante@geosc.psu.edu)
2University of California, Earth and Planetary Science Dept., Berkeley, CA 94520-4767; (depaolo@eps.berkeley.edu)

Numerical modeling, in conjunction with pore fluid chemical and isotopic measurements, can be used to deduce mineral dissolution and precipitation rates in natural systems. The current study reports calcite recrystallization rates for a marine sedimentary section (ODP Site 807A, Ontong Java Plateau). The rates are constrained by Sr isotopes (87Sr/86Sr), which are sensitive at multi-million-year time scales, and Ca isotopes (δ44Ca), which are sensitive at time scales of tens of thousands of years. Recrystallization rates for sediments that are older than 2 Ma are ~0.2 to 2 %/Myr, which are similar to those reported in previous studies for other locations. However, reaction rates deduced for relatively young (~< 2 Ma) carbonate sediments using Ca isotopes are significantly faster (30 to 40 %/Myr), indicating that the approximate inverse age dependence of recrystallization rate extends to carbonate sediments as young as 0.1 Ma.

Rapid rates of recrystallization in relatively young carbonate sediments have implications for the fidelity of elemental and isotopic proxies of past climate and ocean chemistry. Recrystallization may change the original elemental and/or isotopic composition of carbonate, complicating attempts at paleo-reconstructions. The current study presents model results that describe the effects of diagenesis on the Sr/Ca and Mg/Ca elemental ratios, as well as the Ca isotopic composition, of marine carbonates. Using the reaction rates constrained by Sr and Ca pore fluid geochemistry, we use numerical models to estimate that up to 25 to 30% of the initial Sr and Mg in the solid phase may be lost during diagenesis. This conclusion is different from that inferred from the Sr isotope data only. The pattern of loss is dependent on the sedimentation history, so that loss is not constant throughout the column. If there is no externally imposed advection in the sedimentary column, then Ca isotopes are not significantly modified by diagenesis. Given the upper limit of reaction rates determined at 807A, the δ44Ca of the bulk carbonate sediment is altered by no more than +0.15‰. The small degree of diagenetic alteration is due to the fact that Ca is a major element in calcite, as opposed to the trace constituents Sr and Mg. Finally, diagenesis is not likely to account for the fluctuations observed in the seawater Ca isotope curve over the Late Cenozoic that is derived from measurements of bulk carbonate sediments.
Geochemical records of anthropogenic change: lake sediments and peat bogs

J.G. FARMER
School of GeoSciences, University of Edinburgh, Scotland, UK (J.G.Farmer@ed.ac.uk)

Radiometrically dated cores of sediments from freshwater lakes and of peat from ombrotrophic bogs have been used to reconstruct the history of heavy element deposition arising from humankind’s activities over the past few thousand years. The historical records so obtained for lead, by far the most studied element, are probably the most convincing, with confidence augmented by the corroborative use of source-related stable lead isotope variations and by correspondence with independently derived records, for example from ice cores and archival herbarium mosses. Yet the bottom sediments of freshwater lakes and the living/decaying vegetation and peat of ombrotrophic bogs are dynamic systems with potential for perturbation of historical pollution records through remobilization and redistribution of elements as a consequence of inter-related physical, chemical and biological processes. The natural diagenetic enrichment of arsenic, in association with redox-sensitive iron, sometimes observed in the solid and solution phases of near-surface layers of lake sediments, and the vegetative recycling of nutrient manganese in peat bog surface plants are but two examples. Site-specific conditions, as well as element-specific processes, can be important in the case of both lakes and peat bogs and comparative studies of the two systems, where geographically possible and appropriate, may be additionally revealing. The authenticity of historical records in lake sediments and peat bogs depends also upon the accuracy of radiometric dating techniques, such as those based upon naturally occurring $^{210}$Pb, nuclear fallout $^{137}$Cs and $^{241}$Am, and ‘bomb’ and cosmogenic $^{14}$C, each with its own strength and weaknesses, and the current need for routine application of additional methods (e.g. $^{32}$Si) with half-life (~140 y) intermediate between those of $^{210}$Pb (22.3 y) and $^{14}$C (5730 y).

Dynamics and internal structure of a mantle plume conduit

C.G. FARNETANI 1 AND A.W. HOFMANN2

1 Institut de Physique du Globe de Paris, France (cinzia@ipgp.jussieu.fr)
2 Max-Planck-Institut für Chemie, Postfach 3060, Mainz, Germany (hofmann@mpch-mainz.mpg.de)

Plumes are often thought of as thermal structures, the key parameter being their excess temperature with respect to the surrounding mantle, while the associated velocity field is frequently neglected. However, in order to understand the structure of a plume conduit and the internal distribution of geochemical heterogeneities we change perspective and focus on velocities and strain rates. Like the hands of an invisible sculptor, velocity gradients constantly modify the shape of heterogeneities rising in the plume conduit.

Numerical simulations of a vigorous thermal plume provide a high resolution velocity field that is used to advect deep-seated passive heterogeneities. Our first objective is to investigate the relation between initial length-scales of heterogeneities across D'' and the length- and time-scale of geochemical variations induced in the plume conduit. We also explore dynamical differences between the central and peripheral part of the plume conduit, and calculate the strain rate $\varepsilon_{rr}$, the buoyancy flux and the elongation as a function of radial distance from the plume axis. Our results clearly show that most of the plume buoyancy flux occurs in highly sheared parts of the conduit.

We then concentrate on a 'Hawaiian' plume sheared by a fast moving oceanic plate. Our fully three-dimensional numerical model allows us to study the flow trajectories inside a sheared plume conduit and the deformations undergone by passive heterogeneities. Although our approach is simplistic, we consider the lifetime of a volcano carried by the plate over different parts of the plume conduit and we investigate the relation between heterogeneous structures in the mantle and the spatio-temporal geochemical variability registered by the volcano.
Isotopic evidence for mid-Archean anoxia

JAMES FARQUHAR1, MARC PETERS2, DAVID T. JOHNSTON1, HARALD STRAUSS2, ANDREW MASTERSON1, UWE WIECHERT3, AND ALAN J. KAUFMAN1

1Department of Geology, University of Maryland, College Park, Maryland, USA: (jfarcuha@essic.umd.edu)
2Geologisch-Paläontologisches Institut und Museum der Westfälischen Wilhelms-Universität Münster, Corrensstraße 24, D-48149 Münster
3Department of Earth Sciences, Freie Universität Berlin, Malteserstr. 74-100, Haus B, C und N 12249 Berlin

The presence of nonzero $\Delta^{33}$S and $\Delta^{36}$S in the Archean and earliest Paleoproterozoic sedimentary rock record is considered to provide the strongest line of evidence for an anoxic early atmosphere. Low atmospheric oxygen is required both for production and transfer of the signal to the geologic record (Farquhar et al., 2000; Farquhar and Wing, 2003, 2005; Pavlov and Kasting, 2002). Temporal trends of sulfur isotopes in the Archean record reveal periods of large amplitude non mass-dependents signals (Early and Late parts of the Archean), and others when the signal was attenuated (Middle Archean) (Ono et al., 2003; Ohmoto et al., 2006), and some workers argue that this interval lacks a non mass-dependent signal and records an early, transient oxygenation of Earth’s atmosphere (Ohmoto et al., 2006).

We have investigated this interval and present new analyses of samples from the mid-Archean record (ca. ~2.8 and ~3.0 billion years ago (Gya)) that demonstrate the presence of an unambiguous non mass-dependent signal and is inconsistent with an oxygenated mid-Archean atmosphere. Our results for $\Delta^{33}$S and $\Delta^{36}$S indicate however that the character of the non mass-dependent signal is different for this interval in Earth history and provides evidence for changes in the pathways for non mass-dependent chemistry in this interval. This may reflect a change in the chemical composition of the atmosphere and may also be related to the observation of an attenuated $\Delta^{33}$S signal at this time.

Uptake of heavy metals, and arsenic by an aquatic plant in the vicinity of the abandoned Ervedosa tin mine (NE Portugal)

P.J.C. FAVAS1 AND J.S. PRATAS2

1Dep. of Geology of University of Trás-os-Montes e Alto Douro, 5001-801 Vila Real, Portugal, (pjcf @utad.pt)
2Dep. of Earth Sciences of University of Coimbra, Portugal, 3000-272 Coimbra, Portugal, (jpratas @dct.uc.pt)

This paper focuses on the uptake of heavy metals, and arsenic by an aquatic plant (Ranunculus peltatus Schrank) growing in the Tuela river in the vicinity of the abandoned tin mine of Ervedosa in the north region of Portugal. At mine, tin-bearing quartz veins with cassiterite and sulphides were exploited for tin (Sn) and arsenic trioxide (As2O3), until 1969. The waters at the mining site are affected by AMD, with high iron reduction and that is suggested to be associated with oxides and benthic ferrous Fe that is produced by dissimilatory iron reduction and that is suggested to be associated with enrichments in Fe/Al in the Gotland Deep, as Lyons and Sevavermann, 2006b, implying that negative Fe isotopic signatures could be characteristic for euxinic sediment deposition. Enrichments in Fe/Al can be explained by transport of reactive Fe from the shelf to the euxinic basin where it is transferred to the sediment by pyrite formation in the water column (e.g. Raiswell and Anderson, 2005). This is supported by pyrites with mean δ56Fe values of -1.1 ± 0.2 ‰ in the Gotland Deep. Reactive Fe is derived from oxides and benthic ferrous Fe that is produced by dissimilatory iron reduction and that is suggested to be associated with negative δ56Fe values (Severmann et al., 2006b). Therefore, our data support the suggestion of Lyons and Severmann (2006) that Fe isotopes can be used to fingerprint the Fe enrichment process by shelf to basin shuttling of Fe. If negative Fe isotopic signatures are characteristic for euxinic sediment formation, widespread euxinia in the past might have shifted the Fe isotopic composition of the ocean towards more positive δ56Fe values.

The analytical data obtained (Table 1) demonstrate low pollutant concentrations in fluvial water. However, the trace elements are considerable concentrated in the plant samples. The heavy metal, and arsenic concentrations in the plants exceed the corresponding concentrations in the habitat (water) by tens of thousand times. Concentration factor (CF), as a ratio of a chemical element content in plants (Cp) to its content in the corresponding habitat (Cph), was used to estimate the extent of heavy metals, and arsenic concentration by plants (CF=Cp/Cph).

The plant studied can be used to decrease the heavy metals, and arsenic amounts into the aquatic environment affected by acid mine drainages. On the other hand, this aquatic plant can enter the food chains, presenting a potential danger for animal and human health.

Iron isotope variations in Holocene Baltic Sea sediments

M. A. FEHR1, P. S. ANDERSSON1, U. HäLENIUS2 AND C.-M. MÖRTH3

1Laboratory for Isotope Geology, Swedish Museum of Natural History; (manuela.fehr@nrm.se, per.andersson@nrm.se)
2Department of Mineralogy, Swedish Museum of Natural History; (ulf.halenius@nrm.se)
3Department of Geology and Geochemistry, Stockholm University; (magnus.morth@geo.su.se)

Sediments from the Gotland basin in the Baltic Sea display variations in their bulk Fe isotopic compositions from -0.27 ± 0.09 ‰ to +0.21 ± 0.08 ‰ for δ56Fe (differences in 56Fe/54Fe relative to the IRMM-14 standard). Deposits formed in freshwater with oxygenated bottom water before ~8000 years B. P. display identical Fe isotopic signatures as oxic marine sediments and igneous rocks. In contrast, samples from the more recent brackish water and periodically euxinic units have significantly lighter δ56Fe values by ~0.2 ‰ on average (6 samples). Data for Fe/Al provide additional information about the cause for the shift in Fe isotopic compositions.

Enrichments in Fe/Al are characteristic for euxinic sediment deposition and can be used as a paleoredox proxy (e.g. Lyons and Severmann, 2006). Negative δ56Fe values are associated with enrichments in Fe/Al in the Gotland Deep, as has also been reported from the Black Sea (Lyons and Severmann, 2006; Severmann et al., 2006a), implying that negative Fe isotopic signatures could be characteristic for euxinic sediment deposition. Enrichments in Fe/Al can be explained by transport of reactive Fe from the shelf to the euxinic basin where it is transferred to the sediment by pyrite formation in the water column (e.g. Raiswell and Anderson, 2005). This is supported by pyrites with mean δ56Fe values of -1.1 ± 0.2 ‰ in the Gotland Deep. Reactive Fe is derived from oxides and benthic ferrous Fe that is produced by dissimilatory iron reduction and that is suggested to be associated with negative δ56Fe values (Severmann et al., 2006b). Therefore, our data support the suggestion of Lyons and Severmann (2006) that Fe isotopes can be used to fingerprint the Fe enrichment process by shelf to basin shuffling of Fe. If negative Fe isotopic signatures are characteristic for euxinic sediment formation, widespread euxinia in the past might have shifted the Fe isotopic composition of the ocean towards more positive δ56Fe values.

Methane, sulfide and oxygen fluxes at methane and brine seeps of the Nile Deep Sea Fan (Eastern Mediterranean)

J. Felden¹, A. Lichtschlag¹, S. Grünke¹, F. Wenzhöfer¹, D. DeBeer¹ and A. Boetius¹,²
¹Max Planck Institute of Marine Microbiologie, 28359 Bremen, Germany; (jfelden@mpi-bremen.de).
²Jacobs University Bremen, 28759 Bremen, Germany

The Nile deep sea fan (NDSF) of the Eastern Mediterranean hosts a huge number of active seep structures, which have only been discovered very recently. Here we have, for the first time, investigated the in situ benthic oxygen consumption and methane turnover at different seep systems of the eastern and central provinces of the NDSF in water depths of 1000-3000 m. The expedition BIONIL (M70/2) with RV Meteor and ROV QUEST (Marum) contributes to the DFG/BMBF Geotechnologien program MUMM and to the ESF EUROCORES project MEDIFLUX.

For our investigations several in situ instruments were used and combined with on board biogeochemical analyses: a microprofiler system measuring O₂, H₂S, pH and T in micrometer resolution, a benthic chamber to measure oxygen consumption and sulfide export, as well as a newly developed instrument for sulfate reduction rate measurements (INSINC).

The study focused on 3 different types of seep systems – the gas emitting center of the Amon mud volcano, the mud/brine seep at the outer rim of Amon, as well as the large carbonate pavements in the central province of the NDSF characterized by low fluid flow rates.

At cold seeps, the presence of bacterial mats indicates high methane and sulfide fluxes often also linked to high oxygen consumption rates. The three systems investigated here were characterized by very different types of bacterial mats, namely a Beggiatoa type (Amon center), a Thiomargarita type (Amon flank) and an Arcobacter type (carbonate pavements). Here we compare flux rates (methane, sulfide, oxygen) as well as microbial turnover rates of these different mat communities and investigate their link to fluid flow velocity and other environmental parameters.

Geochemical characteristics of Selenium-rich silicalite formation in Ziyang, Southern Qinling, China

Caixia Feng¹, Jiajun Liu², Ruizhong Hu¹ and Shen Liu¹
¹State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China (fengcaixia@vip.gyig.ac.cn)
²Geosciences and Resources School, China University of Geosciences, Beijing, China

A sediment formation, composed of siliceous rocks, mud stone/shale or callys and carbonate and siltstone, has been identified for enrichment of organic matter and bacterium-alga microbe. We define this specific formation as "silicalite formation". This paper aims to study the geochemical characteristics of selenium-rich silicalite formation in Ziyang.

The study area located in the Southern Qinling of China (lower Cambrian in peripheral margins of the Yangtze Block), is known for selenium-rich in rock, and occurred serious selenium-poisoning symptom in the 1960’s. Concerns on health problem and mineral resource of Se, the selenium-rich silicalite formation in this area has attracted scientific interests.

The selenium-rich siliceous rocks are important component of the Cambrian silicalite formation of Ziyang in the north of Daba region, which is characterized by hydrothermal sedimentation. Cherts are characterized by elevated concentrations of SiO₂, Se, Ba, Cu, Ni, V, As, Sb, U but lower MgO and Al₂O₃. The ratio of U/Th>1 , plots for Al-Fe-Mn and Fe-Mn-(Cu+Co+Ni) triangle diagrams, and correlations for P-Y, Zr-Cr and U-Th, all suggest hydrothermally sedimentary origin. The REE patterns show negative Ce and positive Eu anomalies. The isotopic compositions of silicon and oxygen are both similar with the hydrothermal origin. The temperature of hot water is about 78.6ºC-126.20ºC and suggests deep-water reservoir of siliceous rock sedimentation. The silicon-rich hydrothermal liquid contributed to enrichment of selenium in the study area.

In conclusion, further study of the forming environment and metallogenic characteristics of the selenium-rich silicalite formation is of great significance for both Se-related ore minerals and health interests.

δ¹³C carb and δ¹³C org excursions in the post-glacial Sinian to Early Cambrian interval in Guizhou, South China

H.-Z. FENG, H.-F. LING AND J. PENG
Department of Earth Sciences, Nanjing University, Nanjing, China (feng.h@jlonline.com)

The investigated area is located on the southeast border of the Yangtze platform. Five lithostratic units are recognized in ascending order: the Nantuo (NT), Doushantuo (DST), Dengying (DY), Gezhongwu (GZW) and Niutitang (NTT) formations. The DST Fm overlies conformably on the NT Fm characterized by glaciogenous diamictite. In the basal part of the DST Fm is a -4 m thick dolostone bed (so called cap carbonate). Upon this bed is the main part of the DST Formation dominated by phosphorite intercalated with dolostone and dolomitic pelite. The overlying DY Fm is composed of pure dolostone, followed by another set of phosphorite deposits called the GZW Fm. The GZW Fm is rich in small shelly fossils of Cambrian age, and covered by the NT Fm, a set of black shales with copious sponge fossils.

The values of δ¹³C carb show a wide range from -6.20‰ to 4.00‰, roughly consistent with that illustrated by Jacobsen & Kaufman (1999) for the same interval. The δ¹³C carb curve starts with a moderate positive shift after the glaciogenous diamictite and then goes into a negative shift, which persists up to the boundary between the DST Fm and the DY Fm. The second positive shift of δ¹³C carb occurs within the DY Fm, followed by another negative shift in the GZW and NTT formations. The values of δ¹³C org vary from -21.99‰ to -33.58‰, leading to a maximum oscillatory amplitude of 11.59‰. Being similar to the δ¹³C carb curve in shape, the δ¹³C org curve also demonstrates two positive shifts in the NT Fm and the DY Fm, and two negative shifts in the DST Fm and the interval from the GZW Fm to the NTT Fm.

Some studies have provided paired analyses of δ¹³C carb and δ¹³C org. Holland & Mckenzie (1991) show that the temporal carbon-isotopic curves of calcite and particulate organic carbon in a modern eutrophic lake correlate with each other to some extent, and the carbon-isotopic difference (ΔB = δ¹³C POC-calcite) indicating the effect of photosynthetic isotopic fractionation increases in response to increasing concentration of dissolved carbon dioxide (CO₂(aq)). However, the timing of the peaks or valleys of δ¹³C carb and δ¹³C org curves may not always coincide due to other factors besides photosynthesis, which complicates the use of ΔB for evaluating the relative variations of CO₂(aq) with geologic time (Kump et al., 1999). In our study, the coincidence of δ¹³C carb and δ¹³C org profiles suggests a dominating effect of photosynthesis on carbon-isotopic discrimination. Thus ΔB may be useful to understanding the relative changes of CO₂(aq) that may have occurred in the investigated area during the post-glacial Sinian and the Early Cambrian. This work was supported by NSFC (Grant Nos. 40472014 and 40572017).

Cosmogenic ²¹Ne/³He in olivines and pyroxenes from a Pleistocene basalt flow, western Grand Canyon National Park, Arizona, USA

C.R., FENTON¹, S. NIEDERMANN¹, M.GOETHALS¹² AND B. SCHNEIDER³

¹GeoForschungsZentrum Potsdam, Germany (crfenton@gfz-potsdam.de)
²Westfälische Wilhelms-Universität Münster, Germany
³Vrije Universiteit Amsterdam, The Netherlands

The Bar Ten lava flow is a Pleistocene basalt flow located in the western margin of the Unkaret Volcanic Field in Grand Canyon National Park (AZ, USA). It was chosen as a calibration site for the production of cosmogenic ³He and ²¹Ne (³He, and ²¹Ne) because it has more than 600 m of relief and has negligible erosion due to a regional desert climate. Together with other calibration sites of CRONUS-EU, it was selected to evaluate how production rates are affected by changes in altitude and latitude. The lava flow erupted between 60 and 150 ka based on two ⁴⁰Ar/³⁹Ar and one thermoluminescence ages. Low K content, excess Ar, and abundant glass in this basalt flow have made it difficult to obtain more accurate ages. Cosmogenic samples were collected from stable primary surfaces at elevations of 1180 to 1820 m along a vertical transect between 36.2239 and 36.2417° N. He, Ne, and Ar were analyzed by step-heating of olivine and pyroxene separates and ³He, and ²¹Ne components have been determined. We evaluated ²¹Ne/³He values, assuming that eruption age and erosion should have no effect on the ratio, if ³He, and ²¹Ne are produced at constant rates relative to each other. ²¹Ne/³He varies from 0.19-0.20 for pyroxenes and from 0.35-0.39 for olivines. The difference between mineral phases may be due to differences in mineral composition affecting production of ²¹Ne; production of ³He, is less sensitive to variations in mineral composition. Olivines in our study contain 26-27 wt.% Mg, whereas pyroxenes contain 9-11 wt.% Mg. Lower Mg content decreases the production of ²¹Ne, and thus lowers the ²¹Ne/³He value for pyroxenes compared to that of olivines. Production rates based on elemental composition or on published calibrated values were scaled to our specific field site using several scaling methods. These production rates yield cosmogenic ages that are bracketed by the ⁴⁰Ar/³⁹Ar and thermoluminescence ages, but the independent dating techniques are thus far not accurate enough to specify which production rate and which scaling method is best suited for this calibration site.
Comparison of thermodynamic data for aqueous species with focus on hyperalkaline conditions

R. Fernández¹, U. K. Mäder¹ and J. M. Soler²

¹Institut für Geologie, Universität Bern, Batzerstrasse 1-3, CH-3012 Bern, Switzerland (raul.fernandez@geo.unibe.ch, urs.maeder@geo.unibe.ch)
²Institut de Ciències de la Terra “Jaume Almera” (CSIC), Lluís Solé i Sabarís s/n, 08028 Barcelona, Spain (jsoler@ija.csic.es)

Introduction and objective

Presently, geochemical databases lack agreement on thermodynamic properties for a substantial number of aqueous species and minerals. Some discussion of thermodynamic data can be found in the literature for minerals and solid phases (e.g. Arthur et al., 2005), but not much attention has been paid to aqueous species.

The objective of this study is to address the thermodynamic properties of aqueous species with emphasis on major components relevant for hyperalkaline conditions. For this purpose, the most commonly used and accessible thermodynamic databases have been treated in similar fashion. Six databases were included: llnl-EQ3/6, minteq, phreeqc, wateq4f, JAEA and NAPSI.

Method and results

Pertinent temperature dependent thermodynamic data for 66 aqueous species were evaluated. The equilibrium constant for species association (log K at 25 ºC), ΔHR and the temperature dependence of log K (analytical expressions where available) were taken for each species and each database. The data bases were first brought to a common format in terms of basis species. Results for log K up to either 100 ºC or 300 ºC (extrapolated by Van’t Hoff, or given by analytic expressions) were graphically compared relative to the value at 25 ºC, and in absolute terms. Select literature sources and the HKF/SUPCRT model were used in addition to try and resolve some of the discrepancies.

Discussion

The results point at some obvious short comings, limitations and discrepancies, but some of the interpretation is limited by the absence of an absolute reference. Modelling calculations on alkaline systems using different databases and including select solid phases are recommended for a more practical comparison, and this work is currently in progress.

This research project is associated with the Grimsel Test Site (CH) and supported by Nagra (CH), POSIVA (SF) and JAEA (JP).

Passivating layer formation during glauconite dissolution: implications for mineral sequestration of CO₂

Susana Fernandez Bastero and Luis Gago Duport

Dept Geociencias Marinas. Universidad de Vigo.
(sbastero@uvigo.es. Duport@uvigo.es)

The kinetic of glauconite dissolution in the pH range from 2 to 10 (T= 25ºC) has been determined from flow-batch reactor experiments. The textural and microstructural aspects induced by the dissolution process have also been characterized by XRD, HREM and BET. As a result of this analysis it is shown that, in acid conditions, glauconite is slightly more soluble than other silicates ubiquitous in sediments. The dissolution mechanism is incongruent at very acid pH values and tends to be congruent for intermediate and neutral values. Microstructural analysis show that kinetic factors are strongly influenced by structural factors. Dissolution of glauconite takes place in two steps involving, first, the disorder of tetrahedral and octahedral layers and, second, the release of cations to the solution, this process being controlled by the rate of liberation of the interlayer cation (K⁺). As a consequence, an amorphous phase is formed that evolves compositionally to a more silica-rich end-member. The reactive surface is reduced during this process, giving rise to the formation of a passivating layer that has considerable influence on the dissolution rate. These experimental results have been used to analyze, by geochemical modelling, the response of glauconitic sediments during carbonation reactions.

The replacement of gypsum by CaCO₃ polymorphs: Reaction steps and formation of pseudomorphs

L. FERNÁNDEZ-DÍAZ, C.M. PINA, J.M. ASTILLEROS AND N. SÁNCHEZ-PASTOR

Dpto. Cristalografía y Mineralogía. Universidad Complutense de Madrid. E-28040 Madrid, Spain (lfdiaz@geo.ucm.es; cmpina@geo.ucm.es; jmastill@geo.ucm.es; nsanchez@geo.ucm.es)

On the Earth’s surface, the replacement of evaporitic calcium sulphates (anhydrite and gypsum) by CaCO₃ is a common phenomenon that can lead to the formation of large deposits of diagenetic carbonates. In spite of the geological and industrial implications of this phenomenon, very few experimental studies have been conducted to investigate the microscopic mechanisms involved in this replacement process. Here we present an experimental study of the interaction between gypsum and carbonate-bearing aqueous solutions. This interaction leads to the replacement of gypsum single crystals (~3 mm³) by an aggregate of CaCO₃ crystals. Scanning Electron Microscopy (SEM) and glancing incidence X-ray diffraction (GIXRD) were used to monitor the development of the replacement process. The replacement takes place through a number of solvent-mediated transformations, which involves the dissolution of gypsum and the sequential formation and dissolution of different CaCO₃ polymorphs. Although the actual sequence of reactions depends on the initial concentration of carbonate, amorphous calcium carbonate (ACC) is always the first phase that forms and can be considered a precursor for the formation of more stable crystalline CaCO₃ polymorphs. Moreover, the initial concentration of carbonate also controls the kinetics of the replacement and the degree of faithfulness of the pseudomorphs. The phase formation sequence and the textural characteristics of the replacement are interpreted on the basis of the evolution of physicochemical parameters, like the supersaturation with respect to the different CaCO₃ polymorphs and the [SO₄²⁻]/[CO₃²⁻] ratio in the aqueous solution.

From crystals to clusters: A molecular simulation study of CaCO₃ configurations

ÁNGELES FERNÁNDEZ-GONZÁLEZ¹, LUCAS FERNÁNDEZ-SEIVANE², MANUEL PRIETO¹ AND JAIME FERRER²

¹Dept. Geology. Universidad de Oviedo. C/ J. Arias de Velasco 3005-Oviedo, Spain. (mafernan@geol.uniovi.es)
²Dept. of Physics. Universidad de Oviedo, Spain. (ferrer@condmat.uniovi.es)

Equilibrium relationships involving solids are based in bulk thermodynamic properties that concern ideal crystals of infinite size. However, real processes towards equilibrium imply development of finite molecular-scale entities. The configuration of these early-stage clusters and the estimation of their excess energies with respect to the ideal crystal is key to understand the macroscopic behaviour of a given system. Here, starting from the ideal atomic positions in calcite, aragonite, or vaterite, the relaxation in vacuum of finite clusters of CaCO₃ has been explored. With the aim of determining the influence of the cluster size on its energy and on its geometrical configuration, a series of CaCO₃ clusters have been simulated and their lattice energies calculated. The cluster geometry has been fully optimized at constant pressure and its energy has been determined using GULP. A wide variety of clusters ranging from 1 to 2000 formulae has been considered for each (calcite, aragonite, or vaterite) starting structure. GULP calculations have been carried out using the pair potentials set derived by Rhol et al (2003). In a number of cases the final configuration has been checked with good agreement using the DFT code SIESTA (Soler et al., 2002). Although these simulations represent not fully realistic scenarios, some results are relevant from the point of view of the polymorphic precipitation of CaCO₃. A fundamental question like the size that must have a cluster to be considered calcite, aragonite, or vaterite is addressed from the diffraction patterns of the relaxed clusters.

Two large Neoproterozoic bodies, the Cunhaporanga and Três Córregos Granitic complexes (CGC, TCGC) crop out in Paraná state, SE Brazil, constituted mainly by calc-alkaline granitoids. Both show ellipsoidal outlines, with a NE orientation, the prevailing basement structural trend in SE Brazil. CGC shows poor outcrop pattern and a large faciological diversity, not so TCGC. Aerial gammaspectrometric surveys were used to test variations in K, U, Th abundances for definition of facies domains in both complexes. Colorgraded maps were prepared for TC, the three elements and several calculated factors (including U/Th, U/K, Th/K ratios, F factor, triangular K-U-Th, etc.). In the case of TCGC, the color maps clearly reproduce the petrographic distribution pattern established during ground mapping. Aerial gammaspectrometry showed, for TCGC, the potential for accurately pinpointing petrographic variations.

Melt supply and magmatic evolution at a large central MOR volcano located in the Lucky Strike Segment
P. L. FERREIRA¹, B. J. MURTON², J. E. DIXON³ AND C. A. BOULTER²
¹INETI-DGM, Alfragide, Portugal, (pedro.ferreira@ineti.pt)
²NOC, Southampton, UK, (bjm@noc.soton.ac.uk; cab2@noc.soton.ac.uk)
³University of Miami, USA, (jdixon@rsmas.miami.edu)

New major and trace element, volatile (H₂O and CO₂) and Sr-Nd-Pb isotopic, data on samples from the Lucky Strike segment (LSS) are presented. All studied samples are E-MORBs, but different degrees of enrichment are identified. LSS basalts have been subdivided into three distinct compositional groups: In Group 1, the basalts have the highest more-to-less incompatible element ratios (e.g. La/Sm, Nb/Zr, Ba/Y) and have the most Sr-Nd-Pb radiogenic values. They are spatially restricted to the central part of the axial volcano, are highly vesicular, and plagioclase phryic. Group 3 basalts have the lowest more-to-less incompatible element ratios and the lowest Sr-Nd-Pb radiogenic values. They were collected throughout the LSS (from 37°12,0' to 37°27,3' in latitude), are almost aphyric and exhibit low vesicularity. Group 2 basalts have chemical characteristics intermediate between those of Groups 1 and 3. This subdivision is readily recognised in the volatiles data. Group 1 glasses have higher dissolved H₂O concentrations (and estimated pre-eruptive CO₂ concentrations), relative to those of Group 3, but have lower H₂O/Ce ratios (108-197 and 251-343 for Groups 1 and 3, respectively) that are well below the average defined for this MAR region (253±33).

Taking into account the sample spatial distribution, the bathymetric (shallow depths at segment centre), and the gravity data (negative “bull’s eyes” RMBA anomalies at segment midpoint), together with the geochemical data interpretation, a genetic volcanic model is generated. The enriched, more fertile, mantle heterogeneities (Group 1), related to Azores mantle plume material, in the LSS sub-oceanic mantle, are delivered to the centre of the segment by highly focused, sub-lithospheric processes. Forming wetter domains, they start to melt first, deeper in the mantle, melting more, but generating lower melt fractions, than the ambient mantle (Group 3). Group 1 vesiculating melts, having their density reduced, will be aggregated in a high-level axial magma chamber (AMC). The limit of neutral buoyancy of these magmas is never reached, thus the magmas are delivered vertically to the segment centre. Further magmas, formed from melting of the ambient mantle, will be aggregated in the AMC. Thus, initial mixing of Group 1 and 3 melts and, lastly, only differentiation of Group 3 melts will produce Group 2 and 3 basalts, respectively. The disruption of pressure equilibrium of the magmatic system as a result of the ridge extensional stress regime, and the subsequent magnitude of internal overpressure in the magma reservoir will control the magma delivery along the LSS.
**C_{32} N-Alkan-1-ol as specific indicator of C4 tropical plants in marine sediments**

**MONTSERRAT FERRER,1,2, JOAN O. GRIMALT,1 AND JORGE E. SPANGENBERG2**

1Institute of Chemical and Environmental Research (CSIC), 08034 Barcelona, Spain (jgoqam@iiqab.csic.es, Montserrat.FerrerCarrillo@unil.ch)

2Institute of Mineralogy and Geochemistry, University of Lausanne, CH-1015 Lausanne, Switzerland (jorge.spangenberg@unil.ch)

Contents, distribution patterns and molecular stable carbon isotope composition of these compounds have been studied as markers of continental vegetation over the last 320 kyr in a set of samples from the tropical Indian Ocean core MD98-2165 (9°38’96S, 118°20’31E, 2100 m).

The concentration changes of these compounds show a general pattern dominated by the well defined glacial-interglacial oscillation. Eolian inputs were much stronger during the glacial periods. The n-alkanes range between C_{23} and C_{33} and are characterised by high odd-over-even carbon number preference and predominance of the C_{31} n-alkane, whereas the n-alkanols range between C_{20} and C_{32} and are dominated by even-over-odd carbon numbers with maxima at C_{28} or C_{32} n-alkanol. In this respect, warmer and wetter conditions appear to favour deposition and preservation of the C_{30} homologue and colder and drier conditions favour the C_{28} n-alkanol. However, the C_{32} n-alkanol becomes an additional major homologue during the glacial times, suggesting an expansion of C_{4} plants during these arid conditions as reported by Rommerskirchen (2006). The stable carbon isotope weighted mean average of the n-alkanes (n-C_{27} to n-C_{33}) fall in the range between ~30.5 and ~34.5‰, typical of leaf-wax n-alkanes biosynthesised by C_{3} plants. The lower δ^{13}C values are observed during warm and humid interglacial periods, when the estimated C_{4} plants contribution decreased ~15 wt %. This is consistent with the negative relationship existent between δ^{13}C of C_{3} plants and water availability (Liu et al., 2005). The weighted mean average δ^{13}C values of n-alkanols (C_{20}-C_{32}) fall in the range between ~24.4 and ~32.6‰, again with lower δ^{13}C values during interglacial periods. Amazingly, the δ^{13}C of C_{32} n-alkanol reveals a clear C_{4} plant signature during cold and dry conditions. These results demonstrate that n-alkanes and n-alkanols, but most particularly the C_{32} n-alkanol, show a distinct pattern of contributions from C_{4} plants to marine sediments during arid conditions and therefore, they can be used as indirect proxy of continental climate conditions in the tropics.

**Chemical weathering rates inferred from cosmogenic radionuclides and immobile element enrichment: Measurements in the Idaho Batholith**

**K.L. FERRIER, J.W. KIRCHNER AND R.C. FINKEL**

1Department of Earth and Planetary Science, University of California, Berkeley, CA, USA, 94720-4767 (ferrier@eps.berkeley.edu; kirchner@eps.berkeley.edu)

2Center for Accelerator Mass Spectrometry, Lawrence Livermore National Laboratory, Livermore, CA, USA, 94550 (finkel1@llnl.gov)

Chemical weathering rates inferred from cosmogenic radionuclides and Earth surface processes. It nourishes ecosystems by supplying nutrients to natural waters, promotes physical erosion by weakening bedrock, and buffers Earth’s climate over geologic time by modulating atmospheric carbon dioxide concentrations. Long-term measurements of chemical weathering rates (and of their dependence on external factors such as climate) are thus important for understanding the biogeochemical and geomorphological evolution of the Earth’s surface, and for quantifying the recent impact of humans on the environment. Chemical weathering fluxes can be measured in mountainous terrain using cosmogenic radionuclide measurements of long-term denudation rates, coupled with measurements of the rock-to-soil enrichment of chemically inert tracers (Kirchner et al., 1997; Riebe et al., 2001; Riebe et al., 2003). This technique has two major strengths: (1) it can be applied to a wide range of actively eroding landscapes, whereas other methods typically require non-eroding, datable soils, and (2) it intrinsically averages over the long timescales of soil formation and denudation (typically 1000-100,000 years in soil-mantled hillslopes), and thus sheds light on landscape evolution processes. Here we use this method to measure chemical weathering fluxes along an altitudinal transect on Pilot Peak. This transect spans 1500 meters of altitude in the granitic Idaho Batholith, USA, and thus spans ~10 °C in mean annual temperature. Pilot Peak is unglaciated, exhibits little variability in bedrock mineralogy, and is mantled with well-mixed soil at all elevations. Our preliminary data suggest that rates of chemical weathering, as a function of total denudation rates, are not a strong function of elevation, and hence not a strong function of temperature. These results also imply that chemical weathering fluxes account for less than 20% of the total denudation flux at Pilot Peak, and thus point toward the dominance of physical processes over chemical processes in sculpting this landscape.

Revealing the importance of endospores in sediments

J. FICHTEL1, J. KÖSTER1, H. SASS2 AND J. RULLKÖTTER1

1Institute of Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, P.O. Box 2503, D-26111 Oldenburg Germany (joerg.fichtel@icbm.de)
2School of Earth, Ocean and Planetary Sciences, Cardiff University, Cardiff, CF10 3YE Wales, U.K.

Introduction
Endospores are bacterial resting stages being able to remain viable for long periods of time. Consequently, they can be expected to accumulate in sediments during burial and may contribute significantly to total cell counts. This emphasises the need for a new cultivation-independent approach for the quantification of bacterial endospores in sediments.

Application of dipicolinic acid for estimation of endospore numbers
In the present study, dipicolinic acid (DPA), a biomarker for endospores, was used to quantify endospores in sediment samples. Sediment cores of about 6 m length were collected from different sites in the backbarrier tidal flat of the island of Spiekeroog in the southern North Sea and analysed for their DPA content to determine endospore depth profiles. For conversion of sediment DPA contents into spore numbers, purified endospores of tidal flat strains were investigated for their DPA content.

Contribution of endospores to total cell counts
Sediment samples taken from different lithological subunits of the cores showed high variations in DPA contents. Estimated spore numbers were in a range of 10^5 to 10^7 endospores g^-1 sediment and accounted for up to 10% of total cell counts. Huge differences in endospore numbers estimated from DPA contents and determined by viable counts obtained after pasteurization (Köpke et al., 2005) were found. The conversion of sediment DPA contents into spore numbers, purified endospores of tidal flat strains were investigated for their DPA content.

Conclusions
Since quantification of endospores on the basis of DPA content does neither discriminate between viable and non-viable spores nor between different physiological groups, it apparently provides a more realistic estimate of endospores as part of the microbial community than cultivation-dependent approaches. For this reason, we suggest to use DPA for the determination of endospore numbers in addition to total cell counts in order to reveal the importance of endospores in sedimentary microbial communities.

New approaches for the analysis of stable and radiogenic strontium isotopes using LA-MC-ICP-MS

JAN FIETZKE1, VOLKER LIEBETRAU1, KARSTEN ZUMHOLZ2, THOR HANSTEEN3 AND ANTON EISENHAUER1

1RD2 Marine Geochemistry, IFM-GEOMAR, Kiel, Germany (jfietzke@ifm-geomar.de, vliebetrau@ifm-geomar.de, aeisenhauer@ifm-geomar.de)
2RD3 Marine Ecology, IFM-GEOMAR, Kiel, Germany (kzumholz@ifm-geomar.de)
3RD4 Dynamics of the Ocean Floor, IFM-GEOMAR, Kiel, Germany (thansteen@ifm-geomar.de)

Stable strontium isotopes in various marine carbonates have been determined using an “AXIOM” MC-ICP-MS in combination with a NewWave UP193 laser ablation unit. Using new developed measurement protocols we did achieve an external reproducibility of Sr87/Sr86 ratios in carbonates of about 18 ppm (RSD). For recent and sub-recent marine carbonates a radiogenic strontium isotope ratio Sr87/Sr86 of 0.70917(1) was determined, which agrees well with the accepted value for modern sea water. It was achieved without the use of any additional correction of the data. Only the rubidium correction was performed in its accepted form and the strontium isotope ratios were normalized to a Sr86/Sr88 ratio of 0.1194 using the exponential law for fractionation correction.

A major benefit of the applied method is the direct determination of the stable strontium isotope fractionation. Assuming stable plasma conditions and a reproducible sample ablation this method is advantageous when compared to “conventional” MC-ICP-MS. It avoids additional fractionation of the sample strontium due to the chemical pretreatment (ion chromatography and solution preparation).

In aragonitic sclerosponge samples the stable strontium isotope fractionation was determined via LA-MC-ICP-MS. In these samples, spanning a temperature range of about 11°C, stable strontium isotope fractionation was found to be temperature dependent. The Sr86/Sr88 ratio of 0.1194 using the analytical uncertainty with previous findings for coralline aragonite of 0.033(5) per mill/°C (Fietzke & Eisenhauer, 2006).

The evolution of the Ediacaran sulfur cycle: A paired sulfate-pyrite $\delta^{34}$S approach

DAVID FIKE$^1$ AND JOHN GROTZINGER$^2$

$^1$Department of Earth, Atmospheric, & Planetary Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139, USA. (dfike@mit.edu)
$^2$Division of Geological & Planetary Sciences, California Institute of Technology, Pasadena, CA 91125, USA. (grotz@gps.caltech.edu)

An anomalous enrichment in marine sulfate $\delta^{34}$S$_{SO_4}$ is preserved in globally-distributed latest Ediacaran – early Cambrian strata. The proximity of this anomaly to the Ediacaran-Cambrian boundary and the associated evolutionary radiation has invited speculation that the two are causally related. Here we present a high resolution record of paired sulfate ($\delta^{34}$S$_{SO_4}$) and pyrite ($\delta^{34}$S$_{pyr}$) from sediments of the Ara Group, Sultanate of Oman. An enrichment in $\delta^{34}$S$_{pyr}$ coincides with the interval of enriched $\delta^{34}$S$_{SO_4}$, beginning at ca. 550 million years ago (Ma) and continuing through at least ca. 540 Ma. These data are evaluated using a new approach based on paired $\delta^{34}$SSO$_4$$^{--}$$\delta^{34}$Spyr data that enables us to calculate both $\delta^{34}$Sin, the isotopic composition of the sulfur flux entering the ocean, and $f_{pyr}$, the fraction of sulfur buried as pyrite. It appears that basal Ediacaran $\delta^{34}$Sin was significantly enriched beyond bulk Earth composition and became progressively more enriched through at least the earliest Cambrian. The rise in $\delta^{34}$Sin is correlated with the known record of increasing Ediacaran $\delta^{87}$Sr/$\delta^{86}$Sr, indicating a tectonic control on riverine sulfate delivery. The ~30permil decline in $\delta^{34}$SSo$_4$ observed in the Paleozoic is interpreted as representing in part the return of $\delta^{34}$Sin toward bulk Earth values. Against this background of increasing Ediacaran $\delta^{34}$Sin, the Ara $\delta^{34}$S enrichment is caused by an additional increase in $f_{pyr}$, which is most likely driven by enhanced primary production and increased sedimentation rates associated with the assembly of Gondwanaland. The data presented here constrain the changes in biogeochemical cycling that caused the Ara sulfur anomaly and serve as a contextual framework for understanding the E-C boundary, as well as biological and environmental change into the Paleozoic.

Micron-scale resolution of sulfur cycling in a microbial mat

DAVID FIKE$^1$, WILLIAM USSLER$^2$, JOHN EILER$^1$, YUNBIN GUAN$^1$ AND VICTORIA ORPHAN$^1$

$^1$Division of Geological & Planetary Sciences, California Institute of Technology, Pasadena, CA 91125, USA. (vorphan@gps.caltech.edu)
$^2$Monterey Bay Aquarium Research Institute, Moss Landing, CA 95039-9644, U.S.A.

Microbial mats consist of finely laminated layers of diverse microbial communities. Mat organization is thought to result from strong spatial gradients in light intensity and redox in the uppermost few millimeters. Optical examination reveals microbial laminations on scales between 5mm and 5µm throughout the thickness of the microbial mat. However, such fine laminations at depth have usually been regarded as a ‘relict architecture’ inherited from an older mat surface. To further our understanding of microbial processes within this laminated architecture, we have investigated sulfur cycling (as recorded by sulfide production) within a benthic microbial mat.

We present a high-resolution spatial profile of sulfide abundance and isotopic ($\delta^{34}$S) composition on the micron-scale through a microbial mat community analyzed using a Cameca NanoSIMS 50L ion microprobe. We find a fine-scale (0.1-2mm) banding of sulfide throughout the mats as visible to the naked eye. In addition, there are micron-scale (~4µm) laminations observed using the NanoSIMS both in optical CCD and element scanning mode. We have mapped the sulfide $\delta^{34}$S profile from the mat surface down to a depth of ~1cm at ~100µm resolution with a typical analytical error of ±0.5‰ (1σ). $\delta^{34}$S varies over ~25‰ as a function of depth through the mat. An apparent oscillatory behavior in $\delta^{34}$S exists over ~4mm, which approximates the spacing of the coarsest mat laminations. This result suggests that the deeper mat architecture reflects ongoing microbial activity rather than inherited architecture. At any given depth, there can be up to ~5-10‰ variability in $\delta^{34}$S in immediately adjacent (~10µm apart) locations. High-resolution images (5-20µm squares) of elemental abundance and isotopic composition indicate that the ubiquitous banding in sulfide abundance appears to control the $\delta^{34}$S variability, with the offset between high- and low-sulfide regions up to ~10‰. Control experiments in standard solutions did not reveal any banding or the same scale of isotopic variability as observed in the microbial mat. We therefore believe that the banding and isotopic variability observed in the microbial mat are not an analytical artefact, but rather reflect very-fine-scale lamination in microbial activity preserved at depth within the mat, as is supported by microscopic observations. The environmental conditions that maintain such rigid laminations at depth (~1 cm), far from the sharp redox gradients of the mat surface, remain poorly constrained.; however, our results suggest that the full scope of sulfur cycling with microbial mats remains far from being completely understood or fully appreciated.
Structural incorporation of trivalent f elements into the trioctahedral clay mineral hectorite

N. Finck, K. Dardenne, M.L. Schlegel, and D. Bosbach

1 Institut für Nukleare Entsorgung, Forschungszentrum Karlsruhe, Postfach 3640, D-76021 Karlsruhe, Germany (nicolas.finck@ine.fzk.de, kathy.dardenne@ine.fzk.de, dirk.bosbach@ine.fzk.de)

2 DEN/DPC/SCP Centre d’Etudes Nucléaires de Saclay, BP 11, 91191 Gif sur Yvette, France (michel.schlegel@cea.fr)

Clay minerals may play an important role in a high-level nuclear waste repository system. Clay-based materials have a high affinity for trivalent actinides, and several distinct molecular level mechanisms of actinide retention can operate: outer- and inner-sphere complexation, cation-exchange (interlayer), and structural incorporation.

Radionuclide immobilization by incorporation into the bulk structure of clay minerals may occur via coprecipitation. However, the size mismatch with the cations which typically occur in the octahedral sites of sheet silicates would result in large lattice strains [1]. Nevertheless, recent TRLFS data for Eu(III)/Cm(III) coprecipitated with hectorite at 90°C [2] suggest that such a substitution mechanism may operate [3,4].

Conventional EXAFS spectra collected on powders of Eu-containing hectorite suggested that Eu(III) was hexacoordinated with oxygens, as in a Mg structural site [5]. Neighbouring structural cations were not detected, maybe due to cancellation effects between EXAFS waves backscattered by (out-of-plane) Si and in-plane (Mg,Al) cations [6]. Polarized-EXAFS (P-EXAFS) experiments on self-supported films of these oriented clay minerals were thus carried out. Spectra were collected for varying europium contents to determine the influence of the degree of substitution on the local crystal structure.

Potassium content in the Earth’s core: A high-pressure and high temperature study of the Fe-K system

G. Fiquet, N. Coltice, F. Guyot, and P. Gillet

1 Dpt of Mineralogy, Institut de Minéralogie et de Physique des Milieux Condensés, UMR CNRS 7590, Institut de Physique du Globe de Paris, Paris, France (guillaume.fiquet@impmc.jussieu.fr)

2 Laboratoire de Sciences de la Terre, UMR CNRS 5570, Université Lyon 1, Ecole normale superieure de Lyon, Lyon, France (nicolas.coltice@univ-lyon1.fr)

The transition metal behavior of potassium at high pressure suggests that a significant amount of potassium could reside in the Earth's core. The radioactive isotope $^{40}$K could indeed contribute to power the Earth's dynamo but a high concentration may prevent inner core formation. We report a diamond anvil cell study of the Fe-K system up to 42 GPa and 3000K. Using in situ X-ray diffraction carried out at the European Synchrotron Radiation Facility, we show that Fe and K can alloy in reducing conditions, provided the change in the chemical bonding character of K from alkaline- to transition-metal is complete (above 20-25 GPa). The incorporation of potassium causes iron lattice to expand with increasing potassium concentration. However, a precise determination of cell parameters of both Fe and K indicates that a maximum amount of 700±300 ppm in weight of K can be accommodated in the ε-Fe lattice. Such pure metal (K,Fe) experiments provide an upper limit to the potassium concentration in the Earth’s core. Our estimate is lower than those proposed in previous studies and corresponds to a power limited to 4.3TW, may be more consistent with models of inner core growth and core-mantle boundary heat flow.
Hydrogeochemistry of alluvial groundwater in agricultural area: A case study in Gumushacikoy Aquifer, Turkey

A. FIRAT ERSOY, H. ERSOY AND F. GÜLTEKIN
Karadeniz Technical University, Department of Geological Engineering, 61080, Trabzon, Turkey (firat@ktu.edu.tr)

Ground and surface water quality can be affected by three different forms of pollution, which are chemical, biological and physical pollution. These polluting factors can influence natural environment and human health. Nitrites in soil and groundwater generally move relatively slow and there is approximately 20 years lag time between the detection of the pollutant the pollution activity and in groundwater. In this study, groundwater pollution originated from agricultural activities and municipal wastewaters were investigated in Gumushacikoy urban area. The water analyses from 49 water wells in the plain, taken over a 2-year period, were used to determine the NO$_3^-$, NO$_2^-$ and NH$_4^+$ contamination in the alluvial groundwater. The concentrations of nitrate (NO$_3^-$) in groundwater of Gumushacikoy Plain range from 0-15.61 mg/l, nitrite (NO$_2^-$) 0-0.007 mg/l and ammonium (NH$_4^+$) 0-0.5 mg/l. Most of the drinking water samples high in nitrite and ammonium concentrations and exceeding the limit of 0 mg/l (TSE 266, Turkish Drinking Water Standard). However other chemical parameters such as pH, EC, TH, Ca$^{2+}$, Mg$^{2+}$, Na$^+$, K$^+$, HCO$_3^-$, Cl$^-$, SO$_4^{2-}$ and F$^-$ were also measured. The pH and EC values of of the well water samples are changing between 6.8 – 9.9 and 439-1276 respectively. Drinking water well of some villages have low pH value according to the Turkish Drinking Water Standard. Total hardness of the groundwater samples are ranging between 2.5-57.75 according to the FH. The pH and EC values range between “very soft” and “very hard”. Water type of the Gumushacikoy groundwater is Ca-HCO$_3$. Carbonate hardness of the all drinking waters have bigger than %50. To the chemical analyse results, most of the well waters which are using for drinking purposes should not be used when considering to the NO$_3^-$, NH$_4^+$, pH, total hardness. The present state of the quality of the Gumushacikoy alluvial groundwater necessitates taking some technical measurements in order to preserve and improve water quality.

The concept of convergence in surface roughness and its relationship to rock and mineral surface reactivity

CORNELIUS FISCHER AND ANDREAS LÜTTEGE
Department of Earth Science, 6100 Main Street, Rice University, Houston, TX 77005, U.S.A
(cornelius@rice.edu)

In material science, the evolution of surface topography by processes such as abrasion has been traditionally quantified by roughness parameters. These parameters characterize quantitatively analyzed surfaces by a statistical treatment of \{x, y, z\} data. With this approach, we are able to quantify the evolution of surface deviations on a regular relief. However, complications arise because most natural rock surfaces show a multitude of wavelengths in terms of surface relief. To detect and quantify the alteration of rock surface topography, a statistical treatment of surface data must accommodate the occurrence of surface “building blocks” of different length. This is important because various surface building blocks typically show different reaction velocities during dissolution or precipitation.

Our approach makes use of so-called convergent surface roughness parameters, in which surface roughness parameters are calculated for differently-sized “footprints” from vertical scanning interferometry (VSI) data. We show several applications demonstrating the importance of convergent surface roughness parameters. In a study of oxidative weathering of organic matter (OM) in black shales, we can demonstrate that root mean square roughness ($R_q$) is tied to the distribution of OM components having a high reactivity for oxidative weathering. In a second study, convergent $R_q$ data measured at iron oxide incrustations of oxidative-weathered uranium-bearing shale correlate linearly but inversely with the uranium (U) concentration of the incrustation. These surface data show a relationship between the occurrence of macropores (d ~ 500 nm) and the U content of the weathering product. As a third example, we demonstrate the application of surface roughness data to determine corrosion rates of volcanic glass surfaces. All examples underscore the importance of statistical surface parameters in the identification and characterization of the surface components that dominate reactivity.

Magnetite in bacteria: A FMR study

H. FISCHER¹, R.J. WARTHMANN² AND A.U. GEHRING¹

¹Institute of Geophysics, ETH Zurich, 8093 Zurich, Switzerland (hakon.fischer@mag.ig.erdw.ethz.ch; gehring@sl.ethz.ch)
²Geological Institute, ETH Zurich, 8092 Zurich, Switzerland (rolf.warthmann@erdw.ethz.ch)

Under controlled conditions, most of the known magnetotactic bacteria (MTB) precipitate intercellular magnetite crystals within membrane-bound organelles (magnetosomes). The magnetite crystals have an array of physical properties such as size and shape that fall within a narrow distribution. The magnetic properties of cultivated and wild magnetotactic bacteria have been studied in detail by classical rock magnetic methods. Recently ferromagnetic resonance (FMR) spectroscopy has been introduced as an additional tool to assess size and shape distribution in order to identify MTB. We used a pure culture of *Magnetospirillum gryphiswaldense* to analyse FMR effects of magnetite in MTB between 293 and 77K.

Under the TEM the MTB revealed chains of near-equidimensional magnetite crystals of about 50 nm in size which is characteristic for single-domain nanoparticles. For the FMR measurements the MTB were freeze-dried and fixed with paraffin in a glass tube.

At 293 K, the FMR measurement (ν = 9.5 GHz) revealed an asymmetric spectrum with a line width of 187 mT and a g-value of 1.885 (Figure 1). Considering the magnetite in the MTB as a “chain of spheres” the absorption spectrum is dominated by shape anisotropy. No angular dependence of the spectrum was found, which indicates a random distribution of the magnetite chains in the sample. At 77K a different FMR signal with a line width of 198 mT and g = 2.24 was observed. This temperature is below the Verwey transition (Tv = 120 K) where magnetite undergoes a crystallographic transition from cubic to monoclinic symmetry. Based on literature data, it can be postulated that the FMR spectrum at 77K is dominated by magnetocrystalline anisotropy. Considering the spectral development with temperature, the change from a shape-dominated to a magnetocrystalline-dominated anisotropy in the MTB at T < 110 K can be postulated (Figure 1).

**Figure 1:** FMR spectra at 293, 133, 103, and 77K.

The spectral behavior of magnetite nanoparticles in chains at low temperature can be a diagnostic tool to detect magnetotactic bacteria in sediments and soils or magnetite arrays in geological environments indicative of bacterial origin.

Extreme oligotrophy in subsurface sediments of the South Pacific Gyre: Evidence from low oxygen fluxes

J. P. FISCHER¹, T. FERDELMAN¹, S. D’HONDT², F. WENZHÖFER¹ AND KNOX-02RR SHIPBOARD SCIENTIFIC PARTY

¹Max Planck Institute for Marine Microbiology, Bremen (jfischer@mpi-bremen.de)
²Graduate School of Oceanography University of Rhode Island (dhondt@gso.uri.edu)

To study subsurface microbial life at its energy limits, we investigated benthic microbial oxygen consumption as a key parameter for organic matter oxidation during an IODP site survey to the South Pacific Gyre in December 2006. The scientific goal of the expedition with the R/V Roger Revelle was to understand the nature of subseafloor sedimentary life in the most ultra-oligotrophic oceanic region on Earth. Here, primary production, particle fluxes and sedimentation are extraordinarily low. We investigated benthic microbial respiration rates by measuring oxygen concentrations in sediments on different spatial scales ex situ (in piston, gravity and multi-cores), and in situ (using a benthic lander equipped with an incubation chamber, a microelectrode profiler, and an optode profiler). Along a transect from 24° to 46°S and 165° to 117° W, cores at 10 of 11 sites were oxygenated for their entire lengths (as much as 8m below seafloor), at concentrations >150µM O₂. This represents the deepest oxygen penetration ever measured in marine sediments. All profiles showed a similar pattern of a rapid decrease in oxygen concentrations from ~220 µM to ~170µM within the first 50cm, which can be explained by oxidation of sedimented organic matter. In the deeper zones, only a very small gradient of ~6µM m-1 was present, indicating extremely low oxygen fluxes and consequently low respiration rates.

We conclude, that the South Pacific Gyre represents the most oxidized and energy-limited marine benthic habitat on earth, with respiration rates at least 3 orders of magnitude lower than previously analyzed marine sediments.
The kinetics of biologically-mediated mineral oxide reduction and biomineralization using time-resolved X-ray diffraction

T.B. FISCHER1, P.J. HEANEY1, S.L. BRANTLEY1 AND M. TIEN2

1Center for Environmental Kinetics Analysis, Department of Geosciences, Pennsylvania State University, University Park, PA (tfischer@geosc.psu.edu, heaney@geosc.psu.edu, brantley@essc.psu.edu)
2Center for Environmental Kinetics Analysis, Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA (mxt3@psu.edu)

The ways in which microorganisms catalyze or inhibit the breakdown and formation of minerals have broad implications for stable isotope geochemistry, acid mine drainage, climate change investigations, the search for life on other planets, and the evolution of life on this planet. We are investigating the kinetics of microbial-mineral interactions using X-ray diffraction (XRD), an old technique applied in a new way.

With the advent of the high-resolution imaging plate, we can take XRD scans in rapid succession (one every 2-10 minutes) and analyze changes in mineral phases as time progresses. This “time-resolved” XRD technique, combined with Rietveld analysis of the diffraction data, has allowed us to decipher discrete changes in unit cell parameters, phase abundances, and atomic displacements.

Total membrane (TM) fractions of the facultative anaerobe Shewanella oneidensis MR-1 can catalyze reduction of solid-phase metal cations (Ruebush et al., 2006). In our experiments, these TM fractions were placed in a silica glass capillary with the manganese oxide birnessite, HEPES buffer (pH=7.0) and Na-formate, which serves as an electron donor. Using a Rigaku II D/Max X-ray microdiffractometer with a Mo-source, we succeeded in monitoring changes in mineralogy within the reaction cell. Our experiments revealed that the reduction of Mn began within minutes and continued until the birnessite had reacted completely. A secondary phase, rhodochrosite (MnCO3), appeared upon the bioreduction of the birnessite.

We conducted the experiment at TM concentrations of 1.4 mg/ml and 3.5 mg/ml, Na-formate concentrations of 1M and 2M and total birnessite weights of .3 and .6 mg. The rate of reduction and re-mineralization was fastest with low TM and high formate concentration, and slowest with high TM and low formate concentration.

Rhodium, gold and other highly siderophile elements in chondrites

M. FISCHER-GÖDDE, F. WOMBACHER AND H. BECKER
Institut für Geologische Wissenschaften, FR Geochemie, Freie Universität Berlin, Malteserst. 74-100, Haus B, D-12249 Berlin, Germany, (mafische@zedat.fu-berlin.de)

Osmium isotopic data and concentrations of the highly siderophile elements (HSE) Re, Os, Ir, Ru, Pt and Pd, recently obtained on chondrites by isotope dilution and Carius tube digestion in reverse aqua regia indicate systematic differences in the HSE composition of chondrite groups, notably in Re/Os and Pd/Ir. Unfortunately, these studies did not provide data for two other HSE, Rh and Au, because both elements are monoisotopic. Yet, Rh and Au may be critical elements for (1) a comprehensive understanding of the different HSE patterns of the chondrite groups and their origin; (2) distinguishing likely lunar impactor populations during the late heavy bombardment; and (3) for a complete characterization of the HSE pattern of the Earth’s primitive mantle and its origin.

Here, we report abundances of Re, Ir, Ru, Pt, Pd, Rh and Au for a set of carbonaceous, ordinary, enstatite and R-chondrites. The new Rh and Au data, along with previous high-precision HSE concentration data on whole rocks of chondrites, require the presence of several distinct components in order to explain their CI-normalized patterns. (1) Carbonaceous chondrites show nearly flat HSE patterns from Re to Pt with CI-like or lower Re/Ir. Ordinary and enstatite chondrites show systematic fractionations from Re to Ir (decreasing) and from Ir to Pt (increasing) indicative for a complex high temperature history of ordinary and enstatite chondrites and the presence of at least two refractory components. (2) Most chondrites show a sometimes substantial drop in normalized abundance between Pt and Rh, suggesting the removal of a refractory metal phase from solar gas in a narrow temperature range (near 1400 K), and likely before condensation of the major fraction of Ni and Fe occurred (< 1350 K). (3) Chondrites are characterized by variable enrichment or depletion of Pd and Au, suggesting the variable presence of a component depleted in refractory siderophiles and enriched in moderately volatiles.
Search for an $^{60}$Fe supernova-produced isotopic signal in marine sediments

The recent observation of an $^{60}$Fe peak in a deep-sea FeMn crust has been interpreted as due to the signature left by the ejecta of a supernova (SN) relatively close to the solar system 2.8 ± 0.4 Myr ago [1]. To confirm this interpretation with better time resolution and more direct flux estimate, we have performed Accelerator Mass Spectrometry (AMS) $^{60}$Fe measurements along a dated marine sediment core.

FeMn crusts are authigenic objects. Marine sediments are composed of a larger variety of geochemical phases. Since the iron in the alumino-silicate phase is not equilibrated with the soluble $^{60}$Fe in the ocean, its inclusion would lower the $^{60}$Fe/Fe ratio compared to the authigenic fraction. Therefore, we used a chemical procedure to isolate this fraction [2]. The AMS measurements were carried out at the facility of Garching. In order to verify that our chemistry was dissolving the phase containing the $^{60}$Fe seen in the crust, we tested it on samples from the same crust. We also observed an $^{60}$Fe/Fe peak, consistent with that found by [1].

The $^{60}$Fe signal in the FeMn crust was observed over a depth interval corresponding to 800,000 years [1]. However, we initially assumed that this was due to the inherent time resolution associated with the growth and sampling of the FeMn crust. Assuming a short deposition time e.g. 10,000 years [3], and considering the characteristics of the marine sediment core, we can calculate a $^{60}$Fe/Fe ratio in the authigenic phase of the sediment of 5x10$^{-14}$.

We performed $^{60}$Fe/Fe measurements along the sediment core from 1.7 to 3.2 Myr. The extension of the original time interval (2.4-3.2 Myr [1]) is from taking into account (i) that $^{10}$Be dating has been repeated in the crust, (ii) 1/2$^{10}$Be uncertainty.

We found no evidence for an $^{60}$Fe/Fe peak in the sediment in the time interval 1.7-3.2 Myr, with upper limits at least an order of magnitude lower than the value expected under the above assumptions. We will discuss possible reasons for this result, including the possibility that the deposition time was indeed >>10 kyr.

The groundwater beneath Hekla volcano, Iceland; A natural analogue for CO$_2$ sequestration

T.K. Flaathen and S.R. Gislason

1Nordic Volcanological center, Institute of Earth Science, University of Iceland (therese@hi.is)
2Institute of Earth Science, University of Iceland (sigrg@raunvis.hi.is)

The increased concentration of CO$_2$ in the atmosphere has made it necessary to develop methods to store CO$_2$. One of the possibilities for CO$_2$ storage is by reacting it with basalt and thereby precipitating the CO$_2$ as calcite (CaCO$_3$). A pilot project is being performed in Iceland by Reykjavik Energy, University of Iceland, Columbia University and University of Tolouse.

The Hekla volcano is one of Europe’s most active volcanoes (e.g. Flaathen and Gislason, 2007) and its magma chamber degasses even under quiet periods where the main emitted gases are CO$_2$, HF and SO$_2$. These are some of the same gases emitted from geothermal power plants and aluminum smelters in Iceland. This make Hekla volcano a very good natural analogue to CO$_2$ sequestration in basalt.

The lava fields surrounding the volcano host a large ground water body. Water samples from its springs have been collected periodically for 20 years. Analysis and modelling of this water can tell us what may happen when CO$_2$ is being injected into basalt.

The gases emitted from the magma chamber make the ground water acidic. The acidity enhances the dissolution rate of the basalt releasing elements like Ca into the ground water. These reactions consume protons and the increase in concentration of elements in the ground water together with increase in pH leads to the precipitation of secondary minerals like calcite.

Modelling performed by the PHREEQC 2.11 computer code (Parkhurst and Appelo, 1999) shows that calcite goes from being undersaturated to almost saturated with increase in pH.

At the early state of dissolution of the basalt, at low pH, the concentration of toxic metals like Cr and Pb in the ground water might be high. The pH of the groundwaters in the vicinity of Mt. Hekla range from about 7 to 9. The concentration of toxic metals is very low in these waters (nmole/kg) which is also the case for Fe. Modelling shows that Fe-hydroxides are supersaturated in the groundwaters and the precipitation of this phase might scavenge the toxic metals.

Investigation of weathering rinds on Earth and Mars by depth selective Mössbauer spectroscopy

I. Fleischer1, G. Klingelhöfer1, D. Rodionov1,2, and C. Schröder1

1Institut für Anorganische und Analytische Chemie, Universität Mainz (fleischi@uni-mainz.de)
2Space Research Institute IKI, Moscow, Russia

The two Mars Exploration Rovers, “Spirit” and “Opportunity”, each carry a miniaturised Mössbauer spectrometer (MIMOS II) [1]. MIMOS II operates in backscattering geometry and can obtain 14.4 keV gamma ray spectra and 6.4 keV X-ray spectra simultaneously. Comparing 14.4 keV and 6.4 keV spectra yields depth selective information about a sample: 14.4 keV gamma rays have a larger escape depth from a sample than 6.4 keV X-rays because of their higher energy. As a consequence, a 6.4 keV spectrum contains more information about the near-surface part of a sample than a 14.4 keV spectrum. This allows for the detection and characterization of coatings such as weathering rinds without abrading the surface of the sample.

At the landing site of the Spirit rover in Gusev crater, a dark coating was detected on the rock “Mazatzal” [2]. 14.4 keV and 6.4 keV spectra obtained on the brushed surface of Mazatzal show significant differences in the relative intensity of “nanophase oxide”, a “poorly crystalline product of oxidative weathering that contains nanometer-sized particles of Fe3+-bearing material” [3].

To investigate the depth selectivity in Mössbauer spectra experimentally, measurements were done on samples composed of thin sections of one mineral or iron foil, respectively, on another mineral. The influence of coatings of varying thickness and composition on Mössbauer spectra can be studied in a simulation. A Monte Carlo simulation compiled for this work allows the modelling of a sample composed of two homogeneous layers, each containing up to ten different minerals. The thickness of a coating can be determined by comparing measured and the according simulated spectra. In the case of Mazatzal, modelling the coating with a thickness of 10 micrometers leads to best agreement between measured and simulated spectra. [4]

Integrated air quality assessment – Pine needle δ13C, δ15N as proxy for atmospheric CO2 and NOx loads

U. Flenker1, F. Huelsemann1, E. Lehndorf2, and L. Schwark2

1German Sport University Cologne, Carl-Diem-Weg 6, 50933 Cologne, 2Department for Geology and Mineralogy, University of Cologne, Germany; (uli@biochem.dshs-koeln.de; lorenz.schwark@uni-koeln.de)

In a multidisciplinary approach atmospheric quality in the Greater Cologne Area (GCA) was studied using pine needles as pollutant bioreceptors. Here we discuss the potential of the δ13C and δ15N isotopic composition of pine needle biomass to record the atmospheric loading with CO2 and NOx released from anthropogenic combustion processes. The gaseous pollutant load estimated by isotope proxies is compared and interpreted in concert with persistent organic pollutant as well as major and trace element concentration data.

The GCA comprises a variety of CO2 and NOx emission sources, including lignite fueled power plants, regions of high traffic density, domestic heating, intensive agriculture and large industrial complexes along the Rhine Valley. A substantial part of atmospheric CO2 in large conurbations will derive from fossil fuel combustion. Two reaction modes for increased CO2 in atmosphere are known. A fertilizing effect by which the addition of isotopically light CO2 will lead to a decline in foliage δ13C values. Conversely, high concentration of CO2 will cause stress and trigger closure of stomata, resulting in heavier foliage isotopes. For 5 needle age classes taken separately in summer and winter a systematic trend to δ13C values heavier by about 2.5 permil with age was noted, attributed to declining photosynthetic activity. Differences between locations were larger than within location. Although influenced by a variety of environmental conditions the significantly lighter δ13C of pine needles in urban Cologne reflects traffic emissions. The area affected by lignite combustion revealed no deviation in foliage δ13C due to more intensive air mixing in these regions.

The δ15N values of vegetation have been shown react to NOx in surrounding air via direct stomatal uptake or via precipitation and root uptake. Hereby pollution stress induces heavier δ15N values. Most often foliage and soil δ15N are decoupled emphasizing the importance of atmospheric NOx uptake and remineralization for foliage N-isotopes.

Investigation of 5 needle cohorts shows a systematic trends towards slightly lighter δ15N values with age. Intra-site variability was low but inter-site variation high, allowing for excellent spatial discrimination. The δ15N of pine needles showed a trend to heavier values in farming and forested areas but lighter values in urbanized regions and in areas affected by lignite mining. A trend inversion occurred in inner city areas, where changes from high to low δ15N were noted. Heavier N-isotopes of foliage caused by NOx-stress are in compliance with previous observation but seem to be restricted to areas most affected by traffic emissions.
The weathering engine conveyor belt and corestone size distributions

R. Fletcher 1*, E. Hausrath 2, A. Navarre-Sitchler 2, B. Peightal 2 and S. Brantley 1

1Earth and Environmental Systems Institute, The Pennsylvania State University; (rfletcher@geosc.psu.edu)
2Department of Geosciences, The Pennsylvania State University

In weathering profiles developed at Gettysburg (Pennsylvania, U.S.A.), unweathered diabase bedrock fractures and chemically alters by spheroidal weathering to produce a population of corestones surrounded by rindlets overlain by saprolite. It appears that once corestones reach a limiting size they no longer form new rindlets but weather strictly by a diffusion-limited infiltration mechanism.

We model the gross features of the chemistry and mechanics of rindlet formation and the production of weatherable surface area for a steady erosion rate. The model yields a steady state profile of corestone volume fraction, fC, decreasing upwards to the erosional surface from a value fC ≈ 1 at a depth, H, where chemical weathering is negligible. Populations of corestones in eroding or eroded concentrations in organic acids. An additional reaction front was confirmed by precipitation experiments.

There is a linear increase in solubility constant log Ksp calculated for the reaction:

\[ \text{Pb}_5(\text{PO}_4)_3\text{Cl} \leftrightarrow 5\text{Pb}^2+ + 3\text{PO}_4^{3-} + \text{Cl}^- \]

with increasing As content in the series, from -79.60±0.02 for Pb5(AsO4)3Cl at 25°C to -76.32±0.25 for Pb5(AsO4)3Cl at 25°C. For all phases the solubility product decreased linearly with the inverse temperature indicating a constant enthalpy of dissolution reaction in the experimental range.

The Ordovician Galiñeiro peralkaline gneiss complex, Vigo, NW Spain

PETER FLOOR1, GUILLERMO CORRETGÉ2 AND PILAR MONTERO3

1van Beuningenlaan 24, 2334 CC Leiden, Netherlands (floor.p@planet.nl)
2Dept of Geology, Univ. Oviedo, 33005 Oviedo, Spain (corretge@geol.uniovi.es)
3Dept of Mineralogy and Petrology, Fac. Sciences, Univ. Granada, 18002 Granada, Spain (pmontero@ugr.es)

The Variscan mountain chain in Brittany (France), NW Spain, Portugal and SW Spain contains numerous orthogneiss complexes of early Paleozoic age, predominantly cropping out in the central zone of the orogen. Most have calcalkaline, alkaline and some peralkaline compositions. The first two are cut by numerous basic dikes.

The Galiñeiro peralkaline complex, situated mainly South of the city of Vigo near the Atlantic coast, is the largest and best investigated of these complexes. Fieldwork and petrographic studies done by the first author in the fifties and sixties of last century were followed in the eighties and nineties by detailed mineralogical and geochemical work by the third and second authors.

The results of both studies are highly complementary and give evidence of rock and mineral behaviour both at the intrusive stage and under Hercynian lowP, intermediate T metamorphic conditions leading to strong recrystallization, including total unmixing of the supposed original hypersolvus feldspar.

The rocks of the complex are enriched in REE and HFSE, present in a wide variety of accessories: bastnäsite, REE silicates (e.g., allanite, thaleneit-yttrialiet), REE niobotantalates (aeschnyite, fergusonite-formannite, samarskite, pyrochlore-betafite), REE phosphates (monazite, xenotime), Th-rich minerals (thorite, P-rich thorite), and zircon.

Magmatic fractionation, most likely from a mantle-derived volatile-rich alkaline basalt parent, led to peralkaline silicic differentiates with residual fluids extremely enriched in fluorine and other ligands, which complexed the REE and HFSE. Decrease in fluorine activity with falling temperature and the crystallization of F-bearing major minerals caused the breakdown of complexes, releasing the rare earths and the remainder of the high-field-strength elements, and formation of HFSE- and REE-rich minerals.

The elevated fluorine, CO₂ and sulfide contents of the Galiñeiro system, together with the energy inputs of the different phases of Hercynian metamorphism, caused episodic remobilisation, reflected by the zircon U–Pb concordant ages at 370 and 310 Ma, and the exotic geochemical features (Zr/Hf remobilisation, reflected by the zircon U–Pb concordant ages)

The functional species of a mineral surface and their interaction with the adjacent water molecules – Determined by nonlinear optics and quantum chemistry

M. FLÖRSHEIMER1,2, K. KRUSE1,2, R. POLLY1,2, A. ABDELMONEM1,3, B. SCHIMMELPFENNIG1,3, R. KLENZE1,2,3 AND TH. FANGHÄNEL2,4

1Institute for Nuclear Waste Disposal, Forschungszentrum Karlsruhe, Helmholtz-Platz 1, D-76344 Eggenstein-Leopoldshafen, Germany (florshg@ine.fzk.de)

3Virtual Institute Functional Properties of Aquatic Interfaces, Helmholtz-Platz 1, D-76344 Eggenstein-Leopoldshafen, Germany
4European Commission, Joint Research Centre, Institute for Transuranium Elements, Helmholtz-Platz 1, D-76344 Eggenstein-Leopoldshafen, Germany

The functional species of the mineral surfaces, which control the mineral/water interaction, are not definitely known for most crystal faces because it is difficult to obtain chemical in situ information with interface selectivity. Here we apply interface selective vibrational sum frequency spectroscopy to the sapphire (001) surface. Additionally we carry out density functional theory and ab initio calculations on aluminium-oxide clusters as models for the sapphire (001) surface. The results of experiment and theory are well in agreement. This work is part of an ongoing fundamental study of the sorption mechanism of actinides on single crystal faces by various experimental and theoretical techniques. Sapphire serves as a simple model for natural clay minerals.

From the ideal termination of the bulk crystal structure, the (001) surface is expected to exhibit a single type of aluminol species with the OH group in a bridge position. We distinguish four OH species which are all doubly coordinated but exhibit different tilt angles of their OH bonds. Depending on the tilt, different geometries arise for hydrogen bonding with water molecules. At high pH the interaction of the mineral surface with the neighboring water molecules is dominated by electrostatic forces. The net dipole moment of these water molecules points into the direction of the mineral surface which is in agreement with the expected negative surface charge. In the pH range between 1.3 and 6 the interaction of the water molecules with the mineral surface is dominated by hydrogen bonds. Two populations of water molecules exist near the interface which are characterized by specific hydrogen bonding to the different aluminol species. Due to these bonds the net dipole moment of one water population points to the mineral surface, the net dipole of the other population points into the opposite direction. Since the relative concentrations of the different aluminol species depend on the pH, the relative concentrations of the two water populations changes also. In summary, a picture at the molecular level with surprising richness of details is obtained.

(U-Th)/He apatite constraints on the erosional history of the southwestern Colorado Plateau and implications for Early Tertiary uplift and carving of a “proto-Grand Canyon”

R.M. Flowers1,2, B.P. Wernicke1 and K.A. Farley 1

1Division of Geological and Planetary Sciences, California Institute of Technology (brian@gps.caltech.edu; farley@gps.caltech.edu)
2Now at: Division of Geological Sciences, University of Colorado, Boulder (flowersr@colorado.edu)

Resolving the timing and relationships between regional unroofing, canyon incision, and topographic uplift in continental plateaus is a challenging problem. The regional unroofing history of the Colorado Plateau, and its relationship to Grand Canyon incision (up to 1.5 km) and plateau uplift (~1.9 km) since the Late Cretaceous, is controversial. We used (U-Th)/He apatite thermochronometry (36 samples, 230 single-grain analyses) across the southwestern quadrant of the Colorado Plateau to address these issues. Our data document overall southwest to northeast unroofing from plateau margin to plateau interior, during denudation phases in the Late Cretaceous/Early Tertiary (80 to 55 Ma), mid Tertiary (28 to 16 Ma), and Late Tertiary (<6 Ma). Distributions of apatite dates modeled using the radiation damage trapping model [1,2] suggest that eastern Grand Canyon samples from the basement and the Kaibab surface nearby had similar Early to Cretaceous/Early Tertiary (80 to 55 Ma), mid Tertiary (28 to 16 Ma), and Late Tertiary (<6 Ma) distributions of apatite. If these models are correct, they indicate that a significant (~1500 m) paleo-Grand Canyon was carved in post-Paleozoic sediments in this region during Early Tertiary time. Evidence for kilometer-scale topographic relief would require substantial uplift during Sevier/Laramide time, preceding regional unroofing of this portion of the plateau interior. Although the data do not preclude additional post-Laramide uplift, the subsequent regional unroofing phases could be explained by drainage reorganization associated with rift-related lowering of adjacent regions without additional elevation gain of the plateau.

A Comparison of the elemental composition of Wild 2 grains with other extraterrestrial materials

GEORGE J. FLYNN
Department of Physics, SUNY-Plattsburgh, 101 Broad St., Plattsburgh, NY 12901 USA

NASA’s Stardust spacecraft passed through the dust coma of Comet 81P/Wild 2 at a speed of ~6 km/s in January 2004, collecting dust particles in low-density silica aerogel and as impact residue in craters in Al-foil. These samples, which were delivered to Earth on January 15, 2006, provided the first opportunity to analyze material from the Kuiper Belt, the presumed source of short-period comets like Wild 2. The elemental compositions of twenty-three particles captured in aerogel and the residue in seven craters in Al-foil were determined during the Stardust Preliminary Examination (Flynn et al., 2006). The results were generally consistent with the more limited elemental composition data obtained on grains from Comet 1P/Halley, an Oort cloud comet, which were analyzed by impact-ionization mass spectrometers on the Giotto and VEGA spacecraft which flew through the Halley coma in 1986.

To first-order, the mean elemental composition of the Wild 2 particles agrees with the composition of the CI carbonaceous meteorites, which are believed to represent the initial composition of the Solar System, for the refractory elements. However the Fe/Si ratio is somewhat lower than CI in the Wild 2 particles. In addition, S is depleted relative to the CI abundance and several moderately-volatile minor elements (Cu, Zn, Ga, and Ge) are enriched in the Wild 2 samples over the CI meteorite abundances.

Both the depletion of Fe and the enrichment of moderately-volatile elements were previously reported in the fine-grained, anhydrous IDPs, some of which have inferred atmospheric entry speeds suggesting a cometary origin (Brownlee et al., 1993). The CI meteorite element abundances are taken to represent the Solar Nebula composition for non-volatile elements because of the good agreement between CI abundances and the composition of the Solar photosphere, measured by spectroscopy. These preliminary results on the Wild 2 material suggest that the outer region of the Solar Nebula, where comets such as Wild 2 are believed to have formed, may have contained higher concentrations of some moderately-volatile elements and lower Fe than the inner region of the Solar Nebula, where the meteorites formed. Alternatively, since the abundances of Cu, Zn, and Ga are not well-determined in the Solar photosphere, it is possible that abundances of these elements in the Wild 2 particles and the anhydrous IDPs may better reflect the composition of the Solar Nebula for these moderately-volatile elements than does the composition of the CI meteorites.

**Modeling silicate-rich fluids at high pressures**

T. FOCKENBERG, M. BURCHARD AND W.V. MARESCH

1Ruhr-Universitaet Bochum, Institut fuer Geologie, Mineralogie und Geophysik, D-44780 Bochum; Germany (thomas.fockenberg@rub.de, walter.maresch@rub.de)

2Mineralogical Institute, Heidelberg University, Im Neuenheimer Feld 236, 69120 Heidelberg, Germany (burchard@min.uni-heidelberg.de)

Comprehension of rock-forming processes at depths corresponding to the lower crust and active subduction zones requires an understanding of silicate-rich fluids coexisting with rock-forming minerals. However, existing models for aqueous silicate solutions are difficult to extrapolate to pressures higher than 0.5 – 1.0 GPa. An alternative approach is to treat H$_2$O in terms of a statistical thermodynamic model involving a dynamic equilibrium between "gas-like" disordered and "liquid-like" clustered molecules (Gerya and Perchuk, 1997; Gerya et al., 2004), where $X$(aq) is the mole fraction of the latter. Gerya et al. (2005) successfully tested this approach for SiO$_2$-H$_2$O solutions to 1300°C and 2 GPa. We extend this model to include the ionization of water, combining available and also new experimental solubility data for quartz (SiO$_2$), corundum (Al$_2$O$_3$), wollastonite (CaSiO$_3$), grossular (Ca$_3$Al$_2$Si$_3$O$_12$), zoisite (Ca$_2$Al$_3$Si$_3$O$_12$(OH)), sanidine (K$_0.9$Na$_{0.1}$AlSi$_3$O$_8$) and albite (NaAlSi$_3$O$_8$) in pure H$_2$O, as well as quartz and corundum solubilities in KOH solutions, to develop a simple thermodynamic description for aqueous fluids in the model system KNCASH. $\Delta G_r$ of dissolution reactions is thus expressed in terms of the standard-state molar thermodynamic parameters $\Delta H^o$, $\Delta S^o$, $\Delta C_{p}(T)$, $\Delta V(T,P)$, the molality of the dissolved species, pH and $X$(aq). The model successfully returns the available experimental data. The formalism requires data on speciation to define the influence of $X$(aq) and pH on the reaction and to determine the number of species and reactions involved. However, a simplified "component" approach for oxides can be developed to approximately model KNCASH fluids from 0.2 to 3 GPa. The incorporation of pH into the model reduces the need for "mixing terms" to describe the interaction of dissolved oxides. Calculations suggest the formation of alumina-silica, alkali-silica, alkali-alumina as well as silica-alumina-alkali species. This information can also be directly derived from a comparison of the different experimentally investigated fluid-solid systems. There is no indication at present for the formation of multi-oxide complexes with Ca.

**Cosmogenic $^3$He exposure dating of the Quaternary lavas at Fogo, Cape Verdes: Dating flank collapse and magmatic reorganisation**

J.P.T. FOEKEN, S. DAY AND F.M. STUART

1Scottish Universities Environmental Research Centre, East Kilbride, UK

2Benfield UCL Hazard Research Center, University College London, UK

3Institute of Geophysics and Planetary Physics, University of California Santa Cruz, USA

Construction and destruction of young ocean island volcanoes is often episodic and governed by periods of intense volcanism and flank collapse. Conventional dating methods are often insufficient to constrain late Quaternary events; rocks may be too young to be dated precisely by $^{40}$Ar/$^{39}$Ar, or lack datable material (e.g. charcoal) for $^{14}$C. Cosmogenic $^3$He exposure dating of basaltic lavas is a powerful alternative, with potential to date flows beyond a few kyr. We present results from a study to date Quaternary lavas of Fogo, Cape Verdes. The growth of Fogo occurred in two main stages, separated by a large flank collapse removing the summit and eastern flank of the pre-collapse Monte Amarelo volcano. The collapse produced a 9 km wide escarpment with a headwall cliff that is still 1 km high despite the infilling with over 1.5 km of post-collapse lava flows from the Cha das Caldeiras volcano. Dyke swarms in the Monte Amarelo volcano indicate that the collapse was preceded by a structural reconfiguration of an initially radial dyke swarm to a single, dominantly north–south swarm across the summit region. This coincided with an eastward shift in magmatic activity. The recent history of the Cha das Caldeiras volcano has seen similar structural reconfiguration of dyke swarms and eastward shift of volcanism resulting in the extinction of post–collapse volcanic rift zones in the west of the island. Dating these events is vital for understanding the timing of (future) volcano flank collapses of Fogo.

Lava flows erupted immediately prior to, and after the collapse bracket its age and exposure ages from two pre-collapse ankaramite flows yield 24 and 110 ka, while post-collapse flows yield 14 to 9 ka. We infer two possible scenarios; (i) the collapse occurred between 14 and 24 ka or, (ii) the young exposure age of the pre-collapse flow is an artefact of ash cover/erosion and collapse occurred closer to 110 ka. This has profound implications for the interpretation of future flank collapses on Fogo. The post-collapse flows are among the youngest flows on the western side and the early Holocene ages imply that the magmatic reconfiguration and possible onset of renewed instability of the eastern flank has been developing for several thousand years. If the collapse occurred between 14 and 24 ka, flank instability may be in its early stages. If the collapse occurred around 110 ka, the duration of the pre-Monte Amarelo collapse reorganization may be comparable to the duration of the present one, with the prospect of a near-future collapse likely.

Trace metal dynamics and transport in a polar glacier-dominated watershed: Taylor Valley, Antarctica

S. K. FORTNER1,2, W. B. LYONS1,2, R. A. WITHEROW1,2, K. A. WELCH1 and J. W. OLESIK2

1Byrd Polar Research Center, 1090 Carmack Road, The Ohio State University, Columbus, OH 43210, USA
2School of Earth Sciences, The Ohio State University, Columbus, OH 43210, USA

Anthropogenically introduced trace metals travel to even the most remote locations on earth including Greenland and Antarctica. Little is known about metal dynamics in the largest ice-free area in Antarctica, the McMurdo Dry Valleys, which includes Taylor Valley (~78°S). Previous work has examined metal concentrations in Taylor Valley glacier melt streams and lakes (Green et al., 1986). In this work, concentrations of metals (V, Pb, Cd, Cu) in Canada Glacier snow is compared to stream and lake concentrations to determine melt evolution and to ultimately make predictions about stream chemistries.

Samples were collected using ultraclean techniques to minimize contamination. The sequence of median trace metal molar abundance in Canada Glacier snow is Cu>V>Pb>Cd. Canada Glacier’s melt streams have different relative abundances than the snow. The western melt stream, Andersen Creek is V>Cu>Cd>Pb. Whereas the eastern melt stream, Canada Stream, is Cu>V>Cd>Pb. Median Na:Cl ratios increase from snow values (0.4) in both Andersen Creek and Canada Stream (0.9), suggesting in-stream chemical weathering and salt dissolution. The western and eastern lakes fed by these streams, Lake Hoare and Lake Fryxell have similar Na+:Cl surface water values as the streams. In general V, Cu, Cd, and Pb to Cl ratios are all highest in Canada Glacier snow and lowest in its streams. The exception is Cu:Cl, which is highest in lake surface water followed by snow and streams. Total Hg:Cl ratios in the Lake Fryxell Basin indicate substantial removal of Hg relative to Cl as the waters evolve from snow to lake with the largest losses occurring from stream to lake (Lyons et al., 1999). There is no net gain of trace metals relative to Cl through weathering as with Na+. Their concentrations relate more to other processes such as adsorption, biotic uptake and/or removal by suspended material, which are connected to discharge, pH, and biomass abundance.

Quaternary records of ocean pH

G.L. FOSTER1, D. SCHMIDT2 AND T. ELLIOTT1

1Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol, BS8 4BH, UK (g.l.foster@bristol.ac.uk)
2Department of Earth Sciences, University of Bristol, Bristol, BS8 4BH, UK

Atmospheric CO₂ (pCO₂) is an important greenhouse gas that regulates the Earth’s climate on geological and shorter timescales. Proxy data for the ocean carbonate system in the past have a crucial role to play in the understanding how CO₂ is partitioned between the ocean and the atmosphere on these timescales. Of particular importance in this regard are the suite of proxies based on the isotopic and trace element composition of foraminifera, and in particular, the isotopic composition of boron (δ¹¹B) which a number of studies have shown faithfully records the pH of seawater in which the foraminifera grew.

There are a number of factors complicating the application of the boron isotope pH proxy, some of which arise from the analytical difficulties involving the precise and accurate measurement of its isotopic composition. We have recently developed an approach, using multicollector inductively coupled plasma mass spectrometry, that overcomes these analytical problems. This technique is both rapid and precise (better than 0.3 ‰) allowing the routine determination of δ¹¹B in a small number of foraminifera. We present here the first application of this technique.

In contrast to previous work we find that the measured isotopic composition by MC-ICPMS for a variety of Holocene species (ranging in δ¹¹B from 16 to 21 ‰) from a range of depth habitats and physiology, is very close to that of the dissolved B(OH)₄ species predicted using an isotopic equilibrium constant of 1.0272 [1] and pre-industrial carbonate system parameters. This result greatly simplifies the use of the proxy. In this contribution we determine Quaternary and Late Neogene changes in pH on various timescales in several localities in the equatorial oceans (Carribean, Eastern Atlantic, Western & Eastern Pacific). Using these data to gain a global perspective, we can distinguish local short term changes in pH from changes relating to the global reorganization of the carbonate system that accompanied glacial-interglacial climate change, and use our pH reconstructions to estimate the magnitude of pCO₂ changes beyond the reach of the ice-cores.

Reference
Extraterrestrial $^3$He is delivered to the earth surface by interplanetary dust particles (IDPs) characterized by a very high $^3$He/$^4$He ratio (2.4x10$^{-8}$), several orders of magnitude higher than ratios measured in terrigeneous matter (e.g. review by Farley, 2001, and Schlosser and Winckler, 2002).

Several recent studies in marine sediments (Marcantonio et al., 2001, Higgins 2001) and polar ice (Brook et al 2000, Winckler and Fischer 2002) have opened up the application of extraterrestrial $^3$He as a constant flux proxy, at least over the last 400 ka, with a mean flux around 8 ± 3 x 10$^{-13}$ ccSTP/cm$^2$/ka. In order to measure the present $^3$He$_{ET}$ flux, we started in 2001 to collect dust in the Paris region every two months, corresponding to an area-time product of 0.03 m$^2$.a.

As expected from such small area-time products, the data are scattered due to the small number of IDPs sampled, preventing the observation of any seasonal variability: the observed total $^3$He flux range from 1 to 200 x 10$^{-13}$ ccSTP/cm$^2$/ka, with a mean value of (32 ± 9) x 10$^{-13}$ ccSTP/cm$^2$/ka. However, $^3$He/$^4$He ratios are often below 10$^{-7}$ and the terrestrial $^3$He component has to be estimated. Our measurements can be considered as binary mixings between an IDP and a terrigeneous end-member with a $^3$He/$^4$He ratio of 1x10$^{-6}$, leading to an estimate of the present $^3$He$_{ET}$ flux of (30 ± 9) x 10$^{-13}$ ccSTP/cm$^2$/ka.

This flux is significantly higher than the mean accepted value of 8 ± 3 x 10$^{-13}$ ccSTP/cm$^2$/ka, which is all the more surprising that we would expect statistical underestimation due to the small area-time products sampled, especially compared to marine sediments where values up to 0.2 are frequent (Farley et al., 1997). Different explanations can be considered: (1) There may be temporal variations which are smoothed in the data are scattered due to the small number of IDPs sampled, preventing the observation of any seasonal variability: the observed total $^3$He flux range from 1 to 200 x 10$^{-13}$ ccSTP/cm$^2$/ka, with a mean value of (32 ± 9) x 10$^{-13}$ ccSTP/cm$^2$/ka. However, $^3$He/$^4$He ratios are often below 10$^{-7}$ and the terrestrial $^3$He component has to be estimated. Our measurements can be considered as binary mixings between an IDP and a terrigeneous end-member with a $^3$He/$^4$He ratio of 1x10$^{-6}$, leading to an estimate of the present $^3$He$_{ET}$ flux of (30 ± 9) x 10$^{-13}$ ccSTP/cm$^2$/ka.

Chemical and isotopic constraints on water/rock interactions at the Lost City hydrothermal field, Mid-Atlantic Ridge

DIONYSIS I. FOUSTOUKOS

Geophysical Laboratory, Carnegie Institution of Washington, DC 20015 (dfoustokus@ciw.edu)

Low temperature vent fluids issuing from the ultramafic-hosted hydrothermal system at Lost City, 30°N Mid-Atlantic Ridge, are enriched in dissolved volatiles (H$_2$, CH$_4$) while attaining elevated pH values, indicative of the serpentinization processes that govern water/rock interactions deep in the oceanic crust. Most importantly, serpentinization described mainly by the exothermic hydrolysis of Fe-bearing olivine has been directly linked to the heat source that drives subseafloor hydrothermal alteration at Lost City. The extent of exothermic heat generation, however, has been shown to be strongly dependent on the availability of fresh peridotite, with theoretical calculations indicating that low fluid/rock mass ratios (<1) are prerequisites for exothermic reactions to be the primary source of heat in this system [1].

Based on the Sr and $^{87}$Sr/$^{86}$Sr composition of vent fluids sampled from Lost City [2], however, estimations of the integrated w/r ratios range between 6 and 8. Furthermore, constraints on the fluid/rock mass ratios together with reported δ$^{18}$O isotopic vent fluid compositions (0.7‰) permit subseafloor reaction temperatures in excess of 250°C to be approximated, following the temperature-dependent oxygen isotope fractionation between serpentine and water. These estimations are in general agreement with previous theoretical studies [1], further supporting, however, extensive conductive heat loss occurring within the upflow zone of the Lost City hydrothermal system. Evidence of such extended conductive cooling stage include the relatively elevated precipitation temperatures (130-220°C) predicted by the negative δ$^{18}$O composition values (~14.2‰) reported for carbonate veins in basement peridotite. In addition, endmember dissolved boron concentrations of the Lost City vent fluids (~30 μmol/kg) [3] are significantly lower than those measured in other MAR hydrothermal systems, while with δ$^{11}$B isotopic composition maintaining values (~30‰) [3] reflective of elevated temperature hydrothermal alteration conditions, an substantial boron uptake into secondary phases along the discharge zone can be suggested; a process consistent with the proposed extensive conductive cooling that appears to greatly affect the chemical evolution of the Lost City hydrothermal vent fluids.

Geochemical anomalies in stream sediments of the upper Sava River drainage basin (Croatia, Slovenia), determined by statistical methods

S. FRANČIŠKOVIĆ-BILINSKI1 AND G. RANTITSCH2

1Institute “Ruđer Bošković”, POB 180, HR-10002 Zagreb, Croatia (francis@irb.hr)
2Department of applied geosciences and geophysics, Montanuniversität Leoben, Peter Tunner Strasse 5, A-8700 Leoben, Austria (gerd.rantitsch@mu-leoben.at)

Introduction

Sava River is a transboundary river of supraregional interest, draining 95,719 km² in Slovenia, Croatia, Bosnia and Herzegovina and Serbia. It is a typical Alpine river, flowing from Julian Alps. It becomes a typically lowland river when entering Croatia. The upper flow of Sava River can be compared with Soča/Isonzo River, which flows from the other side of Julian Alps toward Adriatic Sea.

The aim of the work was to extend the mineralogical and geochemical dataset of stream sediments from Upper Sava River and to study the possible influence of sub-basins of Savinja, Krka and Kupa rivers on main course of Sava River.

Methods

Mineral composition was determined by X-ray diffraction and chemical composition by inductively coupled plasma mass spectroscopy (ICP-MS). Two different procedures to identify anomalous geochemical data were used: the box plot method and the median absolute deviation (MAD).

Results and discussion

Results obtained by the box plot method showed that anomalous concentrations (extreme or outlier) of Zn, Pb, In, Cu, Co, Se, Zr, Cd, As, K, Na, Ti, Ba, B, Mn, Fe are present in sediments of the Celje region, of Cr, Ni, S, In, Cu, Mo, Pb in Moste Dam (pollution traced down to camping Šobec), and of Hg in Litija-Zagorje mining region. The MAD method is more sensitive. It depicts the same polluted areas, but with more anomalous values, which are above threshold values for toxicity. Both statistical methods (box plot and MAD) show two anomalous values for Hg in Sava River near Kranj and Zagorje. The concentrations are much higher than those causing significant toxic effects (>2 ppm). The two locations of Sava River in Croatia show very clean environment with respect to trace elements, although Sava River passed big cities of Zagreb and Sisak. The results clearly indicate self-purification mechanisms of Sava River.

Recommendations and perspectives

Similar future sediment study is recommended on middle and lower Sava drainage basin of interest for Croatia, Bosnia and Herzegovina and Serbia to detect possible pollution centers. In the case of significant pollution, remediation of sediments and watershed management should be applied.

Isotopic and geochemical evidence of gas producing microbial ecosystems in coal seams and gobs in the SW Upper Silesian basin, Czechia

J. FRANCU1, F. BUZEK2, P. HEMZA3 AND E. FRANCU1

1Czech Geological Survey, Brno, Czech Republic, (juraj.francu@geology.cz, efrancu@cgu.cz)
2Czech Geological Survey, Praha, CZ, (buzek@cgu.cz)
3OKD DPB, a.s., Paskov, CZ, (Petr.Hemza@dpb.cz)

Gas habitat

Gas samples were collected from coal seams of Namurian A-C age, gobs and overburden reservoirs in the Late Carboniferous Upper Silesian basin (USB), NE Czech Republic. The δ13C values of methane and (C1/(C1+C2) ratios suggest occurrence two genetic types of gases. (Fig. 1).

Discussion of the results

Thermogenic 13C enriched and wet gas is extracted from the unmined seams in the Ostrava Fm. Dry and isotopically light gas is encountered in the gobs as reported also from Polish mines (Kotarba 2001).

Conclusions

Presence of microbial gas in the USB evidences activity of deep biosphere down to depth of 1000 m. Supply of oxygenated compounds and H2 is the limiting factor of microbial activity (Horsfield et al. 2006). The temperature conditions of are favorable for methanogenesis at dept range up to 2 km (70°C).

Hydrothermal stability of adenine under controlled fugacities of N\textsubscript{2}, CO\textsubscript{2} and H\textsubscript{2}

M. FRANIATTE\textsuperscript{1}, L. RICHARD\textsuperscript{1}, M. ELIE\textsuperscript{1}, C. NGUYEN-TRUNG\textsuperscript{1}, E. PERFETTI\textsuperscript{1} AND D.E. LAROWE\textsuperscript{2}

\textsuperscript{1}G2R, Nancy-Université, BP 239, 54506, Vandoeuvre-lès-Nancy, France (michael.franiatte@g2r.uhp-nancy.fr)

Demonstrating that organic compounds are stable at high temperatures is important in the context of Archean hydrothermal systems as potential sites for the synthesis of the first organic molecules on Earth. Among such molecules, amino acids have been the subject of numerous studies (e.g. Miller and Bada, 1988; Shock, 1990; Andersson and Holm, 2000). In contrast, nucleic acid bases have received much less attention. Consequently, the present experimental study was undertaken to investigate the stability of adenine at 300°C. The experiments were carried out in sealed autoclaves under fugacities of gaseous CO\textsubscript{2}, N\textsubscript{2} and H\textsubscript{2} representative of those encountered in marine hydrothermal systems. The fluid phase was generated from the decomposition of oxalic acid, sodium nitrite and ammonium chloride, and the oxidation of metallic iron. The results of the experiments seem to indicate that the concentration of adenine stops decreasing after ~ 96 hours (Figure 1). This suggests that an equilibrium state may have been established between adenine and the inorganic constituents of the fluid phase, which is corroborated by independent thermodynamic calculations.

\begin{figure}[h]

The importance of constant flux proxies in paleoceanography

M. FRANK

IFM-GEOMAR, Leibniz Institute for Marine Sciences at the University of Kiel, Germany, (mfrank@ifm-geomar.de)

For all paleoceanographic reconstructions from marine archives a precise chronology is the most essential prerequisite for reliable estimates of processes in the past and for compatibility between different records. All paleoceanographic studies, in particular those aiming at the reconstruction of fluxes from pelagic sediments (for example those on paleoproductivity or dust fluxes) face two main additional problems which complicate a reliable application. For some components of interest (such as organic carbon or biogenic opal) only a small and even variable fraction may be preserved between signal formation in surface waters and deposition in the sediments. The second problem which can affect all paleoceanographic reconstructions from marine sediments is sediment redistribution by currents or within nepheloid bottom layers. These processes can alter the true signatures to variable extents thereby completely masking the original signatures. This is of course particularly important in dynamic bottom current regimes but sediment redistribution can also be active at any other location.

In order to overcome and, in the optimal case, quantify and correct for these effects, a number of so-called constant flux proxies have been developed and applied. The most frequently used of those is the U-series nuclide \(^{230}\text{Th}\), which is produced at a constant rate in the water column of the Ocean from homogenously distributed uranium, and which is only advected with water masses to a very limited extent due to its high particle reactivity. Other examples are \(^{3}\text{He}\) derived from interplanetary dust particles (IDPs), which are deposited on the surface of the earth at a nearly constant rate or, less frequently used, cosmogenic \(^{10}\text{Be}\).

I will give an overview of these constant flux proxies and discuss recent new findings on their strengths and weaknesses. As in most cases in paleoceanographic and geochemical research, none of these proxies is perfect but in view of the possibly huge misinterpretations occurring without their use, their application is absolutely crucial for any reliable paleoceanographic reconstruction. This is because effects of sediment redistribution cannot be readily identified from sedimentary parameters, they may occur at unexpected locations, and places with potentially focussed sediments are preferentially chosen as coring sites due to the expectable high time-resolution of the records.
High-grade metamorphic ortho- and paragneisses are exposed in the proximity of the 0.9 Ga Proterozoic Rogaland anorthosite massif, SW-Norway. The study area is located 5-20 km northeast of the intrusive contact with the anorthosite. In this area, migmatitic opx-bearing granitic gneisses are the main rock type present, transsected by metabasites as dykes. Minor migmatitic garnet-sillimanite-cordierite gneisses, quartzites, calc-silicate rocks, marbles, and rare sapphirine granulites occur as folded layers or discontinuous lenses in between large Opx-gneiss bodies. They aimed of the present study was to elucidate the composition of the protoliths of the different rock units, to reconstruct their tectono-metamorphic evolution, and to investigate the influence of a possible contact-thermal overprint related to the emplacement of the Rogaland anorthosite massif.

Regarding their geochemical characteristics, the Opx-gneisses can be classified as granites, granodiorites and diorites. They are peraluminous in composition and mainly show I-type to S-type, post-collisional granite signatures. Protoliths of the metabasites are tholeiitic mid ocean ridge basalts, whereas those of the paragneisses mainly comprise arkosen and greywackes.

All rock units experienced high-grade regional metamorphism with associated ductile deformation and partial melting. The peak-metamorphic assemblage of the Opx-gneisses is garnet-orthopyroxene-plagioclase-quartz, whereas that of the metabasites is orthopyroxene-clinoxyroxene-plagioclase-quartz. Retrograde biotite and amphibole define a strong foliation. For the thermobarometric calculations Opx-gneiss and metabasite samples from 5 km up to 20 km distance to the anorthosite contact were chosen. For all samples similar granulite facies peak-metamorphic conditions of 900 ± 100 °C at 6 ± 1 kbar are calculated, providing evidence against a contact-thermal effect related to the emplacement of the Rogaland anorthosite. Following this, contact-metamorphism induced by the anorthosite emplacement, as evidenced by pigeonite-in and osmullite-in isograds, is restricted to a distance of < 5 km to the contact.

Clearly, pure pyrocatechol is usually colorless in aqueous systems without autoxidation but its color changed completely to a dark cyan as a result of Al complexation. In particular, no visible change to the color of this complex was observed in the experiment conducted at pH 3.5, 7.0 and 9.0. In the UV region of the spectrum, the absorption maximum of pyrocatechol occurred at 212 nm and 275 nm when compared to the metal-ligand spectrum, here the absorption maximum occurred at 278 nm and the absorption intensity increased considerably. In the Vis region of the spectrum, ligand bands from the complex appeared with absorption maxima of 597 nm and 650 nm that conformed to the orange and red light regions. After the addition of auxochromes, a rise of the chromophore system occurred, and it was this effect that determined the shape of the UV-Vis spectrum of the Al-pyrocatechol complex. This compound, shown in its solid state, had a very smooth surface with sharp-edged breakages as presented in the SEM photomicrograph. Primarily, organic substances with o-hydroxy groups showed specific effects on Al chemistry in the environment due to their favorable reaction to Al chelation.

Occurrence of sursassite in the Lienne valley, Stavelot Massif, Belgian Ardennes

A.-M. Fransolet, F. Hatert, H.-J. Bernhardt, TH. Theye and W. V. Maresch

1Laboratoire de Minéralogie et Cristallochimie, Départ. Géologie, Université de Liège, Belgium (amfransolet@ulg.ac.be and fhatert@ulg.ac.be)
2Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität Bochum, Germany (heinz-juergen.bernhardt@rub.de and walter.maresch@rub.de)
3Institut für Mineralogie, Universität Stuttgart, Germany (thomas.theye@mineralogie.uni-stuttgart.de)

In quartz veinlets crosscutting the red-purple metapelites of the Ottré Formation (Salm Group) in the core of the Lienne syncline, sursassite occurs as orange-red needles associated with manganese oxide masses mostly composed of cryptomelane. Detailed petrographic observation coupled with electron microprobe analytical work reveals sursassite in close association with spessartine, manganooi clinochlore (Schreyer et al., 1986), hematite, and fluorapatite.

The chemical composition of sursassite shows the presence of about 2 wt % MgO, and up to 4 wt % CaO, whereas Fe2O3 does not exceed 1 wt %. These substitutions are interpreted in comparison with pumpellyite-(Mg). Heterogeneities have also been detected in the distribution of V and As. From a chemical point of view, these zones rich in V and As correspond to ardennite s.l., previously identified in Bierleux (Pasero et al., 1994).

Sursassite constitutes a new additional phase among the minerals characteristic of the low-grade metamorphism known in the Lienne valley in the western part of the Stavelot Massif, i.e. about 300°C and 1.5kb (Theye et al., 1996). The formation of sursassite, associated with manganooi clinochlore and spessartine, in relationship with quartz veinlets, shows analogous with the formation of carpholite. Due to the presence of about 0.4 Mn³⁺ per formula unit of sursassite, it seems reasonable to consider that sursassite could play the role of carpholite in the more oxidized horizons of the Ottré Formation in the Lienne Valley.

Onset of MORB melting: High-pressure eclogite-facies pegmatites as an example of internal fluid recycling

G. Franz, A. Liebscher, D. Frei and P. Dulski

1Technical University Berlin; (gerhard.franz@tu-berlin.de, axel.liebscher@tu-berlin.de)
2Geological Survey of Denmark and Greenland; (dfrei@geus.dk)
3GeoForschungsZentrum Potsdam; (dulski@gfz-potsdam.de)

Zoisite-bearing high-pressure pegmatites from the Münchberg Massif, Germany, provide an excellent example for the characteristics of the onset of metasatite melting at eclogite-facies conditions. Pegmatites were derived by partial melting of MORB-like eclogite at T ≥ 680°C/2.3 GPa to 750°C/3.1 GPa, which produced small amounts of tonalitic to trondhjemitic melt. The melt concentrated locally in isolated, small melt pockets and crystallized primary zoisite as liquidus phase at P ≥ 2.3 GPa/680°C to 2.1 GPa/750°C. Compositional zoning of pegmatite zoisite records an ensuing multi-stage uplift history with successive, discrete crystallization events at 1.4 ± 0.2 GPa/650 to 700°C and 1.0 ± 0.1 GPa/620 to 650°C. Resorption textures indicate re-heating and thermal perturbation of the whole system prior to each successive crystallization event. Final solidification of zoisite-pegmatites occurred at 0.9 ± 0.1 GPa/620 to 650°C. The data suggest that isolated melt + zoisite crystal mash pockets formed an integral part of the eclogite throughout uplift from melt formation at T ≥ 680°C/2.3 GPa to 750°C/3.1 GPa to final solidification at ~ 0.9 GPa/620 to 630°C; i.e. over 45 to 60 km. The entire pegmatite-forming process was most likely fluid conserving: Any fluid present during high-pressure melt formation was trapped by fully or nearly water-saturated siliceous melts; due to the small melt fractions these melts did not migrate out of the rock but stayed in isolated pockets within the rock unit; finally, any fluid liberated during pegmatite crystallization interacted with neighbouring, dehydrated eclogite-facies assemblages to form amphibolite-facies hydrous minerals.

Based on average compositions of zoisite-pegmatite, as representative for the tonalitic to trondhjemitic high-pressure melt, and host eclogite, we calculated a set of empirical melt/eclogite partition coefficients. $D_{\text{melt/eclogite}}$ values for Ta, Zr, Hf, Tm, Yb, Lu, V, Sc, Cr, Cu, and Ni range from 0.051 to 0.7 and indicate compatibility with respect to eclogite. Rubidium, Ba, Th, K, La, Ce, Sr, Nd, Sm, Eu, Ti, and Tb are moderately incompatible with respect to eclogite and have $D_{\text{melt/eclogite}}$ values between 1.11 and 10.6.

From microbes to mountains: 
Molecular signatures of life and its environment
KATHERINE H. FREEMAN
Department of Geosciences, The Pennsylvania State University, (kate@geosc.psu.edu)

Biomarkers serve as a rich source of information about ancient environments and provide important proxy tools for studies of past climatic change. Interpretations of molecular and isotopic signatures are grounded in studies of the habitat and growth of modern analogs to biologic sources for ancient compounds. Molecular signatures are rarely simple recorders of material or physical properties (like temperature), and can be influenced by variations in lipid and isotopic properties both within and between organisms. This presentation will highlight two examples of molecular proxies and the importance of ecological and physiological influences on their geochemical record.

The first example underscores the role of ecology on the molecular signatures of modern marine Archaea. Recent studies point to crenarchaeota as important agents in ammonium oxidation, consistent with an apparent affinity of these organisms with deeper habitats and upwelling regions. Archaeal lipid signatures in the modern ocean include inputs from both euryoarchaeota and crenarchaeota, and the relative importance of these inputs can vary with nutrients, especially nitrogen. Ancient archaeal lipid signatures will reflect ecological shifts in regions with variable oceanographic conditions, potentially complicating their utility for temperature reconstruction in such settings.

In the second example, we consider how plant lipids record deuterium abundance in waters in their growth habitat. Large isotopic fractionation associated with lipid biosynthesis can be attenuated by evaporative effects which yield leaf waters enriched in D relative to precipitation. Thus the apparent (or net) fraction between plant lipids and environmental waters reflect both physiological and climatic properties. Understanding of such influences empowers better reconstructions of this emerging proxy for paleohydrologic signatures. We apply such insights to a lipid-based method for reconstructing uplift of the Tibetan plateau and explore implications for understanding tectonic and climatic interactions.

Provenance and genesis of the high Ti heavy mineral sand deposits of South Kerala, SW India: Constraints from CCSEM analysis
D. FREI¹, S. BERNSTEIN¹, R.K. MCLIMANS² AND C. KNUDSEN¹

¹GEUS – Geological Survey of Denmark and Greenland,
Copenhagen, Denmark (df@geus.dk)
²E.I. DuPont de Nemours & Co., DuPont Titanium Technologies, Wilmington, Delaware, USA

Computer Controlled Scanning Electron Microscopy (CCSEM) is a new fully automated method for the chemical and physical characterisation of the heavy mineral fraction in sands (Frei et al., 2005). For example, CCSEM allows to determine the chemical variation of individual mineral groups (e.g. garnet or ilmenite) and their modal abundance. In this contribution we demonstrate the capabilities of CCSEM for investigating the grade, genesis and provenance of Ti heavy mineral sand deposits.

The world-class heavy-mineral deposits occurring in beach sands around the town of Chavara in SW India are characterized by abundant ilmenite with elevated TiO₂ contents, often exceeding 60 wt. %. In order to determine the provenance and genesis of these high-TiO₂ ilmenite deposits, we have collected a large number of beach sediment samples from an approximately 800 km long stretch of coastline from northern Kerala state to well within the Tamil Nadu state. An additional set of river sediment samples was also taken, roughly covering the areas drained inland from the beach samples. The heavy-minerals in all samples were analyzed by CCSEM, providing both chemical analyses of individual grains as well as the modal composition of heavy-minerals in the sediment. The results show that the sediments in the Chavara high-Ti ilmenite deposits are distinct by minor elements in ilmenite and garnet chemistry as well as heavy mineral assemblage: ilmenite has high MgO and low MnO contents, garnets have low grossular components and the heavy-mineral assemblage is dominated by sillimanite-kyanite in addition to ilmenite. These features correlate with basement geology in the hinterland, and with the results for sediments from rivers, draining the basement. Based on these observations we conclude that high-Ti ilmenite from Chavara beaches is derived from the granulite-facies metasedimentary rocks exposed in the khondalite belt. Our study demonstrates that rapid mineral analyses in sediments by CCSEM is an efficient and powerful new tool for the characterization of mineral compositions and assemblages in sediments, the identification of their possible source regions and thus ultimately for refined exploration for industrial mineral resources.

Trace element and isotopic characterization of Neoarchean - Paleoproterozoic BIFs (Black Hills, South Dakota, USA) straddling the first rise of atmospheric oxygen between 2.4 and 2.0 Ga

R. FREI1,2 AND P.S. DAHL3

1Institute of Geography and Geology, University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen, Denmark (robertf@geol.ku.dk)
2Nordic Center for Earth Evolution, NordCEE, Denmark
3Department of Geology, Kent State University, Kent, OH 44242, USA (pdahl@kent.edu)

Banded iron formations (BIF) were deposited in the Black Hills, South Dakota, both prior to and after the first main oxygenation of the atmosphere at ~2.4-2.3 Ga. Paleoproterozoic oxide BIFs deposited before this event still indicate prevalence of reducing conditions in the depositional basins, consistent with the occurrence of stratigraphically associated uranium- and pyrite-rich conglomerates. In contrast, mixed silicate-carbonate-oxide BIFs were formed long after this 2.4-2.3 Ga event, with deposition straddling the end of the ~2.3-2.0 Ga positive δ13C anomaly. The older, oxide-facies and detritus-free BIFs were deposited during rifting at ~2.56-2.48 Ga, associated with initial break-up of the Kenorland supercontinent. These BIFs exhibit REE characteristics typical of ambient seawater signatures (positive La, Eu, Y, and negative Ce anomalies in PAAS-normalized REE diagrams); Sm-Nd model ages of 3.78-2.56 Ga; a high-µ(238U/204Pb) tenor, typical of the Wyoming craton; and low 208Pb/204Pb relative to 206Pb/204Pb ratios, implying pronounced fractionation of U relative to Th during source rock weathering processes and (or) during deposition. Deposition of the younger, silicate-carbonate-oxide BIFs appears to have occurred in a rifted continental margin that developed as a consequence of final break-up of Kenorland beginning at ~2.1 Ga, during discrete episodes of rifting precisely dated at 2.02-1.98 and 1.89-1.88 Ga. These horizons of younger BIF both reveal significant detrital input. They also exhibit Sm-Nd model ages of 3.83-2.51 Ga, comparable to the older BIFs. However, the younger BIFs differ by their less-fractionated PAAS-normalized REE patterns, lack of La anomalies, only weakly positive Eu anomalies, and positive Ce anomalies. Positive Ce anomalies may reflect more oxidative scavenging of Ce(IV) onto Fe-oxyhydroxides, generally pointing to a more oxidized seawater environment during their deposition.

Earth’s oldest BIFs (Isua, W Greenland) – Constraints from Ge/Si ratios, REE systematics and Sm-Nd and Pb isotopes for different interacting water masses during their formation

R. FREI1,2 AND A. POLAT3

1Institute of Geography and Geology, University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen, Denmark (robertf@geol.ku.dk)
2Nordic Center for Earth Evolution, NordCEE, Denmark
3Department of Earth Sciences, University of Windsor, Windsor, ON, Canada N9B 3P4 (polat@uwindsor.ca)

We report trace element, Sm-Nd and Pb isotopic data for individual micro- and mesobands of the Earth’s oldest Banded Iron Formation (BIF) from the ~3.7-3.8 Ga Isua Greenstone Belt (IGB, West Greenland) in an attempt to contribute to the characterization of the depositional environment and to the understanding of depositional mechanisms of these earliest chemical sediments. REE-Y patterns of the individual mesobands show features of modern seawater with diagnostic Ce/Ce*, Pr/Pr* and Y/Ho anomalies. Uranogenic Pb isotope data define a correlation line with a slope of 3691 ± 41 Ma, indicating that the U-Pb system remained closed after the formation of this BIF. High 207Pb/204Pb relative to 206Pb/204Pb ratios compared to average mantle growth evolution models are a feature shared by BIF, penecontemporaneous basalts and clastic volcanogenic metasediments and are indicative of the ultimate high-µ(238U/204Pb) character of the source region, an essentially mafic Hadean protocrust. Sm-Nd isotopic relations on a layer-by-layer basis point to two REE sources controlling the arc basin depositional environment of the BIF, one being seafloor-ventilated hydrothermal fluids (εNd (3.7 Ga) ~+3.1), the other being ambient surface seawater which reached its composition by erosion of parts of the protocrustal landmass (εNd(3.7 Ga) ~+1.6). Systematic trends in Ge/Si ratios support the above theory and suggest that significant amounts of silica were derived from unexposed and/or destroyed mafic Hadean landmass, unlike iron which probably originated from oceanic crust following hydrothermal alteration by deep percolating seawater.
Long-term turnover of plant derived sugars in soils below natural forest and plantation in Ethiopia

K. P. FREIER¹, B. GLASER¹ AND W. ZECH²

¹Soil Physics Group, University of Bayreuth, Germany
(Korbinian.Freier@stmail.uni-bayreuth.de)
(bruno.glaser@uni-bayreuth.de)
²Institute of Soil Science and Soil Geography, University of Bayreuth, Germany (w.zech@uni-bayreuth.de)

Background
Carbohydrates are an important pool in the terrestrial carbon cycle. In order to predict future concentrations of CO₂ in the atmosphere, it is crucial to quantify mean residence times (MRT) of carbon species in soils. Furthermore, it is important to investigate which types of land use are suitable for long-term carbon-storage in soils.

Materials and Methods
In our study, we investigated the MRT of plant derived sugars in tropical soils by compound specific isotope analysis (CSIA). Samples were collected in a natural forest dominated by *Podocarpus falcatus* and in an adjacent 40 year old *Eucalyptus saligna* plantation in southern Ethiopia. Contents of Xylose and Arabinose were analyzed via GC-C-IRMS simultaneously with δ¹³C values to one meter depth. [1] The ¹⁴C age of Black Carbon was used for the calculation of MRT in a model, implying advection, diffusion and decay. [2] Calibration of the model was conducted by using a shift in δ¹³C values as a consequence of a change from C₄ to C₃ vegetation in the study area about 600 years ago.

Results and Discussion
MRT of Xylose and Arabinose were the same in the natural forest and the plantation. MRT was exponentially dependent on depth. 70 percent of the sugars had MRT of less than 20 years. Only 1.3 to 2.0 percent of the Xylose and 5.0 to 5.7 percent of Arabinose reached MRT of more than 1500 years. Nonetheless, the *Eucalyptus* plantation contained 33 to 44 percent less sugars down to one meter depth (p<0.01).

Conclusion
The fewer amounts of sugars below *Eucalyptus* should be due to accelerated mineralisation while clear-cutting of the natural forest and reduced litter input after the conversion. Because MRT do not differ between the natural forest and the plantation, the land use with the highest carbon input in the soil should be preferred for carbon-sequestration.

New method (HR-SF-ICP-MS) to measure biosilica production and dissolution in ocean surface waters

FRANÇOIS FRIPIAT¹, RUDOLPH CORVAISIER², JACQUES NAVÉZ², MARC ELSKENS³, LUC ANDRÉ¹ AND DAMIEN CARDINAL³

¹Geology and Mineralogy, section of Mineralogy and Petrography, Royal Museum for Central Africa, Tervuren, Belgium (ffripiat@afriacmuseum.be)
²Sciences de l’Environnement Marin, Institute Universitaire Européen de la Mer, Brest, France (rudolph.corvaisier@univ-brest.fr)
³Analytical and Environmental Chemistry, Vrije Universiteit Brussel, Brussels, Belgium (melskens@vub.ac.be)

A new method is described for a accurate and simultaneous determinations of the rate of production and dissolution of biosilica in marine surface waters, using isotopic dilution technique. This technique consists to label diatoms sampled from the euphotic layer with ⁴⁰Si spike in the form of Si(OH)₄. The samples are then incubated under *in situ* conditions during a given time (usually 24h). The isotopic dilution of the enriched seawater is used to estimate the dissolution of biosilica and the change in the isotopic composition of silica itself is used to estimate its production.

Such sampling method and the calculation model associated are described in Corvaisier et al. [2005][1].

In this study we propose to measure the silicon isotopic abundances by a HR-SF-ICP-MS (Element 2) in wet plasma mode instead of TIMS (Finnigan THQ) [1].

In this purpose we apply first an alkaline digestion on biosilica or a preconcentration/subsequent-dissolution using the adapted MAGIC method for the dissolved silicon.

The sample is introduced through a glass concentric nebulizer (100µl/min) and a glass jacketed trace cyclonic spray chamber. Instrumental mass bias is measured with the standard-sample bracketing technique using standards with the same matrix as the sample to avoid the matrix effects. We correct the blank contribution by subtraction of the average of two blanks bracketing the sample. A complete analyse (including standards and blanks) is performed in only 20 minutes. The repeatability and the internal precision on the silicon isotopic abundances of a 100ppb Si solution of a diluted alkaline digestion and diluted preconcentration are better than 1%, similar to the TIMS [1].

This new method is much faster and easier than when using TIMS [1]. Moreover because HR-SF-ICP-MS are now widespread instruments it will help to expand biosilica production-dissolution data which are currently very scarce (up to 2003, only 56 published profiles). In fine a better constrain of the silicon budget (production vs. dissolution) in the surface ocean will be gained.

Hydroxyl contents of deep mantle minerals coexisting with CH4-rich fluids: Implications for the focusing of fluids in the upper mantle by redox processes

D.J. FROST

Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (Dan.Frost@uni-bayreuth.de)

The high solubility of hydroxyl in nominally anhydrous minerals such as olivine and wadsleyite at high pressures has been used to argue that they may be important hosts for H2O in the mantle. However, volatiles in the Earth's interior are more accurately described in the system C-O-H where the activity of H2O is a function of the oxygen fugacity. The oxygen fugacities in the lower regions of the upper mantle and in the transition zone and lower mantle are likely to be quite low and at least 4 log units below the FMQ oxygen buffer. Calculations show that at these conditions a C-O-H fluid will be CH4-rich. The lower activity of H2O in the fluid should lower the equilibrium OH- content of coexisting nominally anhydrous minerals such as wadsleyite. Experiments have been performed to study the properties of such reduced fluid phases and examine if they influence the OH- contents of nominally anhydrous mantle minerals at high pressure.

The experiments used a standard double capsule technique with an outer capsule containing a redox buffer (Mo-MoO2 or Co-CoO) plus H2O and an inner Pt capsule containing San Carlos olivine or garnet compositions in a graphite liner. Samples were equilibrated between 10 and 15 GPa in a 5000 tonne multianvil press. Results show that at plausible mantle oxygen fugacities minerals such as wadsleyite have H2O contents over ten times lower than those reported at H2O saturation. CH4-rich fluids do not show evidence of having a significant dissolved silicate component. These reduced, low-density fluids should have a tendency to rise out of the deeper mantle and be oxidised to H2O and CO2 in the shallow upper mantle. This mechanism may tend to concentrate C-O-H volatiles in the upper mantle, leaving the deeper mantle dryer and with a higher viscosity.

Building Lost City: Serpentinization, mass transfer and life in a peridotite-hosted hydrothermal system

1ETH Zurich, Dept of Earth Sciences, CH-8092 Zurich Switzerland (frueh-green@erdw.ethz.ch)
2University of Washington and NOAA/PMEL, Seattle, WA, 98115, USA (david.a.butterfield@noaa.gov)
3School of Oceanography, University of Washington, Seattle, WA 98195, USA (dskelley@u.washington.edu)
4Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (giora@whoi.edu)

The Lost City Hydrothermal Field (LCHF; Atlantis Massif, Mid-Atlantic Ridge, 30°N) is the product of reactions between seawater and ultramafic rocks that produce high alkaline (pH 10 to 11), 40 to 90°C fluids that form up to 60m tall carbonate-brucite towers. The fluids are enriched in H2, CH4 and other hydrocarbons, produced abiotically through Fischer-Tropsch type reactions, and support dense microbial communities that include anaerobic CH4- and S-cycling thermophiles. We present an overview of multidisciplinary investigations of the LCHF and highlight the complex interplay between deformation, fluid flow, mass transfer and microbial activity that occur within this long-lived, peridotite-hosted hydrothermal system and the chemical and biological impacts of such off-axis systems on the global ridge system.

Textures and bulk rock chemistries of the harzburgitic serpentinites reflect formation and uplift of a heterogeneous lithosphere in a magma-starved spreading environment, with progressive serpentinization, talc- amphibole metasomatism and veining. Seawater-peridotite interaction at 150-250°C and high fluid-rock ratios (>100 and up to 106) produced enrichments in B, U and light REE, systematic changes in Sr- and Nd-isotope ratios toward seawater values, and highly depleted bulk rock O-, H-, and B-isotopic compositions in the basement. B-isotope analyses of the fluids and hydrothermal precipitates indicate that brucite is a significant, temporally variable, reservoir for Mg and B in these systems.

High fluid fluxes have important implications for S- and C-cycles: sulfur geochemistry indicates a loss of primary sulfide, an uptake of seawater sulfate, and local microbial remediated sulfate reduction and sulfate oxidation in the basement. Our studies show that the total carbon stored in the serpentinites is dominated by hydrocarbons and suggest that serpentinites may represent an important, as yet unidentified, reservoir for dissolved organic carbon from seawater. We conclude that high seawater fluxes and the interaction with both variably fresh peridotites and pervasively serpentinized peridotites is crucial to the formation of volatile-rich Lost City-type systems and that transform-related normal faulting and mass wasting in the south of the massif facilitates seawater penetration necessary to sustain hydrothermal activity over tens of thousands of years.
Prevention of asbestos floating from outdated construction materials

HIROKAZU FUJIMAKI1, KAZUHIRO SASAKI2 AND SHUNICHI HAMA3

1Graduate School of Science, Tohoku University, Sendai, Japan (h-fujimaki@mail.tains.tohoku.ac.jp)
2Research Institute of Asbestos, Asbestos Safe Network, Sendai, Japan (sasaki@asbestos-safe.net)
3Research Institute of Eco 24 Co. Ltd, Tokyo, Japan (hama@eco24.jp)

Approaching Crisis

Human beings have used a huge amount of asbestos since the stone age because of its good spinnability in the beginning and then because of good physico-chemical properties in industrialized nations. Asbestos is frequently used in construction materials, and they should start to fly as extremely fine fibers many years after they are used and when the construction materials are worn out. The fiber is believed to cause especially malignant mesothelima and other related diseases.

How to Cope with the Problem

Special reagent (Patent pending) has been invented to prevent asbestos floatation into the air. The reagent has high affinity with all kinds of asbestos and envelopes them when it is sprayed on the asbestos-containing materials. Once it envelopes asbestos and dried up, it is hardly possible to separate the reagent from asbestos. Among the asbestos, crocidolite asbestos is the most tough one and we treated crocidolite with the reagent. Then we leached it by strong sulfuric acid (1.8M) for more than 96 hours. The reagent-treated asbestos are then pulverized under 400 micron. Each fine fiber of crocidolite asbestos is entirely enveloped by the solidified reagent. As long as we observed them under the phase contrast microscope, we can hardly identify crocidolite. Using a highly efficient XRD, the crocidolite can be identified.

Conclusion

We of course prefer to recycle as many kinds of materials as possible. However, we may not be able to recycle asbestos at all. On the contrary, we prefer asbestos-free atmosphere. When houses, buildings, facilities and their equipment are reconstructed or repaired, fine asbestos fibers may start to fly even if the construction materials are not yet worn out. Therefore, somehow floatation of fine asbestos fibers have to be prevented. We are going to show how the reagent works to prevent floatation of fibrous asbestos.

Mass transfer by fluid and duration of oxygen isotope exchange during contact metamorphism at Hirao-dai, Japan

MAYUKO FUKUYAMA1, YUICHI MORISHITA1 AND TADAO NISHIYAMA2

1Advanced Industrial Science and Technology (AIST), Central7, Higashi 1-1-1, Tsukuba, Ibaraki,305-8567, Japan (m-fukuyama@aist.go.jp, y.morishita@aist.go.jp)
2Department of Earth and Environment, Kumamoto University (tadao@sci.kumamoto-u.ac.jp)

A reaction zone between a metamorphosed basic dyke (MB) and marble at Hirao-dai, north Kyushu, Japan, consists of well-organized sequential zones of diopside, garnet and wollastonite; textures are characteristic of diffusion-controlled structures. The reaction zone formed during contact metamorphism associated with intrusion of a Cretaceous granodiorite at about 300 MPa and 700°C (Fukuyama, et al., 2004). The MB consists of diopside, biotite and plagioclase (XAb=0.4-0.8), whereas the marble is almost pure calcite.

Minimum estimate of time-integrated flux forming a reaction zone is 3.46 mol fluid/mol reaction zone: 1.29 mol fluid/mole as reactive fluid and 2.17 mol fluid/mol as non-reactive fluid. 1mol of reaction zone consists of 0.42 mol diopside, 0.11 mol garnet, and 0.48mol wollastonite from overall reaction: 0.07K2.00Mg3.89Fe1.42Al2.48Ti0.16Si5.82O20(OH)4 + 0.02Na0.64Ca0.36Al1.36Si2.64O8 + 0.05CaMg0.77Fe0.23Si2.00O6 + 0.42CaMg0.72Fe0.28Si2.64O8 + 0.05CaMg0.77Fe0.23Si2.00O6 + 1.15CaCO3 + 1.09SiO2 + 0.03FeO 0.02AlO2/3 = 0.42CaMg0.72Fe0.28Si2.64O8 + 0.11Ca3.36Fe0.14Al2.06Si3.00O12 + 0.48CaSiO3 + 0.01TiO2 + 0.01NaO1/2 + 0.14KO1/2 + 0.14H2O + 1.15CO2. This estimate is based on the mineralogical evidence and steady-diffusion modelling (Fukuyama, et al., 2006).

We measured 18O and 13C of calcite along a line segment perpendicular to the reaction zone-marble boundary. 15O composition isn't change, but 18O composition changes in proportion to distance from the reaction zone-marble contact. This shows that 18O is strongly fractionated between CaCO3 or CO2 and H2O because mineral reactions may buffer the CO2-H2O content of fluid.

The duration of oxygen isotope exchange (t) can be calculated from effective diffusive width (W) and diffusive coefficient of oxygen in calcite (D) using the following equation: W2/2D=2Dt

The minimum estimated duration of oxygen isotope exchange is 357 m.y. We interpret this duration is the same as the duration of reaction zone formed, giving the fluid velocity 5.3*10-11 m/s.

4Department of Geosciences, National Taiwan University, Taipei 106, Taiwan; (skylin@ntu.edu.tw)

Subducted oceanic crust forms the likely source for a dense and more fertile layer at the core-mantle boundary. Numerical modeling predicts that entrainment of this dense material by an upwelling thermal plume will result in episodic volcanism occurring at episodic intervals on time scales of several to hundreds of millions of years (Lin & van Keken 2005).

Our study of 40 my of mafic eruptive activity in Turkana, Kenya reveals volcanological and geochemical features that are fully compatible with the numerical models, suggesting that magmatism in this part of the East African Rift System reflects deep entrainment of recycled oceanic crust by a thermally-driven plume. Volcanism at Turkana occurred in three distinct pulses separated by several million years each. No flood basalt province typical of strictly thermal plume head volcanism is associated with any of the pulses. The most voluminous pulse (26-16 Ma) led to rift propagation to both north and south, with fault growth and new rift basin development. Episodic volcanism is also reported from Samburu, Kenya, 200 km to the south (Tatsumi & Kimura 1991) and 100 km to the north in Ethiopia (George et al. 1998) in each case subsequent to peak Turkana episodes. These features contrast with observations in Afar, where plume head volcanism occurred 30 Ma and modern basalts are erupted along extensional features in the rift axis.

Mafic lavas from the major episode in Turkana – including abundant picrites – are geochemically distinctive. They have Sr-Nd-Pb-He isotopic signatures characteristic of high-µ ocean island basalts, and olivine Ca, Ni contents indicative of a pyroxenitic source (Sobolev et al. 2005, Herzberg 2006). We postulate that entrained fertile pyroxenite has been a source of mafic volcanism at Turkana.

Impact-generated ultrafine particles of olivine and serpentine suggesting a source of aerogels in the air of the early Earth

Y. Furukawa1, T. Kakegawa1, T. Sekine2 and H. Nakazawa2

1 Institute of Mineralogy, Petrology and Economic Geology, Faculty of Science, Tohoku University, Sendai, 980-8578, Japan (furukawa@ganko.tohoku.ac.jp; kakegawa@mail.tains.tohoku.ac.jp)
2 National Institute for Materials Science, Tsukuba, 305-0044, Japan (SEKINE.Toshimori@nims.go.jp; NAKAZAWA.Hiromoto@nims.go.jp)

Intense impacts of meteorites on to early oceans have been suggested in the period of Late Heavy Bombardment [1, 2]. The mechanism of oceanic impact is different from that of subaerial impact. The oceanic impacts generate Ultrafine Particles (UPs) [3] and have possibility to generate a large amount of UPs of serpentine. However, few experimental investigations of impact-serpentinitization exist. The UPs formation following impact explosion might influence the environment of the early Earth.

We performed shock-recovery experiments using a single-stage propellant gun to simulate simple ocean impact events of meteorites. The samples are powder of olivine with and without water in steel sample container. The products were analyzed with XRD, SEM and TEM.

SEM observation shows the formations of UPs of metal oxides. In addition, TEM observation shows the formation of UPs of olivine with different compositions from the starting one, serpentine and brucite. The grains of such UPs were some hundreds of nanometres in size.

Formation of UPs was unexpected from our impact experiments because the experimental conditions were far below the theoretical vaporization and/or melting conditions of starting materials. Here we propose that the presence of water significantly promoted the conversion of samples into UPs. The UPs formation by oceanic impacts may influence the change of Earth’s environment such as generating aerosol and shielding sunlight.

Sulfide oxidation, acidification and deoxygenation by reaction of resuspended sulfidic benthic sediments.

Diane Fyfe, Richard Bush, Edward Burton and Leigh Sullivan

Centre for Acid Sulfate Soil Research, Southern Cross University, Australia (dfyfe@scu.edu.au)

Black, gel-like, benthic sediments with high acid volatile sulfur (AVS) concentrations (1-6% dry mass) are common in waterways affected by acid sulphate leachate. These sediments are often called monosulfidic black ooze (MBO). Floodwater re-suspension of MBO has been implicated in massive fish kills associated with severe deoxygenation and acidification of coastal lowland rivers. This study examines changes to sediment and water chemistry during laboratory experiments designed to simulate flood-induced sediment re-suspension events. Re-suspension of MBO in water decreased dissolved oxygen from 7.70 mg.L-1 to 0.86 mg.L-1 within 1-2 minutes. The oxidation of the acid volatile sulfur fraction in the MBO resulted in the rapid formation of elemental sulfur. pH remained near-neutral during this oxidation step. It was 4 days until the elemental sulfur began to oxidise, causing acidification (pH <3.5). Metal concentrations within the MBO material were within sediment quality guidelines. However, the oxidation of AVS and acidification of the MBO material mobilised metals to the water column at concentrations greatly exceeding the recommended water quality guidelines. The current sediment quality guidelines for metals can be a poor estimate of the environmental risk, particularly as shown here for sediments that contain elevated acid volatile sulfur contents.

Fe, Co and Ni in Ureilites: Metal-silicate equilibration in the UPB

A.D. Gabriel and A. Pack

Universität Göttingen, Geowissenschaftliches Zentrum, Goldschmidtstrasse 1, 37077 Göttingen (apack@uni-goettingen.de)

Ureilites are coarse-grained olivine- and pigeonite-bearing achondrites with carbon-rich material occurring along grain boundaries [1]. It is suggested that Ureilites represent asteroidal mantle restites [2].

In this study we present Fe, Co and Ni concentration data of olivine from eight Ureilites with different Fe-contents, ranging from 8 to 22% fa. Measurements have been conducted by means of LA-ICP MS at the University of Göttingen.

Starting from a CI1 composition we calculated a model core compositions for each Ureilite. With the equations taken from Seifert et. al [3], we calculated the Co and Ni content of olivine that equilibrated with metal of the model core composition at temperatures ranging from 1000°C to 1500°C. These data are compared to measured Ureilite olivine compositions. Our data give olivine-metal equilibration temperature of about 1185°C. Exceptions are LEW85440 and ALHA77257 which show a higher equilibration temperatures of ~1230°C. EET96331, which is very low in Co and Ni compared to Ureilite olivine with similar Fe-content, gives a significantly lower equilibration temperature of ~800°C.

Ureilite olivines seem to have been equilibrated with a metal with a composition similar to the core of the UPB. Except for EET96331, equilibration temperatures range from 1173 to 1240°C, which is broadly in agreement with olivine-pigeonite thermometer data published by Singletary et al. [4]. The Fe-, Co- and Ni-composition of the Ureilite olivine has been established during metamorphism. This has implications for future Fe-Ni-isotope relative age dating, which is in progress.

Zircon as a magma mixing proxy: 
Textural, chemical and isotopic evidence from a young plutonic system

DAMIEN GAGNEVIN1, J. STEPHEN DALY1 AND MARTIN J. WHITEHOUSE2

1UCD School of Geological Sciences, Belfield, Dublin 4, Ireland (stephen.daly@ucd.ie, damien.gagnevin@ucd.ie)
2Laboratory for Isotope Geology, Swedish Museum of Natural History, Stockholm, Sweden (martin.whitehouse@nrm.se)

Ion microprobe U-Pb zircon analyses of the Miocene Monte Capanne Plutonic System (MCPS, Tuscan Magmatic Province, Italy) reveal a range of ages (ca. 7-10 Ma) pointing out to a protracted magmatic history (2-3 Ma; Daly et al., 2007) where magma mixing is believed to have played a significant role. As a companion study, we have investigated the textural, chemical and Hf isotopic response of zircon to various magmatic processes, with particular emphasis on magma mixing. For this purpose, we are using CL, BSE imaging as well as electron microprobe chemical data on a variety of magma products, including mafic microgranular enclaves, host monzogranites, mafic (Orano) dykes and granite porphyries. Importantly, zircon ages for these components partially overlap, suggesting that zircon was transferred and/or recycled throughout the lifetime of the whole plutonic system. A variety of textures have been encountered (inclusion-rich cores, patchy-zoning, small and large scale oscillatory zoning, pristine cores) as well as an extremely large range of trace to minor elements compositions (e.g., Hf: 7159-21284 ppm, Y: 39-8661 ppm, U: 67-65319 ppm and Th: 0-46225 ppm). While partitioning of Hf is largely temperature-dependent, intra-grain variations (zoning) in other elements (P, Th, U and HREE) are interpreted to reflect changes in melt chemistry due to mixing between mafic and felsic magmas, where growth/resorption of zircon was also associated with reactions between other accessory minerals (particularly apatite and monazite; Dini et al., 2004). The chemical signature of the dominant oscillatory zoning texture suggests growth from melts relatively depleted in trace elements, emphasising the important role of crystal fractionation in the evolution of the MCPS. These interpretations are in perfect agreement with models involving other phases, namely plagioclase (Gagnevin et al., 2004) and K-feldspar (Gagnevin et al., 2005a, b).

Sr/Ca as a proxy for temperature in the deep-sea coral Desmophyllum dianthus

A.C. GAGNON1, J.F. ADKINS2 AND D.P. FERNANDEZ3

1Division of Chemistry, California Institute of Technology, Pasadena, USA (gagnon@caltech.edu)
2Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, USA (jess@gps.caltech.edu)
3Department of Geology and Geophysics, University of Utah, Salt Lake City, USA (diego.fernandez@utah.edu)

We test Sr/Ca as a proxy for temperature in the cosmopolitan deep-sea coral species Desmophyllum dianthus. Several individuals of recent coral from regions of the deep-ocean typified by near constant temperate were selected from existing collections. Sub-samples were removed from the most recent portions of each skeleton and subjected to a full trace-metal cleaning protocol. Skeletal Sr/Ca was determined using isotope-dilution on a Neptune (ThermoFinnigan) multi-collector magnetic-sector ICP-MS. Intra-run reproducibility of a deep-sea coral consistency standard was better than 1‰ (2s), an improvement over most existing ICP-MS and optical spectroscopic methods. Across 8 individuals of D. dianthus spanning a 12°C range of growth temperatures, skeletal Sr/Ca decreases linearly as a function of temperature ($R^2 = 0.82$) with a shallower slope than most surface coral calibrations. Applied to the new archive of deep-sea coral, the Sr/Ca temperature proxy has the potential to generate high-resolution records of past deep-sea temperature.
Oxygen gas-phase formation in iron chemical gardens

LUI S GAGO DUPORT AND SUSANA FERNANDEZ BASTERO

Dept Geociencias Marinas. Universidad de Vigo. (duport@uvigo.es, sbastero@uvigo.es)

In this work we have employed the chemical gardens reaction as a laboratory device for in situ, follow the mixing of aqueous solutions of iron salts with sodium silicate and to characterize the reaction products by SEM HREM, XRD and XPS.

Chemical gardens are well known tubular structures formed in reaction–precipitation systems given rise to the formation of colorful, plant-like aggregates. Moreover, recent investigations have contributed to a renewed scientific interest in these self-organised structures. Although the reaction in chemical gardens is largely driven by pH gradients between the dissolving iron salt and the Na-silicate, recent works suggest that a strong redox processes can also take place during the formation of iron-silicate membranes.

One intriguing aspect related with silica gardens formation is the presence of small bubbles that are, in some instances, attached to the surface of the silica membranes, thus acting as templates for the formation of hollow tubular structures.

The aim of this research was to experimentally verify the composition and mechanisms of bubbles formation on Fe-Silica garden. From experiments performed in strictly anoxic environments will also be discussed.

In situ determination of iron species by UV-VIS showed the presence of Iron(VI)-ferrate oxyanion. Thus, a model for O2-bubble formation in silica garden is proposed, based on the rapid reduction of Fe(VI) to Fe(III) species through the of the strong pH gradient taken place across the silica membrane. Implications of these results for the formation of Fe-silicate phases in anoxic sedimentary environments will also be discussed.

The double-spike cookbook

S.J.G. GALER

Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (sjg@mpch-mainz.mpg.de)

In recent years there has arisen considerable interest in exploring natural stable isotope fractionation of "non-traditional" elements. Here, the techniques of standard/sample bracketing or addition of a second element in the mass range (e.g. Cu with Zn) can be used on MC-ICP-MS instruments, but not TIMS. But the obvious method of choice in terms of accuracy – as well as simplicity in preseparation chemistry – is to add a double spike (DS) of the same element to the sample. The DS "freezes in" the natural fractionation at the time of its addition, and is thereafter insensitive to any chemical or instrumental fractionation.

The natural fractionation is solved for via mass balance of 3 independent isotope ratios (effectively a 3D isotope space). The DS technique can thus be used for any element with four or more isotopes—or 33 elements in all. Nevertheless, it has been seriously underutilized, in part due to the unease of data reduction, but mostly from uncertainty in the choice of the double spike itself. The task is made all the more difficult from the sheer number of candidate double spikes and isotope spaces to consider. For example, for Fe there are only 4 such spaces, while for Sn, with its 10 isotopes, there are 840 possible isotope spaces. The rigorous "optimization" of any double spike problem, then, presents a formidable challenge.

What is presently hampering the widespread use of double spikes is a lack of a comprehensive solution to the problem. Here, I remedy the situation by tackling all 3868 isotope spaces of the 33 elements (201 isotopes) that can be double spiked. The approach yields (1) an estimate of the "best" mixture (M) to use within a given 3D isotope space (and its corresponding spike, S), along with (2) a "figure of merit" enabling comparison between different isotope spaces of each element. Together, these provide first-order answers to questions of what DS to use, what the optimal mixture is, and what isotope space yields the best error propagation? Exclusion of particular isotopes (e.g. isobaric interferences) becomes an easy task since all isotope spaces have been evaluated. The methodology contrasts with that of previous studies in two ways: first, the "optimal" mixture is explicitly solved for rather than the spike composition, and second, more rigorous criteria are used. Normal compositions (N) were taken from IUPAC. The "optimization" was performed by multi-dimensional numerical minimization using a penalty function approach. Four criteria are built into the function: (1) M should lie far from S and close to N, (2) the angle between the fractionation vector through N and the mixing line should be large, (3) the so-called "intersection angle" should be large, and (4) the absolute magnitudes of the 3 isotope ratios of M should lie close to unity. Once a promising DS has been identified, its performance as a function of spike-to-sample ratio can then be examined.

These calculations should remove a major obstacle to implementing the double-spike technique, and hopefully make its use more routine and in vogue in future stable isotope studies.
Geochemical and Sr-Nd-Hf isotopic variations in Tajikistan loess: In search of source and climatic proxies

SYLVAIN GALLET\(^1\) AND BOR-MING JAHN\(^2\)

\(^1\)Department of Geosciences, National Taiwan University, 10617 Taipei, Taiwan (sylvain.gallet@gmail.com)
\(^2\)Institute of Earth Sciences, Academia Sinica, Taipei 115, Taiwan (jahn@earth.sinica.edu.tw)

Late Tertiary to Quaternary loess-paleosol sequences provide invaluable record of the changing environment in continental areas during that time interval. Climatic proxies in loess-paleosol sequences have been retrieved by a number of ways, including palynology, grain-size analysis, clay minerals, carbonate or organic matter contents or magnetic susceptibility. Loess source proxys include quartz morphology, heavy minerals assemblages, major and trace elements and Sr-Nd isotopic compositions. Some proxies are useful both as dust source proxy and as climatic proxy. We have been studying various loess-paleosol sequences in the Chinese Loess Plateau (Gallet et al. 1996, Jahn et al. 2001). On these sections we tested and proved the usefulness of geochemical and isotopic tools in loess research. Recently we extended our area of investigation to Central Asia, and the Chashmanigar (Tajikistan) loess section was chosen because some detailed stratigraphic and magnetic susceptibility data have been published by Ding et al. (2002). This section is about 200 m thick and consists of an alternation of loess and paleosol layers. A combination of geochemical and isotopic data is used to trace back the source(s) of these eolian deposits and their weathering history. Isotopic data (Sr-Nd-Hf) for whole-rock samples and for chemically separated fractions allow to document the change in protolith composition in response to climatic and tectonic events in the area. Major-elements, organic matter and carbonate content were measured on whole-rocks samples. Preliminary results show that our previous understanding of loess-paleosol geochemistry, first established on the Loess Plateau of China, is still valid here. Pedogenesis is clearly distinguished by the depletion or relative enrichment of a number of chemically mobile elements. There is a direct relationship between magnetic susceptibility increase in paleosol and depletion/enrichment of some chemical elements. We are currently working to translate this relationship into more quantitative laws.

The effect of variable source of terrestrial organic carbon on geochemical records of atmospheric level of CO\(_2\)

ALBERT GALEY AND ROBERT G. HILTON

Department of Earth Sciences, Cambridge University, UK (albert00@esc.cam.ac.uk; rgh31@esc.cam.ac.uk)

Carbon isotope analyses of fossil plants (\(\delta^{13}C\)\(_{\text{plant}}\)) have been widely used as chemostratigraphic and palaeoenvironmental tools. It has even been suggested that \(\delta^{13}C\)\(_{\text{plant}}\) can be used as a proxy of \(\delta^{13}C\) of palaeo-atmospheric CO\(_2\) [1-2]. This parameter is an important variable for calculating p\(_{\text{CO2}}\) from the \(\delta^{13}C\) of soil carbonate [3], the current largest database on records of atmospheric level of CO\(_2\). However, the \(\delta^{13}C\) of modern plants varies between species and palaeo-studies have attempted to go around this issue by focussing on monospecific dataset through time [4].

Here, we present evidences that in addition to species, the provenance of the woody debris will also introduce a significant variability in \(\delta^{13}C\)\(_{\text{plant}}\). The transfer of particulate organic carbon (POC) has been studied in suspended material carried by small rivers draining active mountain belts (Southern Alps, New Zealand and Taiwan). In this active mountain belt, sediment discharge is dominated by landslide-derived material. The altitudinal spread of these landslides means that the POC samples vegetation dominated by C3-type plants and therefore having a variable \(\delta^{13}C\)\(_{\text{plant}}\) [5]. Our sampling of pine trees along an altitudinal transect in Taiwan shows a range of in \(\delta^{13}C\)\(_{\text{plant}}\) of 2‰, in line with previous findings [5]. The \(\delta^{13}C\) of the POC in a single river sampled throughout the rainy season in Taiwan ranges from -21.5 to -25‰, while the range is >5‰ in Western Southern Alps. Of course not all of these variations can be attributed to a variable isotopic composition of the vegetation and the fossil component can be as large as 90%. But in some Taiwanese rivers this fossil component corresponds to the recycling of Miocene woody debris. Based on these observations, we would argue that the use of \(\delta^{13}C\)\(_{\text{plant}}\) for calculating p\(_{\text{CO2}}\) is of very little help and also that it can be misleading in chemostratigraphy.

Diel iron cycling in acidic rivers of southwestern Spain

C. H. GAMMONS1, S. R. PARKER2 AND D. A. NIMICK3

1Dept. of Geol. Engineering, Montana Tech of The University of Montana, Butte, MT, USA (cgammons@mtech.edu)
2Dept. of Chemistry & Geochemistry, Montana Tech of The Univ. of Montana, Butte, MT, USA (sparker@mtech.edu)
3U.S. Geological Survey, Helena, MT, USA (dnimick@usgs.gov)

Background
In June 2006, diel sampling was conducted on the Tinto, Odiel, and Agrio Rivers of Huelva Province, Spain. These rivers are highly acidic due to acid rock drainage from massive sulfide deposits of the Iberian Pyrite Belt (Cánovas et al., 2007). Variables quantified included streamflow, temperature, pH, Eh, photo-synthetically active radiation, and concentrations of dissolved and total metals, anions, Fe(II)/Fe(III), and As(III)/As(V).

Results
Average 24-h pH values were 2.36, 2.30, and 3.04 at the Tinto, Agrio, and Odiel Rivers, respectively. Both pH and streamflow were essentially constant with time in each river. The only solute that showed a robust diel concentration cycle in all three rivers was dissolved Fe(II). Concentrations of Fe(II) at mid-day were 1.8 to 28 times higher than concentrations in the early morning (pre-dawn). The daytime mFe(II) increases were most likely caused by photoreduction of dissolved or solid-phase Fe(III). The night-time mFe(II) decreases were attributed to biologically catalyzed re-oxidation of Fe(II) to Fe(III). First-order rate constants of (2 to 7) x 10^-5 sec^-1 for the bacterial oxidation of Fe(II) were estimated from the observed decreases in mFe(II) during the night. Maximum rates of bacterial Fe(II) oxidation (estimated to be > 3 µmol/L/h) occurred at mid-day. This amount of Fe(II) oxidation can support a growth rate of over 10^6 cells/L/h for At. ferrooxidans, the dominant procaryote in the Tinto River (López-Archilla et al., 2001).

Conclusions
Photoreduction plays a key role in biogeochemical cycling of Fe in the Tinto and neighboring rivers, and it has not been reported in previous geochemical and ecological studies of this extremely acidic and Fe-rich environment (e.g., Amils et al., 2007). Further work is needed to quantify the relative rates of Fe(II) production by photoreduction and by heterotrophic Fe(III)-reducing bacteria. The results of this study have implications for the primitive life that may have existed in acidic aqueous environments on early Earth or other planetary bodies such as Mars.

Interaction of the magma with the sedimentary wall rock and magnetite ore genesis in the Panzhihua mafic layered intrusion, SW China

CLEMENT GANINO AND NICHOLAS T. ARNDT
LGCA, OSUG Grenoble, France (clement.ganino@ujf-grenoble.fr; Nicholas.Arndt@ujf-grenoble.fr)

The Panzhihua intrusion is a gabbroic Fe-Ti-V oxide ore-bearing sill associated with the Emeishan flood basalts in SW China (Zhou et al. 2005). It is overlain by a syenitic body and it concordantly intrudes late-Proterozoic dolomitic limestones, remnants of which can be found as metamorphosed xenoliths in the gabbroic body. Compositions of metasediments from the contact aureole show evidence for a pronounced transfer of certain major and trace elements between magma and sediments, perhaps linked to hydrothermal circulation driven by magma emplacement.

Numerical modeling with PELE (Boudreau, 1999) shows that when magma with the average chemical composition of Emeishan basalt fractionally crystallizes under oxidising conditions (oxygen buffer > FMQ) and/or with high water contents, magnetite appears early in the crystallization sequence. This is a condition for an efficient segregation of magnetite and for the formation of the ore deposit.

Mineralogical and chemical studies of the contact aureole demonstrate that footwall dolomites were degassed during intrusion of the gabbro. We propose that CO2-rich fluids released by this degassing increased the oxygen fugacity of the magma and caused early and massive crystallization of magnetite.

Because magnetite crystallized when the intrusion was largely molten, it migrated to the base of the gabbroic body. The increase of the viscosity in the magma and the decrease of its density during the late stages of crystallization promoted the segregation of evolved felsic liquids that solidified as syenite intrusions. The association of gabbroic and syenitic bodies in Panzhihua region results from fractional crystallization of common parental magmas.

Stability of hydrous ringwoodite in the Martian mantle

G. GANSKOW, F. LANGENHORST, K. POLLOK, D. FROST AND H. KEPPLER

1Institut für Geowissenschaften, Universität Jena, Burgweg 11, D-07749 Jena, Germany (geertje.ganskow@uni-jena.de)
2Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany

Introduction
Branching networks of valleys and huge outflow channels on Mars provide evidence for the previous existence of water on its planetary surface. The water was probably once stored in the Martian interior and was then liberated to the surface. To understand this process, knowledge of Martian mantle structure and stability of hydrous phases is required.

Experiments
In order to identify possible hydrous high-pressure minerals in the Martian mantle and to determine their stability fields, we have conducted a series of multi-anvil experiments at the Bayerisches Geoinstitut, University of Bayreuth. First experiments were performed at pressures of 15 to 18 GPa and at variable temperatures between 750°C and 1150°C using a mixture of 2 Mg(OH)2 + Fe2SiO4 + SiO2 as starting material. Experimental run products were examined by transmission electron microscopy, microprobe, IR and RAMAN spectroscopy.

Results and discussion
At 15 GPa and temperatures between 750° and 1150°C cubic ringwoodite exists as single phase. Microprobe analyses yield the expected ringwoodite composition nominally equivalent to Fa48. At 18 GPa and 950 °C we observe a change to the three-phase assemblage ringwoodite + wüstite + stishovite, while the specimen compressed to the same pressure was melted at 1150°C. In comparison to the dry, Mg-rich system [1], the enhanced iron and water contents lower thus the transformation pressure by 3 GPa (from 21 GPa to 18 GPa) as well as the liquidus temperatures by at least 500°C. IR spectroscopy attests to an uptake of about 2800 ppm H2O. To understand the incorporation mechanism of water we have also used Fe L3/2 electron energy loss spectroscopy, revealing that the iron is purely ferrous. Thus, the water is probably accommodated by the replacement of Mg2+ by 2H+.

Application of the field seismic data in the security assessment of coal mining in Marbi Area

E.G. GAO* AND S.Y. SONG

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*grg@ustc.edu.cn)

Introduction
The Marbi area is located in Shanxi Province in north China, where plenty of coal resources are mined. In the past decades, a large amount of seismic exploration work with the aim at coal recourses has been done in the area successively. Based on the foundation of seismic exploration data, this study focuses on the structure of sedimentary basin and the security assessment of coal mining in the Marbi area.

Experiment and Results
Our data processing, combined with the existed local geological information, can be summarized concisely into the following steps (Claerbout, 1985; Ecker et al., 1996; Li et al., 2006): (1) carefully checked the positions of field shot-receiver pairs to obtain accurate localities; (2) calculated the static corrections in details; (3) eliminated bad shots, bad courses and abnormal amplitudes; (4) selected appropriate deconvolution parameters; (5) made accurate velocity analysis and got residual static corrections through stacking; (6) carried out the post stack processing and precise migration.

The result shows that there is a large syncline structure in the center of the region, suggesting long-term tectonic compression influenced Marbi area since Triassic. This crustal deformation was accompanied with dense rock cracking in both coal sills and their wall rocks, which could lead to the security difficulty and potential danger to the deep exploitation for coal mines.

Acknowledgment
The study is supported by the National Natural Science Foundation of China (40674071) and the Foundation of Hubei Provincal Theoretical-Technological Key Lab for Oil-Natural Gas Exploration and Development (YQ2006KF11).

Recycling continental lithosphere via foundering is suggested to be an important geodynamic process but is difficult to document (Sobolev et al., 2005). Here we show that Early Cretaceous alkaline picrites and high-magnesium basalts from the North China craton provide evidence for such recycling. These mantle-derived lavas contain both xenocrystic and magmatic olivines. The former have high Fo92-93 and low CaO (<0.10%) and suggest derivation from the Archean mantle lithosphere. More importantly, these lavas contain unusual reversely zoned clinopyroxenes. Compositions of their low Mg cores and high Mg mantles are consistent with crystallization from eclogite- and peridotite-derived melts, respectively. The cores are high in Na2O (up to 2.4%) and frequently contain ilmenite exsolution lamellae, whereas the mantles are low in Na2O (<0.92%) and lamellae-free. These lines of evidence suggest that the cores formed at a significantly greater depth (≥2.5 GPa) than the surrounding mantles (≥1.5 GPa). The whole-rock compositions of the basalts also contain chemical evidence (high Ni/Cr, Fe/Mn, Sr/Y LaN/YbN, and Th/U ratios and low Lu/HF ratio) for their derivation from an olivine-free source and incorporation of melts derived from foundered eclogitic continental crust. Together with our previous studies of the late Jurassic high-Mg intermediate to felsic lavas from western Liaoning in the northeastern North China craton (Gao et al., 2004), these findings indicate that thinning of the North China craton was caused by recycling of the lower lithosphere (mantle and lower crust), and demonstrate that continental lithosphere recycling is a viable means of producing mantle heterogeneity.

The building-up exercise of a thermodynamic data set on ISA-actinide system

X. GAONA1, V. MONTOYA1, E. COLÁS1, M. GRIVÉ1, L. DURO1 and E. GIFFAUT2

1Enviros Spain S.L., Passeig de Rubí 29-31, 08197 Valldoreix, Spain (xgaona@enviros.biz)
2ANDRA, 1/7 rue Jean Monnet - 92298 Chatenay Malabry cedex - France

Isosaccharinic acid (ISA) is one of the most important degradation products of cellulose expected in the hyperalkaline conditions defined by cementitious environments. Despite the high affinity shown by this ligand toward actinides complexation, the number and reliability of available experimental studies is still limited (Hummel et al., 2005). Due to the potential effect of these complexes in the performance assessment exercises, this work aims at providing a comprehensive and coherent thermodynamic data set on the ISA-actinide system. For this purpose, the thermodynamic data available in the literature have been complemented with further modelling exercises and estimations based on ionic radii correlations among actinides.

Under slightly reducing conditions and absence of carbonate and calcium, M(OH)ISA ternary complexes (M=Th, U(IV), Np(IV), Pu(IV)) are expected to dominate aqueous speciation. The available publications show a moderate agreement among the stability constants of these complexes, although their structure is still ill-defined and some authors propose complexation reactions where the alcohol groups of ISA are partly deprotonated. Under hyperalkaline conditions and the presence of calcium, the species CaM(OH)4ISA2(aq) has been described for Th and may dominate aqueous speciation of further tetravalent actinides.

The limited number of experimental studies assessing the complexation of An(V) and An(VI) with ISA indicates the possible formation of An(V)O2(OH)x(ISA)y-like complexes. This work has allowed to obtain a complete set of stability constants for complexes of ISA with tetravalent actinides under alkaline to hyperalkaline conditions. Similarly, stoichiometries and stability constants for An(V)-ISA and An(VI)-ISA complexes have been proposed, although further experimental efforts would be advisable to gain confidence on these complexes.

2Dept. of Geology, Univ. de Huelva, Huelva, Spain (dorado@uhu.es, jesus@uhu.es)

Introduction

As a way to settle the difficulties regarding the origin and evolution of granitic rocks, we studied the C_i/C_o values of Rb, Sr and Ba from melts of the Ollo de Sapo Gneiss (modal comp.: Qtz: 42; Pl (An19): 20; Kfs: 8; Bt (Mg 40): 10; Ms: 20) at 6 and 10 kbar, 750, 800, 850 and 900 ºC, and 10% wt water. Experiments were run in a piston-cylinder apparatus at the High Pressure Laboratory of the University of Huelva, and analysis were made using an ICP-MS of the Central Services of the University of Huelva.

A diamond trap has been used to separate melt from residual minerals, so a pressure gradient between powder and trap (which can be a source of disequilibrium) exists, but disappears or is minimised if melt soaks the trap and residual minerals. Thus, melting process begins as a fractional melting followed by a batch melting if melt quantity exceeds a critical amount.

Discussion

At 6 kbar, C_i/C_o values for Rb are lower than 1 (0.67-0.98) with a minimum at 800 ºC due to the high productivity of melt by the breakdown of feldspars; for Sr, C_i/C_o is upper than 1 (1.01-1.24), with a maximum at 800 ºC. Comparing these values with calculated for High Himalayan leucogranites, assuming a greywacke source in presence of water, a clear resemblance for Rb and a difference for Sr and Ba can be seen.

Conclusion

The election of the K_0 values has a decisive influence in C_i/C_o values, although this discrepancy can also be due to a disequilibrium melting because of the diamond trap.

Radium isotopes as tracers of submarine groundwater and nitrogen discharge in a karstic area

E. GARCIA-SOLSONA1, J. GARCIA ORELLANA1, P. MASQUÉ1, M. MEJAS2 AND B. BALLESTEROS2

1ICTA – Dep. Física, Universitat Autònoma de Barcelona, 08193 Bellaterra, Spain (Esther.Garcia@uab.cat)
2Instituto Geológico Minero de España, 28003 Madrid, Spain

Introduction

A mass balance for ^223Ra (T_{1/2}=11.4 d) and ^224Ra (T_{1/2}=3.66 d) is applied to a karstic area (Badum, Spain) to evaluate the submarine groundwater discharge (SGD) through coastal springs. The strategy is based on the enrichment of Ra in groundwater compared to surficial waters.

Ra isotopes were measured from coastal, brackish springs and seawater samples by using a Radium Delayed Coincidence Counter (Moore and Arnold, 1996).

Results and discussion

All coastal samples are enriched in radium activities compared to the open sea, the highest activities being found in the springs. ^223Ra and ^224Ra concentrations are highly correlated and Ra vs. salinity plots suggest a mixing process between the springs and the coastal sea endmembers (Fig. 1).

A Ra mass balance allows obtaining a groundwater fraction of 38%. By considering this fraction, the water residence time (0.5 d) also derived from the short-lived Ra isotopes and the sampled water column, a SGD flux is calculated to be 5·10^6 m^3 yr^-1. This flow accounts for a nitrate input of 3 mmol m^-2 d^-1, which is comparable with literature values of SGD-derived nitrogen inputs to coastal areas (Charette and Buesseler, 2004).

5School of Science and Technology, University of Waikato, New Zealand

A re-evaluation of the petrogenetic links between the andesites and rhyolites from the Taupo Volcanic Zone of New Zealand’s North Island by Price et al. (2005) led to the proposal of an evolutionary pattern from andesite-dominated to rhyolite-dominated magmatic systems with time.

In order to understand the processes involved in this long-term shift towards catastrophic rhyolite eruptions, we must first ensure that we fully comprehend the factors controlling short-term variations. However, detailed, stratigraphically controlled sampling of well-documented single eruptive episodes and eruptive sequences has revealed considerable internal complexities at several arc-type volcanoes.

Here we present analyses of multiple samples from an accurately dated, (3115±35 yrs BP, Carroll et al. 1997) andesitic block- and ash-flow deposit on Mount Edgecumbe at the active volcanic front of the TVZ. Our results are based on whole-rock analyses for major element oxides, trace and rare earth elements in addition to Sr and Nd isotope ratios resolving the extent of geochemical variability within a strict time-frame.

Cooling rates contraints on the accretion of the plutonic crust at fast-spreading mid-ocean ridges

C.J. Garrido1 and P. Machetel2

1Dep. Mineralogía y Petrología, Universidad de Granada, 18002-Granada, Spain (carlosg@ugr.es)
2Équipe Manteau-Noyeau, Géosciences Montpellier, CNRS-Université de Montpellier 2, 34095-Montpellier, France.

We report the results of a thermo-mechanical model of crustal flow beneath fast spreading mid-ocean ridges considering the effect of deep, near off-axis hydrothermal cooling and variable igneous accretion modes. The accretion mode determines the flow lines along which gabbro crystallize and the lateral advection of heat and mass. Near, off-axis hydrothermal cooling determines the shape of the magma chamber and viscosity, which influence the stream function and the shape of flow lines along with plutonic gabbro crystallize. The cooling rate of the plutonic crust along a flow line depends on the velocity and geothermal gradient along it, which are in turn imposed by: (i) the accretion mode, (ii) the extent of off-axis hydrothermal cooling, and (iii) conductive thermal rebound far from the ridge axis. The conventional wisdom that the igneous and metamorphic cooling rates of exposed sections of lower oceanic crust are similar and both reflect the on-axis thermal cooling of the oceanic crust is too simplistic. The cooling history is inherently related to the method used to retrieve it; particularly to the temperature interval recorded by the method. The cooling history may integrate cooling at different depths at distances from the ridge axis, which are not necessarily those of their final depth of emplacement. While igneous cooling rates record the thermal structure of the magma chambers, metamorphic cooling rates may record different extent of the off-axis thermal structure depending on the effective temperature of diffusion initiation and closure temperature. Igneous and metamorphic cooling rate variations with depth are markedly different for a given accretion mode and, if available, both might be used to discriminate among different scenarios proposed for the accretion of the oceanic crust a fast-spreading mid-ocean ridges.
Thermodynamic modelling the sorption of heavy metals and actinides onto clay minerals by Gibbs energy minimization approach

O.L. GASKOVA

Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (gaskova@uigm.nsc.ru), RFBR # 06-05-64528

One of the major aims in the development of sorption models was to set up the simplest chemically reasonable model with the least number of variable parameters capable of describing and predicting sorption over a wide range of conditions. In this study we have investigated the sorption of heavy metals and actinides onto montmorillonite, illite and kaolinite in aqueous solutions by applying the Gibbs energy minimization computer code “HCh” (Yu.V. Shvarov, Moscow State University) via a non-electrostatic model. The emphasis is made on the named clay minerals because of their importance in terrestrial weathering processes and designed industrial applications. The thermodynamic model combines cation exchange at a permanent negatively charged sites and pH-dependent surface complexation at the amphoteric edge-type sites. Site types, their individual capacitance and the acidity constants associated with them, were considered to be non-adjustable parameters and were fixed in all of the calculations: the cation exchange capacity (CEC) is 0.9, 0.25 nd 0.05 equiv/kg and equal to concentration of exchangeable acidity constants associated with them, were considered to be pH-dependent surface complexation at the amphoteric edge-type sites. Site types, their individual capacitance and the acidity constants associated with them, were considered to be non-adjustable parameters and were fixed in all of the calculations: the cation exchange capacity (CEC) is 0.9, 0.25 and 0.05 mol/kg. The equilibrium constants for the adsorption and ion exchange reactions could be found due to correlations with the aqueous hydrolysis constants.

The calculated sorption models showed good approximation of experimental distribution coefficients of majority sorbates onto named three clay minerals. We note that the model parameters discussed here are closely dependent on the decisive variables, namely the surface site capacities. Indeed, the value of the CEC and the density of edge sites directly control the metal uptake by considered clay minerals. It allows to show that: a) the influence of ionic strength and pH of solutions on the metal sorption is differentiated depending on the crystallochemical type of clay mineral. The more sorption capacity of a phase, the influence of concentration of electrolyte is more strongly revealed. As a result, kaolinite could be successfully used in the solutions with I > 0.1 and pH > 5 instead of montmorillonite, which exhibits the highest exchange capacity; b) the sorption show a higher difference in selectivity of the cations in the pH range 4-8, where it is greatly affected by the element chemical properties (affinity to the hydrolysis in solutions and the surface-binding complexation); c) on the contrary, at weakly acidic pH of diluted solutions (low ionic strength), selectivity coefficients Kc could be accepted the same for analogous type of cations, if was not determined exactly. Usually, Kc values for bivalent-monovalent exchange are ~3 to 4 and for bivalent-bivalent exchange around unity.

The Bicaz lake (Romania): Hydrodynamics and trace element behaviour

N. GASSAMA1, C. COCIRTA1 AND H.U. KASPER2

1GeEAC, Univ. de Tours, France
(nathalie.gassama@univ-tours.fr; constantin.cocirta@univ-tours.fr);
2Institut für Geologie und Mineralogie, Universität zu Köln, Germany (hu.kasper@uni-koeln.de)

The dammed lake of Bicaz (East Carpathians, Romania), presents the following physical characteristics: 31.1 km length, 2 km wide, water volume of 1.150·109 m3. The Bistriţa river is the main tributary with a mean water contribution of 1.721·109 m3/year and a mean suspended matter flow of 291,000 tons/year. This river drains a catchment rich in formerly mined mineralizations of polymetallic sulfides.

Three locations, an upper, a middle, and a down site as well as the main tributary river were sampled for one hydrological year.

The electric conductivity and the concentration of major ions allow to evidence a water layer whose position varies along the lake and according to season (water temperature and lake depth). This current which originates from the Bistriţa river is intensified by the sluice drawing off. The distribution of Fe between dissolved and particulate forms, along the lake and for each season, and the distribution of Mn, excepted in some cases, show the lake is mainly oxidizing. In the dissolved phase, the concentration of Fe and Mn is smaller than in the river. Some trace elements such as Cr and V occur mainly in the particulate form, and are enriched in the dissolved phase compared to the Bistriţa. On the contrary, Ni, As and U are found mainly in the dissolved phase: Ni is enriched compared to the river whereas As and U are similar.

The distribution of Co between particulate matter and solution is variable and does not follow Mn. The concentration of Co in the dissolved phase is smaller than in the river. Thus, stratification of the water column within the lake is disturbed by the river current and by the sluice. The weak relationship between Fe and Mn and analyzed trace elements may be linked to hydrodynamics of the lake.
**A radium and radon investigation of the submarine estuary under Venice**

J.C. GATTACECA\(^1\), A. MAYER\(^2\), O. RADAKOVITCH\(^1\), C. CLAUDE\(^1\) and B. HAMELIN\(^1\)

\(^1\)CEREGE, UMR 6635, CNRS-Université Paul Cezanne, Européole de l’Arbois, 13545 Aix-en-Provence, France (jgatta@cerege.fr, cclaude@cerege.fr, hamelin@cerege.fr, rada@cerege.fr)
\(^2\)IDPA-CNR, Via Mario Bianco 9, 20131 Milano, Italy (adriano.mayer@idpa.cnr.it)

Submarine groundwater discharge (SGD) is now recognised as a major pathway for nutrients and contaminants. Mass balance models based on excesses of natural radioactive isotopes in coastal environments (estuary, lagoon) can provide integrated estimates of SGD. In this work, we measured \(^{226}\)Ra and \(^{222}\)Rn activities in the southern part of the Venice lagoon, a most emblematic case of highly vulnerable coastal flatland heavily impacted by anthropogenic activities.

\(^{226}\)Ra activities measurements were performed by isotope dilution and thermal ionization mass spectrometry on small samples (0.5L). Very small variations in \(^{226}\)Ra can be resolved by this technique, thanks to the high precision that is attainable (1 to 5% on 20 to 200 fg samples). \(^{222}\)Rn activities were measured by in-situ continuous-monitoring \(\alpha\)-counting technique with a precision of 10%.

\(^{226}\)Ra and \(^{222}\)Rn activities are significantly higher in the lagoon samples (2.3-5.3 and 26-82 Bq/m\(^3\)) respectively than in the open Adriatic Sea (2.2 and 10 Bq/m\(^3\)) respectively. Mass balance models taking into account riverine inputs, diffusion from sediments, loss, production and decay of the isotopes, do not explain the lagoon excesses and suggest the existence of another source of \(^{226}\)Ra and \(^{222}\)Rn in the lagoon.

Groundwater from the semi-confined aquifer (0-30 m) connected with lagoon waters presents significant enrichment in \(^{226}\)Ra and \(^{222}\)Rn (c.a. 35 Bq/m\(^3\) and 1300 Bq/m\(^3\)), and may be considered as an additional source to generate the required excess. Using these activities, the input of groundwater necessary to explain the observed excess in the lagoon is 5.2x10\(^5\) and 5.5x10\(^5\) m\(^3\)d\(^{-1}\), based on \(^{226}\)Ra and \(^{222}\)Rn mass balance respectively. Furthermore, Rn monitoring during tidal cycles shows that the excess activity is produced during the falling tide, when aquifers significant discharge interstitial waters through the sediments.

**Cryptic zoning in garnets from the Nufenen Pass area**

K. GAUCHAT AND L. P. BAUMGARTNER

Institute of Mineralogy and Geochemistry, University of Lausanne, CH-1015 Lausanne, Switzerland; (Karine.Gauchat@unil.ch); (Lukas.Baumgartner@unil.ch)

Garnets from graphite rich black shales of the Mesozoic cover of the Gotthard Massif in the Swiss Alps display textural sector zoning with birefringent lamellae emanating from sector boundaries. Central sections of garnets cut along [110] display 6 sectors, which are in places crowned by a graphite rich cap. The birefringent lamellae are oriented normal to the sector end face. Individual lamellae have a length of up to 300 microns and a thickness of typically 10 microns. The lamellae have an elliptical cross section of a few tens of microns for their long axis on sections parallel to the sector end face. A cross hatched pattern is created with lamellae orientations parallel to the edges of the sector walls. Lamellae are absent in the graphite inclusion rich rim. EPMA analysis of the birefringent lamellae show that they are Ca richer than the adjacent isotropic lamellae which are Fe richer. The composition difference in calcium and iron between the two type of lamellae can be up to 0.2 cation per formula unit. The lamellae are zoned along their length, following the overall garnet zoning pattern. Composition ranges for the two lamellae overlap for a single garnet.

The coexistence of two garnet composition and structure could be explained by a miscibility gap in the solid solution or by crystallisation of one or two metastable precursors. The composition difference between the two type of lamellae is too small to reflect a miscibility gap and lamellae composition overlap. Hence they are not exsolutions. Other type of zoning have been explained by the replacement of heterogeneities in the matrix or concentric zoning due to rythmically changing conditions (Yardley et al., 1996). The crystallographic orientation of the lamellae indicates that they do not represent replacement of matrix heterogeneities. The orientation of the lamellae demonstrates, that at any time, both types of lamellae were crystallizing.

We propose an alternate mechanism for this case. Two garnets with a slightly different composition and structure nucleate topotactically on the surface of a growing garnet with a similar probability. It is enough that continued nucleation of a new garnet layer slightly prefers the same structure to assure a fiber-like growth of both compositions side by side.

**Water solubility in clinopyroxene**

POLINA GAVRILENKO AND HANS KEPPLER

Bayerisches Geoinstitut, Universität Bayreuth, 95440
Bayreuth, Germany (Polina.Gavrilenko@uni-bayreuth.de,
Hans.Keppler@uni-bayreuth.de)

Clinopyroxenes, in particular omphacites, have the highest water contents among the minerals from mantle xenoliths. In subducting slabs, water in omphacite may contribute significantly to the recycling of water into the mantle. We have therefore measured the solubility of water in both pure CaMgSi$_2$O$_6$ diopside and in diopside containing variable amounts of aluminum as Ca-Tschermak CaAl$_2$SiO$_6$ component. Single crystals of the pyroxenes were grown in piston-cylinder and multi-anvil experiments using oxide/hydroxide mixtures with excess water as starting materials. Water contents were quantified from polarized infrared spectra of clear single crystals.

Water solubility in pure diopside is rather low, in the order of a few hundred ppm at 1.5 – 3 GPa and 800 – 1100 °C. The type of infrared spectra observed varies with the bulk composition of the sample. Diopside crystals synthesized with excess silica show several bands at low frequency between 3280 and 3480 cm$^{-1}$. These bands are attributed to protons on Ca or Mg vacancies. Diopside crystals synthesized with excess MgO or a deficiency of SiO$_2$, which coexist with olivine, show only one sharp band at 3650 cm$^{-1}$. This band is therefore probably due to protons associated with silica vacancies.

Water solubility in pure diopside is rather low, in the order of a few hundred ppm at 1.5 – 3 GPa and 800 – 1100 °C. The type of infrared spectra observed varies with the bulk composition of the sample. Diopside crystals synthesized with excess silica show several bands at low frequency between 3280 and 3480 cm$^{-1}$. These bands are attributed to protons on Ca or Mg vacancies. Diopside crystals synthesized with excess MgO or a deficiency of SiO$_2$, which coexist with olivine, show only one sharp band at 3650 cm$^{-1}$. This band is therefore probably due to protons associated with silica vacancies.

Water solubility in clinopyroxene strongly increases with alumina content and reaches up to 3000 ppm already at 1.5 GPa (Fig. 1). Aluminous diopside samples only show one infrared band at 3650 cm$^{-1}$, corresponding to the substitution of Al$^{3+} + H^+$ for Si$^{4+}$. Our data therefore confirm that Al in pyroxenes largely controls water storage in the uppermost mantle.

**Cosmogenic $^3$He production rate in pyroxenes and olivines at low latitude**

ERIC GAYER$^1$, TIBOR J. DUNAI$^1$ AND FINLAY M. STUART$^2$

$^1$Department of Geography, University of Edinburgh, Edinburgh, UK
$^2$Scottish Universities Environmental Research Centre, East Kilbride, UK

In the past decade cosmogenic $^3$He has become a widely used chronometer of surface exposure. The low cost of noble gas measurements and the relatively high production rate in mafic minerals have, in particular, been exploited for dating exposure of basaltic rocks. Cosmogenic $^3$He production rate in olivine is well documented, however, only few studies have been dedicated to the determination of the production rate in pyroxene (i.e. [1-2], 39-46°N and 47°S latitude). The study presented here is designed to measure long-term cosmogenic $^3$He production rate in pyroxenes and co-existing olivines at low latitudes, and to document the variation of cosmogenic $^3$He production rate with chemical composition.

Four olivine- and pyroxene-rich basalt flows between 132 and 482 m altitude were sampled from Ascension Island (7.5°S) where the arid climate preserves ropey-flow tops. In pyroxenes, cosmogenic $^3$He concentrations were calculated using (i) the magmatic $^3$He/$^4$He released by in vacuo crushing and melting, and (ii) the $^4$He concentrations measured by melting. The magmatic $^3$He/$^4$He is remarkably constant (6.8±0.4 $R_a$) while the $^3$He/$^4$He of melt extractions range from 100 to 500 $R_a$, suggesting that the correction for non-cosmogenic He is minimal. Cosmogenic $^3$He concentrations in multiple pyroxene samples from each flow range from 1.41 x 10$^7$ to 2.69 x 10$^7$ atoms/g, corresponding to approximately 220 to 350 kyr exposure. Error-weighted mean values have total uncertainties of 5% implying that the flow tops have not been significantly covered or eroded. Measurements of cosmogenic $^3$He concentrations in olivines from the same samples will be conducted and compared to the pyroxenes to constrain the cosmogenic $^3$He production rate in pyroxenes and to explore the production rate variation with chemical composition.

Actinide geochemistry: From the molecular level to the real system

H. GECKEIS

Institut für Nukleare Entsorgung, Forschungszentrum, Karlsruhe, Postfach 3640, D-76021 Karlsruhe, Germany

Geochemical processes leading to either mobilization or retention of radionuclides in an aquifer are significantly influenced by their interaction with rock, sediment and colloid surfaces. Therefore, performance assessment of nuclear waste disposal requires the elucidation and quantification of those processes. State-of-the-art analytical techniques as e.g. laser - and X-ray spectroscopy are increasingly applied to study solid-liquid interface reactions and to obtain molecular level speciation insight.

We have studied the sorption of trivalent lanthanides and actinides (M(III)) onto aluminium oxides, hydroxides and purified clay minerals by the time-resolved laser fluorescence spectroscopy and X-Ray-Fluorescence spectroscopy [1, 2]. Chemical nature and structure of surface bound actinides are proposed based on spectroscopic information. Similarities of spectroscopic data obtained for M(III) sorbed onto γ-alumina, gibbsite and clay minerals suggest the formation of very comparable inner-sphere surface complexes like =S-O-\text{An(III)}(OH)_{4-(2-x)}(H_2O)_{5-x} at pH > 5. Those speciation data are found consistent with those predicted by surface complexation modelling. The applicability of data obtained for pure mineral phases to actinide sorption onto heterogeneously composed natural clay rock is investigated by experiments and by geochemical modelling.

The assessment of clay colloid borne actinide migration observed in the frame of in-situ experiments at the Grimsel underground laboratory [3] also calls for detailed information on actinide speciation. Combined spectroscopy and wet chemistry experiments provide a fairly consistent picture of the actinide speciation under given groundwater conditions and impart insight into the dynamics of actinide-colloid interaction. Notably for tetravalent actinides we observe significant impact of ageing on the rate of actinide desorption from clay colloids. Studies are ongoing to elucidate underlying mechanisms.

Above mentioned studies demonstrate the appropriateness of combining spectroscopy and wet chemistry as an appropriate strategy to validate geochemical model assumptions and to reduce uncertainties.

Microbial reduction of arsenate with sulfide as electron donor at neutral pH

JEANINE S. GEELHOED AND ALFONS J.M. STAMS

Laboratory of Microbiology, Wageningen University, Hesselenk van Suchtelenweg 4, 6703 CT Wageningen, The Netherlands (jeanine.geelhoed@wur.nl)

Arsenic is a common trace element found in most natural waters, as well as a documented human carcinogen. In the environment, arsenic occurs in the valence states As(V) and As(III). The bioavailability of arsenic is in general controlled by the presence of iron, by sorption of arsenate (As(V)) to iron minerals, and sulfide, resulting in the precipitation of arsenite (As(III)) as arsenic sulfides.

It is well known that arsenate may be microbiologically reduced under anaerobic conditions, and recently microbial reduction of arsenate coupled to the use of sulfide as electron donor was described [1, 2]. This process occurred in soda lakes, with pH 10 and high salt concentration, conditions under which sulfide is less toxic due to the virtual absence of H_2S. Chemical reduction of arsenate with sulfide has been shown to take place at acidic to neutral pH.

We investigated the possibility of biological reduction of arsenate with sulfide as electron donor at neutral pH. Batch incubations were set-up using anaerobic sediment amended with arsenate and sulfide. Arsenate was removed from solution in 5-9 days. In control experiments with autoclaved sediment, part of the arsenate in solution was removed, which may indicate relatively slow sorption of arsenate on soil particles or chemical reduction of arsenate.

Incubations in which arsenate conversion occurred were transferred to fresh culture medium several times and yielded stable enrichment cultures. In these enrichment cultures two dominant bacterial species were present. Application of molecular biological techniques showed that the two species were related to the genus Sulfospirillum and to sulfate reducing bacteria belonging to the delta-proteobacteria. We aim to isolate these two organisms in pure culture and study their physiology and ability to reduce arsenate with sulfide in more detail.

Hg accumulation in reducing sediments of the Mediterranean Sea: Trace metal and Hg isotope evidence

G.E. GEHRKE, J.D. BLUM AND P.A. MEYERS
Department of Geological Sciences, 1100 N. University Ave,
University of Michigan, Ann Arbor, MI, USA
(gegehrke@umich.edu)

Mercury (Hg) has a complex biogeochemical cycle involving multiple oxidation states with gaseous, dissolved, and particle-associated species. We investigated the effects of different redox conditions on Hg partitioning in the marine environment. We analyzed Hg concentration and isotopic composition, as well as concentrations of a suite of trace metals that are widely used as indicators of productivity and redox conditions, in sediments from a mid-Pleistocene sapropel sequence in the Tyrrhenian Basin of the Mediterranean Sea. During episodes of sapropel formation, high productivity and reducing conditions produce organic-rich sediments, with characteristic trace metal patterns. Concentrations of Hg and other metals covary with total organic carbon (TOC) content, with a Hg enrichment factor of 3.9 in high TOC sapropels versus low TOC non-sapropels. Enrichment factors determined for other elements are 1.3-2.1 for Cr, Cu and Zn; 3.0-4.9 for V, Co, Ni and U; 5.0-8.0 for Mo and Cd; and 13 for Re. Hg concentrations in these sediments are highly correlated with trace elements normally associated with organic matter delivery (Co, Ni, Cu, Zn and Cd) as well as with elements associated with enrichment in reducing sediments by mineral precipitation and adsorption occurring below the sediment-water interface (V, Cr, Mo, Re and U) (Tribovillard et al., 2006). The strong correlation between Hg and both suites of trace metals suggests that particulate scavenging and/or in situ precipitation contributes to Hg accumulation in marine sediments. If we specifically look at the variation in metal concentrations in only those samples with low TOC content deposited under oxic conditions (non-sapropel layers), we find that Hg does not covary with V, Cr, Ni, Mo, Cd, Re or U, but does covary with Co, Cu, and Zn. These patterns may be related to variations in terrigenous sediment sources or preservation of these metals in sediments.

We also explored whether Hg isotope values could provide insight into changes in Hg deposition between sapropel and non-sapropel layers. Preliminary isotopic analyses show that sapropels have lower δ²⁰⁶Hg values (Blum and Bergquist, 2007) than non-sapropel layers (-1.1‰ vs -0.7‰). This likely reflects either a change in Hg sources or isotopic fractionation during redox transformations.

Depleted uranium (DU) from penetrating ammunition was exposed to several environmental conditions in order to determine the binding forms of uranium as well as its dissolved and solid forms.

In a first series fresh disks of DU were treated with a calcium phosphate solution. The results from time-resolved laser-induced fluorescence spectroscopy clearly show that metaautunite Ca(UO₂)₂(PO₄)₂ x 2-6(H₂O) has formed during alteration [1].

In a second experiment the corrosion and leaching of used DU was investigated for three years in a column with a soil core. The columns were irrigated with synthetic rainwater.

The luminescence spectrum of a yellow material, which was crystallized at the soil surface was assigned clearly to be the mineral sabugalite AlH(UO₂)(PO₄)₄ x 16(H₂O).

In contrast to the luminescence spectra of the solid material the spectra of the uranium species in the dissolved samples could only obtained at temperatures below 220 K. From the shape of the spectrum and the emission maxima of the luminescence of seepage water samples it could be clearly concluded that the solution species are mostly uranyl carbonate species UO₂(CO₃)³⁻ [2].

NWA 2999, an angrite with unusual bulk chemistry or a new type of achondrite?

M. GELLISSEN1, H.PALME1, R.L. KOROTEV2 AND A.J. IRVING3

1Institut für Geologie und Mineralogie, Universität zu Köln, Zülpicher Str. 49b, D-50674 Köln (m.gellissen@uni-koeln.de)
2Department of Earth and Planetary Sciences, Washington University, C/B 1169, Saint Louis, MO 63130 (korotev@wustl.edu)
3Department of Earth & Space Sciences, University of Washington, Seattle, WA 98195 (irving@ess.washington.edu)

Introduction

NWA 2999 is classified as an angrite based on mineralogy and oxygen isotopes [1]. Chemical data indicate differences in bulk chemistry to other angrites, making this a unique meteorite.

Chemistry

Major elements were determined by XRF, trace elements on a different sample by INAA. For analytical procedures see [2,3]. Compared to average angrite, the Mg content is significantly higher, Si and the refractory elements Ca, Al and Ti as well as P are much lower. Unlike other angrites, NWA 2999 has abundant FeNi-metal, and corresponding levels of Ir, Au, Ni and Co.

Interpretation

Mixing calculations with average angrite composition were performed: Delivering the excess siderophiles is possible by contributing 8% of the mass by an iron meteorite. But this is unlikely, because it cannot explain the high Mg and the low Ca, Al and Ti contents.

Adding more than 60% of a primitive meteoritic component would have diluted the refractory elements to the measured values and led to the high Mg, Cr and siderophile element contents. The added component could have lost its P by metal-silicate equilibration before the metal was incorporated in NWA 2999. However the assumption of more than 60% of external matter is difficult to reconcile with the angritic oxygen isotopic data and the low contents of volatiles.

An alternative view is to take both components from the same parent body. A differentiated lithology with elevated Ti, Ca, Al and REE, but with low Mg, Cr and almost no Ni and Ir is mixed with a core-mantle component, high in Mg, Cr, Fe, Ni, Au and Ir of the same parent body. Mixing could be the result of a large impact on the APB.

Another yet possibility is an origin from a different, until now unknown parent body, which is similar to angrites with respect to mineralogy and oxygen isotopes.

Physicochemical Speciation of Iron in the Baltic Sea

JOHAN GELTING AND JOHAN INGRI

Division of Applied Geology, Luleå University of Technology, 971 87 Luleå, Sweden (johan.gelting@ltu.se; johan.ingri@ltu.se)

Size fractionated classes of Fe in surface water at two stations, one in central Baltic Sea (the Landsort Deep) and one in Bothnian Sea, were measured from spring until autumn to evaluate temporal variations in the physicochemical speciation. Membrane filtration, cross-flow ultrafiltration and DGT (diffusive gradients in thin films) were among the applied techniques. Average concentrations for total, <0.22 and <1kDa Fe were 32, 7.0 and 5.9nM respectively at the Landsort Deep. For the Bothnian Sea, these figures were 96, 21 and 6.2nM. DGT-labile concentrations of Fe were significantly lower than <1kDa at both stations. This probably indicates that a large portion of the DGT-labile Fe was organic bound, which would slow down the diffusion rate. The DGT-labile Fe concentration was on average 0.6 nM at Landsort Deep, and 1.0 nM in the Bothnian Sea. If assuming that all DGT-labile Fe was bound to fulvic acids the concentrations becomes about 5 times higher, but still lower than <1kDa. No clear trends were observed for the DGT measured concentrations. In both areas the concentration of Fe in all but the DGT-labile fraction decreased 60-80% towards end of the sampling period. Average ratios between total Fe and <0.22µm were about 4-5 at both stations, but in the Bothnian Sea also a clear difference between <0.22µm and <1kDa was observed, indicating a significant colloidal fraction. At the Landsort Deep, a peak of <1kDa Fe was evident in end of July, despite stable total concentrations during the summer. A small peak of <1kDa Fe was also observed in the Bothnian Sea, but not as clear as in Landsort. These peaks coincide with drops in biomass, indicating that this is a mineralization event. We hypothesize that the difference in concentration between DGT-labile and <1kDa is caused by organically bound species that are influenced by the presence of phytoplankton.
Imperfect accretion during the giant impact stage of terrestrial planet formation

H. GENDA1, E. KOKUBO2 AND S. IDA3

1Research Center for the Evolving Earth and Planets, Tokyo Institute of Technology, Tokyo, Japan (genda@geo.titech.ac.jp)
2Division of Theoretical Astronomy, National Astronomical Observatory of Japan, Tokyo, Japan (kokubo@th.nao.ac.jp)
3Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan (ida@geo.titech.ac.jp)

In the standard scenario of planet formation, terrestrial planets are formed in two stages: the formation of several tens of Mars-sized protoplanets through accretion of planetesimals, and collisions among these protoplanets (called giant impacts). Although the nature of giant impacts determines the final masses, spin parameters, and orbital elements of the terrestrial planets, all the previous N-body simulation of terrestrial planet formation (e.g., Chambers 2001, Raymond et al. 2004, Kokubo et al. 2004) have been based on the assumption of the perfect accretion, that is, colliding two protoplanets always merge without mass loss. Agnor and Asphaug (2004) performed 48 SPH simulations for mutual collision of 1 Mars-mass protoplanets. They showed that the two protoplanets bounce and escape to infinity for collision with relatively faster impact velocity (e.g., > 1.4 × escape velocity for 30 deg of the impact angle), and they estimated that more than roughly half of giant impact events are not coalescence events.

In order to incorporate the effect of imperfect accretion into N-body simulations, we need to know the accretion condition for various types of giant impacts. Using the specialized computers for gravitational N-body problems (GRAPE), we performed more than 1000 runs of impact SPH simulations for various mass ratios (γ), impact angles (ξ), and impact velocities (vinp). From the results of more than 1000 runs, we formulated the boundary of vinp between coalition and rebound as parameters of γ and ξ. We also formulated the mass(es) and orbit(s) of post-impact planet(s).

We applied the above formulation to the impact events obtained by Kokubo et al. (2006), and found that 261 out of 635 giant impacts, that is 41%, are not coalescence events. We will also report the effects of imperfect accretion on the final states of the terrestrial planets such as the largest mass and rotation velocity.

Isotopic evidence for Silicon within the Earth’s core

R.B. GEORG1,2, A.N. HALLIDAY3, E.A. SCHAUß3 AND B.C. REYNOLDS1

1ETH Zurich, Department of Earth Sciences, Isotope Geology, Zurich, Switzerland (bastian.georg@earth.ox.ac.uk, reynolds@erdw.ethz.ch)
2University of Oxford, Department of Earth Sciences, Oxford, UK (Alex.Halliday@earth.ox.ac.uk)
3University of California Los Angeles, Department for Earth and Space Sciences, Los Angeles, USA (schauble@ucla.edu)

We present the first isotopic evidence for Si within the Earth’s Core. It has long been proposed that the Earth’s core must contain significant quantities of light elements, such as H, C, Si, S and K [1]. The high Mg/Si of the terrestrial mantle has been used to argue that Si in particular is an important component in the core [e.g 2]. Recent estimates indicate that it contains as much as 5–7 wt% [e.g 3], and the partitioning of Si into the metallic core should yield isotopic effects because of differences in bonding of Si between metals and silicates.

We analysed the Si isotope compositions for different bulk silicate reservoirs of the solar system as sampled by chondrites, basaltic achondrites thought to come from Vesta and Mars, and basaltic rocks from the Moon and the Earth’s mantle. The mean values of these reservoirs obtained for this study are in excellent accord with previous estimates, however, the spread in the data is an order of magnitude lower. A significant difference is found between the bulk silicate Earth (BSE) and Moon on the one hand and meteorites on the other.

It appears unlikely that this observed Si isotope shift can be produced by volatilisation processes during the early accretion history of the Earth. Rather, the observed Si isotope shift was probably produced during Si partitioning into the Earth’s core. We modelled the potential Si isotope fractionation during silicate-metal partitioning and can show that both the direction and magnitude of such fractionations are consistent with the observed isotopic differences between BSE/Moon and meteorites.

Resolving the evolution of a subduction zone: Eastern Srednogorie, SE Europe

S. GEORGIJEV1, A. VON QUADT1, P. MARCHEV2, C.A. HEINRICH1 and I. PEYTCHEVA1,3

1ETH Zurich, IGMR (georgiev@erdw.ethz.ch; vonquadt@erdw.ethz.ch; heinrich@erdw.ethz.ch)
2Geological institute, BAS, Sofia (pmarchev@geology.bas.bg)
3CLMK, BAS, Sofia 1000 (peytcheva@erdw.ethz.ch)

Eastern Srednogorie zone is the easternmost part of the mineralized ABTS (Apuseni-Banat-Timok-Srednogorie) belt in SE Europe. This belt is a former Late Cretaceous island arc that was formed during the process of northward subduction of the Tethyan ocean beneath the European platform. Compared to the other parts of the belt, magmatic products exhibit the most variable composition. However, the zone is the least studied, and here we present new geochronological, isotope and geochronological data with the aim to understand the genesis of the magmatism. We try to isolate the most primitive initial magmas that fractionated and assimilated parts of the crust to produce the abundant Late Cretaceous magmatism, and to trace the across-and along-arc change in the age and composition of the magmatism.

Magmatic products in the Eastern Srednogorie show the entire spectrum of rocks typical for island-arc environments. Based on their chemical composition three main regions are subdivided from south to north; (1) tholeiitic to calc-alkaline, basic to acid intrusives in the southern; (2) predominantly potassic to ultrapotassic mafic-intermediate volcanics in the central (3) calc-alkaline basic-intermediate volcanics in the northern part. Trace and REE distribution patterns argue for subduction related magmatism for all rock varieties.

TIMS and LA-ICPMS dating of single zircon grains shows that magmatic activity started at about 86 Ma with few intrusions but the climax of the magmatism was in the Campanian (81-78 Ma). Whole-rock Pb and Sr isotopes of most mafic magmas show the least radiogenic compositions (87Sr/86Sr of 0.7040, 206Pb/204Pb 18.38, 207Pb/204Pb 15.57 and 208Pb/204Pb, 38.27). These values are less radiogenic compared to Late Cretaceous magmatic rocks of the adjacent Central Srednogorie zone. In addition, the majority of the analysed rocks contain Cretaceous zircons with positive εHf at 80 Ma (from 0 to +12), suggesting a mantle-dominated origin. However, these rocks contain variable amounts of inherited zircons with negative, crustal-like εHf at 80 Ma This fact clearly show that the rocks suffer some contamination by crustal-derived lithologies. The amount of crustal contamination increases with time. Potential candidates for the contaminants are the Carboniferous and Permian basement rocks, as revealed by the U-Pb single zircon ages of the inherited crystals. The DM model Hf ages of inherited zircons and zircons from the basement rocks cluster around 900 Ma.

Chronological history of UHP rocks from the Chinese Continental Scientific Drilling: A multi-methodical approach

AXEL GERDES1, FULAI LIU2, STEFAN WEYER1 and GERHARD BREY1

1Institute of Geosciences, Mineralogy, J. W. Geoth University, Frankfurt 60438 (gerdes@em.uni-frankfurt.de)
2Institute of Geology, Chinese Academy of Geological Science, Beijing 100037 (liufulai@ccsd.cn)

Ultrahigh pressure (UHP) rocks from the Chinese Continental Scientific Drilling (CCSD) program were chosen to study the Sm-Nd and Lu-Hf isotope systems in combination with U-Pb LA-ICP-MS and SHRIMP dating of distinct zircon domains. Comprehensive studies of the different lithologies on various sections of the drill hole should provide a better understanding of the metamorphic evolution of the Sulu terrane. Additionally, our multi-methodical approach provides the opportunity to compare the different chronometers and test their robustness and limitations (e.g. mineral inclusions, incomplete equilibration, resetting). Multistage zircon growth can be observed in most Sulu-Dabie UHP rocks. Inherited and metamorphic zircons were distinguished on the basis of transmitted light microscopy, cathodoluminescence (CL) imaging, trace element contents, Hf isotope composition and mineral inclusions. Inherited zircon of middle Neoproterozoic age have variable trace element pattern that are considerably different from that of metamorphic zircon domains. Based on CL, mineral inclusion and U-Pb ages up to three phases of Triassic zircon growth or re-crystallisation can be identified in a single sample. The ages are interpreted to date the time of (1) prograde and (2) UHP metamorphism during subduction, and (3) later retrograde metamorphism during exhumation.

Metamorphic domains from a single sample have commonly a uniform Hf isotope composition indicating isotope equilibration in the decimetre-scale during the Triassic UHP event. This composition varies between different samples and is generally significantly more radiogenic than that of the inherited cores and thus the bulk rock. Its respective value is controlled by the percentage of dissolved or re-crystallized inherited zircon, with low Lu/Hf and relatively unradiogenic 176Hf/177Hf, and the bulk rock composition.

Analyses of the Lu-Hf and Sm-Nd system of mineral separates (garnet, clinopyroxene ...) are currently in progress. According to SHRIMP and LA-ICP-MS U-Pb ages of metamorphic zircon from the same and various other UHP rocks ([1-3] and references therein) lasted the metamorphic evolution of the Sulu-Dabie terrane around 30 Myr, with about 20 Myr of HP or UHP metamorphism.

3Department of Earth Sciences, The Open University, Milton Keynes, MK7 6AA, UK

Furnas is the easternmost of the three active trachytic central volcanoes on the island of São Miguel, Azores. It is regarded as one of the most active and dangerous volcanoes in the Azores archipelago owing to a population of several thousand people living within the caldera and in the immediate vicinity of the volcanic complex. Throughout its history, volcanic activity at Furnas has been essentially explosive but eruptive styles have varied from mild effusive activity to at least two caldera-forming eruptions ~30,000 and 12,000-10,000 years BP [1].

During the past 5,000 years, ten explosive eruptions occurred at Furnas, which produced a total of ~0.9 km$^3$ (DRE) of fairly homogeneous trachytic magma. The deposits of these eruptions are collectively referred to as Furnas A-J members of the Upper Furnas Group [1,2]. The latest eruption (Furnas J) occurred after the settlement of the Azores archipelago in 1630 AD. Eruptions of the Upper Furnas Group were mainly characterised by alternating episodes of magmatic and phreatomagmatic activity producing deposits of interbedded ash and lapilli that overlie the widespread Fogo A deposit from adjacent Fogo volcano [3]. At least three of these eruptions, namely Furnas E, Furnas I and the 1630 AD event (Furnas J), were accompanied by trachyte dome extrusion in the final phases of the eruption [3].

To develop a fuller understanding of the underlying dynamics of the magma system of Furnas, we have investigated the whole-rock major and trace element geochemistry of the products of the Upper Furnas Group and the older caldera-forming events. These data are discussed together with U-Th-Ra isotopic disequilibria obtained on trachyte pumice clasts and lavas to place constraints on the dynamics and longevity of the magma system of Furnas.

Designing a dissimilatory iron reducer. Reconstitution of the Fe(III)-reducing electron transport chain of Shewanella oneidensis MR-1 in Escherichia coli

J. GESCHER2, C. CORDOVA-ARDY1 AND A. SPORMANN1

1Dept. of Civil and Environmental Engineering, Stanford University, Stanford, USA (spormann@stanford.edu)
2Universitaet Freiburg, Institut fuer Mikrobiologie, Freiburg, Germany (johannes.gescher@biologie.uni-freiburg.de)

Shewanella oneidensis uses several electron acceptors to support anaerobic respiration including soluble species and remarkably insoluble species such as iron(III) and manganese(IV) oxides. The pathway of electron flow from the cytoplasmic membrane to the outer membrane remains elusive after years of research with different Shewanella species. We are pursuing a novel approach to identify the essential components of the electron transport chain by reconstituting the pathway for iron(III) reduction by S. oneidensis in Escherichia coli. We generated a suitable E. coli strain as a platform for this work and integrated the central electron transfer protein, CymA into the genome. CymA allows for electron transfer from the cytoplasmic membrane to the periplasmic space in Shewanella species. We showed (i) that the expressed CymA activity is growth supporting for E. coli, (ii) that CymA couples directly to the soluble fumarate reductase of S. oneidensis, and (iii) that CymA in vitro facilitates reduction of ferric citrate and the soluble quinone analog AQDS. Our generated E. coli strain is a dissimilatory iron reducer in that it can use ferric-NTA as a terminal electron acceptor during growth with glycerol as the sole carbon and electron source. We could furthermore show through in vitro assays that a direct interaction between CymA and the periplasmic decaheme cytochrome MtrA from S. oneidensis is possible.
Magma mixing and mingling textures and geochemistry of microgranular enclaves in granitoids of SE Semnan, N Iran

G. GHORBANI
Faculty of Earth Sciences, Damghan University of Basic Sciences, Damghan, Iran (ghasemghorbani@yahoo.com)

Discussion

Many granitoid intrusions display textural and geochemical evidence for the intrusion of mafic and silicic magmas during their genesis [1]. The post-middle Eocene granitoids from SE Semnan, N Iran have many fine grained mafic microgranular enclaves, with diameters between 1 to 15 cm. Their composition varies from monzonite, quartzmonzodiorite – monzodiorite and monzogabbro – and exhibits evidence for magma mixing and mingling both at outcrop and at thin sections. These textures are antarapakivi feldspars, acicular and prismatic apatites, inclusion of mafic zones in feldspars, spongy cellular plagioclase, reverse zoning in plagioclases and etc.. In host granitoid rocks there are also two types of biotites in composition (that one types have high TiO2, Al2O3, MgO and low SiO2, are similar to contents of these elements in mafic microgranular enclaves and second types are depleted in TiO2, MgO and enriched in Al2O3 and SiO2) and reverse plagioclases zoned. The magmatic origin of enclaves is suggested by their typical igneous textures, such as with abundant acicular apatite, elongate zircon, the euhedral form of the mafic phases, porphyritic texture and plagioclase zoned [2]. These observations suggest that the mafic microgranular enclaves are derived from a hybrid magma formed as a result of the intrusion of mafic magma into the base of a felsic magma chamber.

Conclusions

The mafic microgranular enclaves have igneous mineralogy and textures. The petrographic, chemistry of minerals and whole-rock geochemical relations, in the mafic microgranular enclaves and their host rocks, indicate that magma mixing and mingling played a important role during their evolution.

Carbonate clumped isotope thermometry of molluscs and its applications to Pleistocene gastropod fossils from South Dakota

P. GHOSH1, J. EILER2 AND S. PETERSEN3
1Department of Environmental Chemistry and Engineering, Tokyo Institute of Technology, Japan (ghosh.p.aa@m.titech.ac.jp)
2eiler@gps.caltech.edu
3sierra.petersen@gmail.com

Ghosh et al., (2006) [1] present a carbonate clumped isotope palaeo-thermometer. Otolith aragonite from fishes collected over a range of known temperatures [2] validates the original calibration of this thermometer for inorganic calcite precipitate (ICP) and coralline aragonite [1]. Here we present a calibration for molluscs, including gastropods collected from nature and inferred to have grown at widely different temperatures (2-25°C). The growth temperatures for these samples were estimated based on mean annual temperature (MAT) at the site of collection. We speculate that these growth temperature estimates could be biased by unknown and possibly variable amounts to due seasonality of growth and/or other factors. Despite these uncertainties, the mean trend in the relationship between inferred growth temperature and 47 is the enrichment, in per mil, of 13C-18O-16O in CO2 relative to 12C-16O-16O. 

The proportionality for molluscs can be described between 18O of rainfall from the same area. Our results suggest that the statistically indistinguishable and more precisely known trend for ICP should be used for molluscs.

We apply the carbonate clumped isotope thermometer to gastropods (Physella) deposited concurrently with mammoth skeletons in a sinkhole deposit in South Dakota, USA. The age of deposition of the analyzed samples was 26,075 ± 880 years BP, based on 14C dates for bone apatite collected from the same strata [5]. We analyzed aragonite powder from 15 Physella shells collected from various depths across a 255 cm vertical section from this location. Our results provide an estimate of 31.2 ± 3.34°C for the average temperature of water at the time of deposition. The average δ18O value of sinkhole water was (calculated assuming an equilibrium fractionation of 18O between carbonate and water [6]) -0.0496, where 47 = the enrichment, in per mil, of 13C-18O-16O in CO2 relative to the amount expected for a stochastic (random) distribution of isotopes among all CO2 isotopologues [3,4], and T is the temperature in Kelvin. However, due to scatter in these new data, we suggest that the statistically indistinguishable and more precisely known trend for ICP should be used for molluscs.

Ground water is a potential source of methane (CH$_4$) in Arsenic affected area of Bengal Basin. Harvey et al. (2002) observed high CH$_4$ concentration in the water with high As abundances at depth and predicted increase in CH$_4$ concentration during dry seasons. We present our study on tube well water samples collected during dry season (middle of February 2007) from two different localities in West Bengal, belonging to two different palaeodrainage systems i.e. Bhagirathi Ganges delta (BL) and Damodar river fan delta (BG) (tributary of river Bhagirathi) (Acharyya and Shah, 2007). Many of these wells were previously studied for As concentration (Acharyya and Shah, 2007).

CH$_4$ and $\Sigma$CO$_2$ present in the water samples were analyzed for carbon isotopic ratios to trace the sources of carbon to the ground water. Most of the samples analyzed for $\Sigma$CO$_2$ in this study have $\delta^{13}$C in the range -10.8‰ to -13.5‰, suggesting that the CO$_2$ in these samples originate from silicate weathering with CO$_2$ from vegetation ($C_3$ type). Barring one sample, we saw two distinct clusters of $\delta^{13}$C values in CH$_4$: -74.9 ‰ to -87.5 ‰ for BL water compared to a range of -30.5 to -40.2 ‰ in BG water. Isotopic signatures suggest a predominance of the carbonate reduction pathway in BL sites and high activity of CH$_4$ oxidation or substrata depletion in BG sites. Our preliminary results suggest that the process of release of arsenic from hydrated iron oxide is triggered by the activities of anaerobic bacteria in a reducing environment with consequent production of CH$_4$ with distinctly depleted isotopic character.

We also observed an anomalous enrichment of $\delta^{13}$C value (+55 per mil) in one of the samples with low CH$_4$ concentration from BL locality.

Nanoscale size effects on reduction of hematite nanoparticles and surface reactions of Uranium(VI)

DANIEL E. GIAMMAR, BEIZHAN YAN, HUI ZENG, BRIAN WRENN, SOUBIR BASAK AND PRATIM BISWAS

Department of Energy, Environmental and Chemical Engineering, Washington University, St. Louis, Missouri 63130, USA (giammair@wustl.edu; yan@seas.wustl.edu; zh@cec.wustl.edu; bwrems@seas.wustl.edu; SBasak@wustl.edu; Pratim.Biswas@seas.wustl.edu)

The high surface area to mass ratios of hematite nanoparticles can increase the extents of surface reactions that affects the environmental biogeochemistry of pristine and contaminated environments. Surface reactions of interest include adsorption and surface-mediated reduction. Microbial iron reduction can produce Fe(II), which, when adsorbed to Fe(III) oxides, is an effective reductant of contaminants including uranium(VI). In order to understand nanoscale effects on the rate of microbial iron reduction and surface-mediated uranium(VI) reduction, hematite nanoparticles with diameters of 8, 50, and 200 nm were synthesized using gas phase methods that provide control of their composition and sizes.

The microbially-mediated rate of hematite reduction by the iron-reducing bacteria Geobacter sulfurreducens has been studied in anaerobic batch experiments. Abiotic reductive dissolution rates using ascorbic acid and the reduced form of the electron shuttle AQDS have also been studied. The dissolution rates increase with decreasing particle size; however, when normalized to surface area, the dissolution rates are similar for all but a few conditions.

Uranium(VI) adsorption to the three sizes of hematite particles was evaluated over the range of pH (3-11) and total uranium concentration ($10^{-6}$ to $10^{-4}$ M) to elucidate the size dependence of U(VI) adsorption to hematite. All experiments were conducted in a CO$_2$-suppressed glovebox to prevent the formation of dissolved U(VI)-carbonate complexes, which can affect U(VI) adsorption. Surface complexation modeling was used to provide a quantitative reaction-based framework for evaluating the effects of particle size on adsorption. A model was developed that can predict U(VI) adsorption over a range of pH values and total U(VI) loadings.

Rates of U(VI) reduction by adsorbed Fe(II) were investigated in batch experiments. Reduction is interpreted as a pseudo-first-order reaction with respect to the activity of the adsorbed U(VI) with an excess of Fe(II) relative to U(VI). At each sampling time, a portion of the suspension was filtered and analyzed for dissolved iron and uranium using ICP-MS. Additional portions of the suspension were chemically treated for the extraction of total U(VI) and Fe(II). Selective extraction of U(VI) uses 0.1 M NaHCO$_3$ while that of Fe(II) uses 0.5 M HCl. The concentration of Fe(II) was subsequently measured using the ferrozine method.
Tracking CO₂ leakage with noble gases

SOPHIE GIANNESINI¹,², ALAIN PRINZHOFER¹,², MANUEL MOREIRA¹ AND CAROLINE MAGNIER²

(alain.prinzhofer@ifp.fr, caroline.magnier@ifp.fr)

The geological storage of greenhouse gases such as CO₂ in saline aquifers is an active research topic. By this way, effects of these gases on the environment may be significantly reduced. One limiting parameter of this type of storage is actually the hypothetical CO₂ leakage through the caprocks. Some studies of natural CO₂ gas fields have shown that noble gases are able to trace CO₂ origins and physical processes which have occurred in the subsurface (Gilfillan, 2006). Unfortunately, the migration of noble gases through low permeability media is still poorly constrained.

Here, we describe experimental results concerning the diffusion of gases through different porous clayey media. The experimental setup is a diffusion reactor composed of two gas reservoirs separated by a water saturated clay membrane. Initially, one side is filled with CO₂ mixed with trace amounts of noble gases (He, Ne, Ar, Kr and Xe), the other side is filled with pure oxygen to equilibrate pressures on both sides of the membrane.

Unexpectedly, diffusion of CO₂ is faster than those of He and any of the other noble gases. This result points to the effect of the solubility in the migration process, allowing CO₂ to migrate faster as it is highly soluble in water. In addition, in clay rocks, the “bound water” plays a role in this migration because solubility and diffusion factors contrast with those associated with “free water”. We used a 2D diffusion model at the pore scale (Kara, 2004) to determine diffusion and partition coefficients of noble gases between free and bound water as a function of petrographical parameters (mineralogy, porosity, tortuosity). The behavior of noble gases during a diffusion process will be presented in order to highlight the main parameters likely to control their migration.

A δ¹³C depth gradient from a mid-Cryogenian platform margin: Evidence for Neoproterozoic ocean stratification

J.A. GIDDINGS AND M.W. WALLACE
School of Earth Science, University of Melbourne, Parkville, Victoria, 3010, Australia

A δ¹³C depth gradient of at least 8‰ between shallow and deep water is evident in Neoproterozoic carbonates from the Umberatana Group in the northern Adelaide Fold Belt, South Australia. The progradation of an extensive mid-Cryogenian platform margin allows direct isotopic comparison between shallow-water reef carbonates and synchronous deep-water slope and basinal sediments. With over 1 km of relief this platform margin allows an estimation of seawater δ¹³C in the upper 1000-1400 m of the water column.

We suggest that the observed δ¹³C gradient is the result of poor ocean circulation brought about by salinity stratification that persisted at least for the progradational history of the Oodnaminta platform margin. Such conditions enhanced the effect of the ‘biological pump’ by drawing ¹²C out of the surface ocean and accumulating it in the deep ocean. After prolonged stratification, the vertical δ¹³C gradient increased to the observed magnitude.

Furthermore, we propose that stratification was persistent throughout Neoproterozoic time, and can explain many of the unusual features that characterise this era – large-scale δ¹³C variation, extreme climatic fluctuations, and the presence of cap carbonates. Stratification creates an unstable climate system in which gradual accumulation of CO₂ in deep waters eventually leads to global glaciation due to the lack of deep ocean ventilation. Subtle changes in ocean circulation ventilate the deep ocean and rapidly transfer large amounts of CO₂ to the surface ocean and atmospheric reservoirs, leading to greenhouse temperatures, and facilitating rapid global deglaciation and cap carbonate deposition. Additionally, oxygen accumulated in the surface ocean and atmosphere during prolonged periods of stratification may have triggered the evolution of the Ediacaran fauna during the terminal Neoproterozoic.

The results also imply that the use of carbon isotope chemostratigraphy as a high-resolution chronostratigraphic correlation technique for the Neoproterozoic may be invalided by evidence for strong facies-dependant δ¹³C variation.
Metal sulfates in PM emissions from a coal-fired power plant

R. GIERÉ¹, M. BLACKFORD², K.L. SMITH², H. LI³, C.T. WILLIAMS³ and C. KIRK³

¹Mineralogisch-Geochemisches Institut der Universität, D-79104 Freiburg, Germany (giere@uni-freiburg.de)
²Materials and Engineering Science, ANSTO, Australia
³Department of Mineralogy, The Natural History Museum, SW7 5BD London, UK

Coal combustion facilities represent a major source of fine particulate matter (PM) in the atmosphere. The particle-capture efficiency of air pollution control devices is size-dependent, and is considerably lower for particles with diameters <2.5 micrometers (PM2.5) than for larger ones. These particles are thus emitted preferentially and, moreover, exhibit relatively long atmospheric residence times. To assess the environmental and health impacts of such PM, it is necessary to obtain information about its mineralogical composition.

We report results from SEM, TEM and XRD investigations on PM emitted from a stoker boiler. The samples, collected on filters placed in the smokestack above all air pollution control devices, represent PM that would have escaped into the atmosphere. Our study demonstrates that these fugitive particles in the PM2.5 fraction consist of amorphous material (Al-Si-glass, soot, native Se) and a variety of crystalline phases, including lime, mullite, and various euhedral metal sulfates. Electron diffraction patterns and chemical compositions obtained by quantitative analytical TEM revealed the presence in the PM of the following sulfates (Gieré et al. 2006): anglesite (PbSO₄) as main host of Pb; anhydrite (CaSO₄); gymnite (ZnSO₄·H₂O); and yavapaite (KFe(SO₄)₂), a mineral that is exceedingly rare in the geosphere. In the larger size fraction, we have identified the following additional phases: voltaiite and zincovoltaiite - Kₓ(Fe²⁺,Zn)ₓ(Fe³⁺,Al)ₓ(SO₄)ₓ·18H₂O, millosevichite - Alₓ(SO₄)₂, meta-aluminite - Alₓ(SO₄)(OH)ₓ·5H₂O, and tamarugite - NaAl(SO₄)ₓ·6H₂O.

It is concluded that most of these metal sulfates were precipitated from the flue gas, that large quantities of these phases may be emitted globally into the atmosphere through combustion processes, and that they have, through hydration and dissolution, a major environmental and health impact.

Comparative apatite fission track study of conventionally versus selFrag Lab fragmented samples

J. GIESE¹, D. SEWARD², E. GNOS³ AND D. KURZ⁴

¹Geological Institute, University of Bern, Switzerland (giese@geo.unibe.ch)
²Geological Institute, ETH Zurich, Switzerland (diane.seward@erdw.ethz.ch)
³Muséum d'histoire naturelle, Genève, Switzerland (Edwin.Gnos@ville-ge.ch)
⁴Geological Institute, University of Bern, Switzerland (kurz@geo.unibe.ch)

Geochronological dating methods like apatite fission track analysis require an efficient liberation of single mineral grains for analysis. The selFrag Lab machine (produced by Amman AG, Langenthal, Switzerland) disaggregates geological materials by releasing short pulsed high-voltage discharges to an in water immersed sample. The produced, fast-expanding plasma channel induces shockwaves, similar to an explosion, that propagate through the sample. Refraction at discontinuities like grain boundaries, crystal internal surfaces or fluid inclusion trails results in selective break-up of the aggregate, yielding natural shaped homogeneous grains (Gnos et al., 2006 and references therein). However the HV-discharge may also produce local temperature peaks of up to 10'000°C of very short duration within the narrow plasma channel. Does this heat production affects fission tracks in apatite? Test were conducted to control whether this very localized heat production leads to partial fission track annealing starting at approximately 60°C. Prolonged exposure to temperatures exceeding 110°C would result in a complete reset of the apatite fission track record. Hence, any temperature impact on the apatite during processing could change the resulting fission track data.

Therefore a comparative study using two different samples, prepared by conventional and selFrag Lab processing, has been performed in order to investigate a possible influence of the selFrag Lab disaggregation method on apatite fission tracks.

Both investigated samples, a granitoid gneiss from Madagascar, and the Fish Canyon Tuff, a frequently used age standard in geochronology, yield statistically identical track length distributions when comparing conventional and selFrag Lab separation methods. This study yields a first confirmation that selFrag Lab processing does not cause annealing under the applied machine settings and seems to provide an alternative method for rock disaggregation for apatite fission track analysis.

Surface and electronic structure effects on interfacial charge transfer at iron oxide nanoparticle surfaces

BENJAMIN GILBERT
Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720 (bgilbert@lbl.gov)

Transition metal oxides and oxyhydroxides form important reactive nanomaterials in certain terrestrial environments. There is considerable interest in defining and understanding nanoparticle reactivity with respect to (bio)geochemical processes, but the task is challenging due to the complex interplay of structural and chemical properties in nanoscale solids. Iron oxide and oxyhydroxide nanoparticles are of particular importance, participating in redox cycles driven by (bio)geochemical processes including inorganic precipitation, (photo)reduction and microbial metabolism. The reductive dissolution of such nanoparticles is an important link between biological and mineral geochemistry. For example, dissimilatory iron reducing bacteria use fine grain iron oxyhydroxide nanoparticles as terminal electron acceptors during anaerobic carbon respiration. Interfacial electron transfer is a key step in such reductive transformations, and is highly sensitive to the interaction between the electron donor and the surface and electronic structure of the substrate.

Soft x-ray spectroscopy can reveal the electronic structure of semiconductor minerals [1] and nanoparticles [2] and is anticipated to be a versatile method for predicting the thermodynamic basis of charge transfer at nanoparticle surfaces. Nanoscale iron oxide and oxyhydroxide nanoparticles exhibit modified electronic structure [2] that would alter the ability of surface adsorbed electron donors to drive reductive dissolution. However, aqueous chemistry studies that attempt to validate these predictions are difficult to interpret on the basis of the x-ray spectroscopy data alone.

We discuss ways to distinguish (i) the thermodynamic and kinetic controls on iron oxide nanoparticle reduction and (ii) the electronic and structural causes of modified reactivity. Optical and infrared spectroscopy do not detect differences in the binding of bidentate organic ligands to iron oxide bulk and nanoparticle surfaces, suggesting a minor effect of modified surface structure. However, deviations from the anticipated the pH-dependence of photoreactivity [3] suggests there may be considerable heterogeneity in nanoparticle redox behavior.

Phosphoric acid fractionation factors for aragonite between 25 and 72°C with implications on aragonite-calcite oxygen isotope fractionation

H.A. GILG1, H. TAUBALD2 AND U. STRUCK3

1Lehrstuhl für Ingenieurgeologie, Technische Universität München, 80333 München, Germany (agilg@tum.de)
2Institut für Geowissenschaften, Universität Tübingen, 72074 Tübingen, Germany (taubald@uni-tuebingen.de)
3Museum für Naturkunde, Humboldt-Universität Berlin, 10099 Berlin, Germany (ulrich.struck@museum.hu-berlin.de)

We determined the intramolecular kinetic oxygen isotope fractionation between CO2 and CO32- during reaction of phosphoric acid with aragonite and calcite between 25 and 72°C. We analyzed clear single aragonite crystals from Bilina (Czech Republic), Leogang (Austria), and Agrigento (Italy), a fine-grained coralliform aggregate from the Styrian Erzberg (Austria), and for comparison calcite NBS-19. The aragonites show a wide range of total oxygen isotope values from 17.5 to 39.5‰ (VSMOW). Our result for NBS-19 (28.76‰ VSMOW) is within 0.12‰ of the recommended value.

The oxygen isotope fractionation between acid-activated CO2 and aragonite at 25°C expressed as a 1000ln value is consistent for our samples with 11.14 ±0.20‰ (n=4). Our new value is significantly larger than the commonly applied values of 10.34 or 10.20 (Sharma and Clayton, 1965) and our new value for calcite NBS-19 (10.08‰), but is similar to those of synthesized aragonite reported by Kim and O’Neil (1997). At temperatures between 25 and 72°C, the phosphoric acid fractionation (PAF) of aragonite can be expressed as:

\[ 1000\text{ln} \alpha_{\text{PAF}} = 5.32*(1000/T[K]) + 5.07 \]

Our results imply that the published equilibrium 18O/16O fractionation factors between aragonite and water (e.g. Kim et al. 2006) need to be revised. Considering our new acid fractionation factors, oxygen isotope fractionation between aragonite and calcite is very small (~0.2‰) as suggested by recent theoretical calculations (Schäuble et al. 2006).

Geothermometry of oxidized Zn-Pb ores: Oxygen isotope systematics and a new femtosecond laser technique on monophase fluid inclusions

H.A. GILG1, Y. KRÜGER2, P. STOLLER3, M. FRENZ3 AND M. BONI4

1Lehrstuhl für Ingenieurgeologie, Technische Universität München, 80333 München, Germany (agilg@tum.de)
2LFA - Labor für Fluideinschluss-Analytik, Cäcilienrain 3, 3007 Bern, Switzerland (lfa@fluidinclusion.ch)
3Institut für Angewandte Physik, Universität Bern, 3012 Bern, Switzerland (patrick.stoller@iap.unibe.ch, martin.frenz@iap.unibe.ch)
4Dipartimento di Scienze della Terra, Università di Napoli “Federico II”, 80134 Napoli, Italy (boni@unina.it)

We studied the 18O/16O systematics of carbonate minerals from supergene oxidized Zn-Pb deposits and from submarine alteration of ancient slags to constrain oxygen isotope fractionation factors for smithsonite, cerussite, and phosgenite. The temperature dependence of oxygen isotope fractionation between Pb and Zn carbonate minerals and water below 100°C can be expressed as

\[
1000 \ln \alpha_{\text{cerussite-water}} = 2.29 \left(10^6 / T[K]^2\right) - 3.56
\]

\[
1000 \ln \alpha_{\text{smithsonite-water}} = 3.10 \left(10^6 / T[K]^2\right) - 3.50
\]

\[
1000 \ln \alpha_{\text{phosgenite-water}} = 2.55 \left(10^6 / T[K]^2\right) - 3.50
\]

Average formation temperatures of the studied supergene deposits (SW Sardinia, E Belgium, Broken Hill district, Australia, and others) are calculated to be 20 ± 5°C using the estimated isotope compositions of local paleometeoric waters.

We also applied a new technique using a femtosecond laser to nucleate the vapor bubble in monophase fluid inclusions. Homogenization temperatures of inclusions in cerussite and hemimorphite from the same deposits range from +6.1 to +25.5°C and confirm our stable isotope results.

New fluid inclusion and oxygen isotope data from willemite-bearing oxidized Pb-Zn ores from E Belgium and S Portugal, however, suggest that certain mineralization stages in these districts were formed by distinct low-temperature (<50°C) hydrothermal systems involving saline fluids.

Thus, oxygen isotope and fluid inclusion data for base metal carbonate minerals can be used to distinguish ores produced by weathering from very-low-temperature hydrothermal ores. They may also provide valuable paleoclimatic information.

Organic geochemical assessment of the onset of an Oceanic Anoxic Event

A.S. GILL1, H. VELD2 AND T. BEHRENDSD1

1Faculty of Geosciences, Utrecht University, Utrecht, The Netherlands (a.s.gill@students.uu.nl; behrends@geo.uu.nl)
2TNO Built Environment and Geosciences, Princetonlaan 6, Utrecht, The Netherlands (harry.veld@tno.nl)

A geochemical study was conducted on cored Posidonia Shale sections and underlying sediments derived from two wells located in the southern North Sea offshore the Netherlands. Samples were subjected to a variety of analytical techniques including CS analysis, Rock Eval pyrolysis, GC-MS and carbon and sulphur isotope analysis. It is well established that the Posidonia Shale (Early Toarcian) is marked by the deposition of organic-rich shales throughout Europe as a result of an Oceanic Anoxic Event (OAE). Our data provides evidence that establishment of these anoxic conditions is a gradual process from sediment anoxic conditions into true anoxia within the Posidonia Shale. This is indicated by the depth profile of most of the measured parameters. The values of sulphur content, TOC, hydrogen index, Ts/Tm ratio and pristane/phytane ratio gradually increase in the underlying sediments with decreasing depth towards the Posidonia Shale. Within the Posidonia Shale the values of those parameters remain constant.

The carbon isotope data show a negative excursion within the Posidonia, in agreement with earlier reports. This indicates that OAE might have been a global event. Our research focuses, among others, on the question whether this proto OAE development can be recognised throughout the basin.

![Figure 1: Illustration of the carbon isotope excursion (approximately 7 ‰) in the Posidonia Shale (shaded region)](image-url)
Oceanic hornfels: Records of heat transport near axial magma chamber roofs

KATHRYN GILLIS
School of Earth and Ocean Sciences, P.O. Box 3055, University of Victoria, Victoria, BC CANADA V8W 3P6 (kgillis@uvic.ca)

The transfer of heat from the lower to upper ocean crust is the most fundamental process shaping the morphology of mid-ocean ridges and determining the mechanism of accretion of the lower crust. At fast-spreading mid-ocean ridges, the heat that drives high temperature hydrothermal systems is focused at the top of axial magma chambers (AMCs) that reside 1–2 km beneath the seafloor. Theoretical models predict that heat is exchanged across thin (<100 m), hot (>650°C), impermeable conductive boundary layers (CBLs) sandwiched between AMCs and permeable upper crust. The thickness of the CBL is predicted to vary with time, in response to magmatic activity and would have a finite life that is dependent upon the longevity of an AMC. Thus, CBLs are not static features, but rather should vary in thickness and position, depending on the magma supply and frequency of diking. While conceptually robust, there is sparse evidence in support of these predictions, perhaps because CBLs are transient and short-lived, thus preventing their preservation.

The expected characteristics for CBLs were recognized within hornfelsic dikes found within a contact aureole at the base of the sheeted dike complex in the Troodos ophiolite (Gillis and Roberts, 1999), and dikes intruding the uppermost gabbros in the Oman ophiolite and two regionally extensive tectonic escarpments of young fast-spreading East Pacific Rise crust exposed at Pito and Hess Deeps. These very fine-grained, granoblastic hornfels occur either as in situ dikes or xenoliths in the gabbro sequence. Where in situ, they form massive, indurated outcrops that lack the common ladder-like fracture patterns of sheeted dikes. Hydrothermally altered dikes are partially to completely recrystallized to pyroxene and/or hornblende hornfels, recording episodes of re-heating at 750–1050°C. Field relationships and temperature constraints indicate that the heat flux across the CBLs is 12–33 Wm−2, similar to the latent heat of crystallization released to build a vertical thickness of 6 km crust. These are also similar to normalized values for hydrothermal plumes (20–40 MW/km), indicating that the heat that drives hydrothermal convection is transferred across a conductive boundary layer.

Collectively, widespread distribution of hornfelsic dikes at or just below the sheeted dike – gabbro transition indicate that thermally metamorphosed rocks are common feature in ocean crust. I will argue that these thermally metamorphosed rocks are remnants of preserved CBLs that record the migration of magma–hydrothermal boundaries, thus providing tangible evidence for AMC dynamics.

Assimilation of the plutonic roots of the Andean arc: Evidence from CO2-rich fluid inclusions in olivines

C. GINIBRE AND M.A. DUNGAN
Département de Minéralogie, Université de Genève, 13 rue des Maraîchers, 1205 Genève Switzerland (catherine.ginibre@terre.unige.ch, michael.dungan@terre.unige.ch)

Assimilation of young plutonic rocks by magmas of similar compositions is not easily seen in isotopic signatures because of their low isotopic contrast with the magmas. However, variability of trace element ratios in Tatara-San Pedro basalts (SVZ of the Andes) suggests assimilation (Dungan et al., 2001). Mineral inclusions and healed microfractures (HMF, Dungan and Davidson, 2004) show the xenocrystic nature of their crystals.

We compare olivine xenocrysts from a basaltic unit with amphibole- and phlogopite-bearing gabbroic xenoliths from a Holocene dacite (Costa et al., 2002) and analyse the contents of their HMFs using SEM, electron microprobe, Raman spectroscopy, microthermometry and LA-ICP-MS.

The better preserved fluid inclusions and textures in xenoliths reflect interactions between CO2-rich, saline H2O-bearing fluids and gabbroic intrusions. This subsolidus history then influences the partial melting and assimilation of the gabbros at the contact of the dacite host. The presence of hydrous minerals, especially micas, favours melting even at moderate magmatic temperatures.

In olivine xenocrysts from the basaltic units, most of the healed microfractures have been reopened upon ascent or eruption, thereby partly destroying the subsolidus signal. Diffusion modeling on iron-rich zones along the HMFs give a very short residence times (a few hours) suggesting syn- or post-eruptive healing. This is easily explained by the higher temperature of the basaltic host compared to the dacite. However some fluid inclusions are preserved and their similarity with those found in the xenoliths suggests similar origins for the xenocrysts.

Distinct mineralogical assemblages between xenocrysts-bearing basalts (olivine + plagioclase + clinopyroxene) and the gabbroic xenoliths (lacking clinopyroxene) show the diversity of the plutonic crust that was sampled by these magmas. Variable amounts of micas and amphiboles in the original gabbro will influence the chemical effect of assimilation on the bulk rock chemistry of the host magma.

**Proton and lead adsorption onto roots of the grass species**

*Festuca rubra*

**BRIAN GINN AND JEREMY B. FEIN**

University of Notre Dame; Civil Engineering and Geological Sciences; 156 Fitzpatrick Hall; Notre Dame, IN 46556 USA (bginn@nd.edu)

Metal adsorption onto biological surfaces can significantly affect metal speciation and mobility in near-surface environments. Cell wall adsorption, whether involving bacterial or root cells, is likely the first step in nutrient acquisition, but can affect the distribution of heavy metals and radionuclides as well. Many previous studies have focused on bacterial cell wall adsorption. However, plant roots can adsorb a range of metals as well. Quantifying metal adsorption onto plant root surfaces will assist in understanding the speciation of metals in complex soil systems, and can provide insights into how plants compete with soil bacteria for metal nutrients.

In this study, we measured proton and Pb binding onto roots of *Festuca rubra*, a species of grass commonly referred to as red fescue. Potentiometric titrations were performed on washed root material, using 0.1 M NaClO₄ to buffer ionic strength. Like bacteria, the roots exhibited continuous buffering behavior from pH 3 to 9. We use a discrete-site non-electrostatic surface complexation model (SCM) to constrain acidity constants and concentrations for root cell wall functional groups from the titration data. The Pb adsorption experiments were conducted at fixed Pb and root concentrations, with fixed ionic strength, as a function of pH. The roots displayed a typical adsorption edge, with the extent of adsorption increasing with increasing pH, and we use the Pb adsorption data to constrain the values of the thermodynamic stability constants for the important Pb-root surface complexes.

Our results indicate that the cell wall material associated with *F. rubra* roots has a different functional group chemistry than the cell wall material associated with bacteria. Nevertheless, plants and bacteria show a similar overall ability to uptake metals. We use the modeling results from this study to estimate Pb distributions in realistic soil systems containing root material, bacterial cells, and mineral surfaces, and we demonstrate that each reservoir can be important in determining the distribution of Pb in soil settings.

The major long term climate moderating process on the surface of the Earth is the link between climate and chemical weathering through the greenhouse effect; the higher the temperature, the faster the weathering rate and CO₂ sequestration. Weathering releases divalent cations to the ocean via riverine transport, either in dissolved and suspended form, where they promote the drawdown of CO₂ from the atmosphere by carbonate mineral precipitation (e.g. Walker et al. 1981; Gislason et al. 2006). To test this widely held hypothesis, we performed a field study determining the weathering rates of 8 Icelandic watersheds over the past 40 years. The annual average temperature of individual watersheds increased by 0.4 to 1.4 °C. Precipitation increased or decreased depending on the catchment. Riverine transport of weathering products from each watershed has continuously increased. The increase in dissolved riverine inorganic carbon and calcium transport range from less than one percent to 70 percent for the period 1960 to 2000. The riverine suspended inorganic particulate matter in the same catchments for the same period has increased by 2 – 600 percent. These results clearly indicate 1) the strong feedback between climate and Earth surface weathering, and 2) that the climate moderating effect of weathering, and therefore atmospheric CO₂ sequestration, may be far faster than previously thought.

The sedimentation rate controls microfossil preservation

S.M. GLASAUER\textsuperscript{1} AND A.U. GEHRING\textsuperscript{2}

\textsuperscript{1}Land Resource Science, University of Guelph, Guelph, ON N1E 4G5 Canada (glasauer@uoguelph.ca)
\textsuperscript{2}Institute of Geophysics, ETH Zurich, 8093 Zurich, Switzerland

One of the greatest challenges to finding definitive evidence for life on early Earth is the discovery of well preserved fossils. The microscopic, soft bodied organisms that are expected to dominate early or extreme environments do not preserve well. Several laboratory studies have recreated microbial “fossils” \cite{1, 2}, but the conditions under which microfossils are formed in natural environments are still poorly understood. Knowing these conditions and being able to predict where they occur are key factors to discovering preserved microorganisms. Exposure to iron in particular appears to control the formation of microfossils in many terrestrial and marine environments \cite{3}.

We present new data from oolitic ironstones at the Callovian-Oxfordian boundary in the eastern Jura mountains of northern Switzerland linking the preservation of fossil microorganisms to the depositional environment and to the concentration of iron. The lowest Oxfordian deposits contain lithic- and bioclasts, which are indicative of a highly condensed sequence with reworking and a sedimentation hiatus. In this sequence, filamentous, tubular structures of 1-2 μm are found in ferriferous encrustations and goethitic ooids. The filaments appear identical to those formed by a recently characterized modern analog, the NO\textsubscript{3}- reducing, iron-oxidizing bacteria. Depositional sequences from the upper Callovian stage exhibiting a higher sedimentation rate do not contain the same structures. We hypothesize that 1) the activities of iron-oxidizing and -reducing bacteria contributed to the form of iron that was accumulated and 2) a hiatus in sedimentation during development of the sequence enabled the microbial structures to be preserved. In contrast, when the sedimentation rate was increased, the burial of the microorganisms facilitated the breakdown of their associated structures. We suggest that this environment provides a model system for establishing the relationship between sedimentation and the preservation of soft bodied, microscopic organisms.

Single crystal X-ray refinement and thermodynamic properties of stoichiometric jarosite, KFe\textsubscript{3}(SO\textsubscript{4})\textsubscript{2}(OH)\textsubscript{6}

P. GLASNÁK AND J. MAJZLAN

Institute of Mineralogy and Geochemistry, University of Freiburg, D-74104, Germany
(peter.glasnak@minpet.uni-freiburg.de)

Jarosite and related minerals are invariably found in natural environments acidified either through the action of acid rain or by acidic mine drainage. In spite of their importance and common occurrence, the data which could describe the solubility, precipitation, and distribution of elements between jarosite and aqueous solutions are fragmented or questionable.

The first goal of this study is to prepare stoichiometric jarosite samples for further thermodynamic investigation. We have synthesized only jarosite samples which have been prepared according to the published procedures \cite{1} by oxidizing metallic iron in acidic K\textsuperscript{+} and SO\textsubscript{4}\textsuperscript{2-}-containing solutions under hydrothermal conditions. Iron was added in the form of an iron wire. Synthesis was carried out in a Teflon cylinder placed into a conventional oven at 200°C. The yellow product was readily identified by X-ray diffraction (XRD) as jarosite and no other crystalline phases were detected. The yield of the synthesis was 230 mg. The single-crystal XRD refinement for the sample with \(R_i=0.0316\) for the unique observed reflections \((|F_o| > 4\sigma_F)\) and \(wR_i=0.0423\) for all data gave the unit-cell parameters \(a = 7.288(1)\) and \(c = 17.203(4)\) Å. The Fe site occupancy in this sample is 97(1) %, significantly higher than the ~85 % reported from a conventional synthesis routes.

The second goal of this study is to determine thermodynamic properties of the jarosite sample. The thermodynamic measurement will be carried out using acid-solution calorimetry to obtain the enthalpy of formation. Heat capacity and entropy at standard temperature and pressure will be measured by adiabatic calorimetry. The measured enthalpy and entropy will be combined to a Gibbs free energy of formation. Then we will proceed to refine the existing values by comparing them to phase equilibrium data, either in nature or laboratory.

The data which will be presented can be used to calculate phase diagrams for this group of phases at conditions relevant to low-temperature geochemical processes (25 °C, 1 bar), metallurgical treatment (75 – 110 °C), and stability of phases on the surface of planets.

Loihi Seamount is a submarine, active volcano located on the southeast flanks of the Big Island of Hawaii. It is considered to be the youngest volcano in the Hawaiian chain, sharing the hot spot magma chamber with Mauna Loa and Kilauea. Sites of both vigorous and diffuse hydrothermal venting can be found surrounding the pit crater summit (~1000m) and on the flanks of the seamount, down to its base (~5000m). Vent fluids at Loihi are chemically distinct from other well-studied marine hydrothermal systems and have been shown to be enriched in carbon dioxide, iron(II), and manganese(II), and deplete in sulfur species. The Loihi summit is located within a zone of low oxygen, further enabling elevated iron(II) concentrations and support for a dominant community of iron-oxidizing bacteria.

We deployed a combination of a sensor wand consisting of up to four voltammetric working electrodes and the ROV Jason temperature probe, and/or a submersible micromanipulator with voltammetric electrodes to provide real time in situ redox characterizations of hydrothermal fluids and geochemical gradients associated with iron-oxidizing microbial mats and flocs. Our in situ electrochemical analyses provided an efficient and valuable means for directed discrete sampling of hydrothermal fluids and microbial flocs, as well as previously unattainable high spatial resolution geochemical profiles through the mats.

**Automated fission track dating of apatite and monazite by image analysis and ICP-MS**

A.J.W. GLEADOW¹, S.J. GLEADOW¹, B.P. KOHN¹ AND M.S. KROCHMAL²

¹School of Earth Sciences, University of Melbourne, Victoria 3010, Australia (gleadow@unimelb.edu.au)
²Autoscan Systems Pty Ltd, Melbourne, POB 112, Ormond Victoria 3204, Australia

The microscopic identification and counting of fission-tracks in accessory minerals by a manual observer has been a significant limitation to the widespread adoption of fission track dating (FTD). Manual counting methods require a high level of observer skill and calibration, and provides a practical limit to the number of tracks counted and hence on the precision achieved. It has long been hoped that automated methods for track recognition and counting could enhance the objectivity of fission-track analysis, and improve both precision and overall productivity. We have recently developed a new image analysis method, called 'Coincidence Mapping', that for the first time shows great promise in achieving these aims.

Another limitation in traditional FTD arises from the use of thermal neutron irradiation to induce more fission-tracks as a proxy for uranium abundance in the same area counted for fossil fission-tracks. While providing an elegant analytical solution at the ppm level with high spatial resolution (typically <100µm), this approach involves sample turnaround times of mostly several months. Laser-ablation ICP-MS techniques are now able to provide rapid uranium analyses with similar spatial resolution to the older method (Hasebe et al., 2004). This approach greatly improves sample throughput, but has the disadvantage that the target grain and its fossil fission-tracks are destroyed. A combination of automated fission-track counting and laser ablation ICP-MS analysis, however, should prove particularly advantageous.

Implementation of our automated fission-track counting system requires a microscope with both transmitted and reflected light optics, a motorised stage and digital microscope camera, all under computer control. The software system consists of an image acquisition module that automatically acquires a series of reflected and transmitted light images at each area selected for counting. These are archived and a separate automated counting and review module is then used offline to analyse the data. The archived images constitute a digital replica of the mineral grains which are then analysed by laser ablation ICP-MS using the stage coordinates to control positioning. The system has so far been applied successfully to fission track dating of accessory apatite and monazite.

Water column structure of the Eocene Arctic Ocean from Nd-Sr isotope proxies in fossil fish debris

J.D. GLEASON1, D.T. THOMAS2, T.C. MOORE, Jr.1, J.D. BLUM1 AND R.M. OWEN1

1Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109 (jdgleaso@umich.edu)
2Department of Oceanography, Texas A&M University, College Station, TX 77842 (dthomas@ocean.tamu.edu)

Nd-Sr isotopic compositions of Eocene fish debris (teeth, bones, scales) and reduced organic coatings reveal details of Arctic Ocean Basin water column structure at Lomonosov Ridge. Nd in marine fossil fish debris is acquired post-mortem at the sediment-water interface, recording bottom water composition; Sr is metabolized by fish (in this case a variety of smelt) living in equilibrium with their surroundings, recording the 87Sr/86Sr of the photic zone. Samples from IODP Expedition 302 all record isotopic values consistent with a brackish-to-fresh water surface environment (87Sr/86Sr = ~0.7079-0.7087) that was poorly mixed with Eocene global seawater (~0.7077-0.7078). Leaching experiments show reduced organic coatings to be consistently more radiogenic (~0.7090-0.7094) than cleaned ichthyolith phosphate. Ichthyolith Sr isotopic variations likely reflect changes in localized river input as a function of shifts in the Arctic hydrologic cycle. We suggest that 87Sr/86Sr might be used as a proxy for salinity of surface waters. Model mixing calculations indicate salinities of ~5 to ~20 per mil, close to but lower than estimates based on O isotopes. Significant salinity drops (i.e., 55 Ma PETM and 48.5 Ma Azolla event) do not show large excursions in 87Sr/86Sr. Epsilon Nd in cleaned ichthyoliths (-5.7 to -7.8) overlaps Neogene Arctic Intermediate Water (B. Haley, pers. comm.), distinct from modern AFW (-10.5) and North Atlantic Deep Water. Eocene ichthyolith Nd may record some deep-water exchange with Pacific/Tethyan water masses, but inputs from local sources are also permissible. The Sr-Nd isotopic record is consistent with highly restricted basin-wide circulation in the Eocene, indicative of a poorly mixed ocean and highly stratified water column with anoxic bottom waters. A stable, “fresh” water upper layer was likely a pervasive feature of the Eocene Arctic Ocean, recording enhanced continental runoff during an unprecedented warm interval lasting from the 55 Ma PETM to the first appearance of ice rafted debris at ~45 Ma.

Trace element zonation of plagioclase from the Kunene Intrusive Complex (NW Namibia)

PHILIPP GLEIßNER AND KIRSTEN DRÜPEL
TU-Berlin, Institut für Angewandte Geowissenschaften
ACK9, Ackerstr. 71-76, 13355 Berlin (philipp.gleissner@tu-berlin.de)

The Mesoproterozoic Kunene Intrusive Complex (NW Namibia) consists of two main anorthosite bodies. A pale coloured so-called white anorthosite is intruded by the dark anorthosite which comprises leucogabbroanorrites, anorthosites and leucotroctolites. Anhedral cumulus plagioclase of the white anorthosite is often turbid due to post-emplacement alteration. The An contents range from 40 to 50 mol.%. Individual grains either display a constant composition or minor An variations (±5 mol.%) which in some grains appear oscillatory with wavelengths of up to 1000 µm.

Anhedral to subhedral tabular coarse cumulus plagioclase of the dark anorthosite is optically clear and contains dust like Fe-Ti oxide inclusions. The An contents range between 43-75 mol.%. Some plagioclase phenocrysts display oscillatory zoning with wavelengths of up to 1500 µm and differences in the An-content of up to 8 mol.%, whereas others are characterized by a homogeneous composition.

Oscillatory zoning patterns of plagioclase from both anorthosite units are interpreted to be ingneous in origin, reflecting movements of the crystals in the magma reservoir. Plagioclase phenocrysts that display a nearly constant composition, on the other hand, are suggested to be affected by a post-magmatic reequilibration.

Since plagioclase is the main mineral present in anorthosites, major and trace element zoning patterns can provide important information about processes like cumulate formation, ascent of magma, and possibly also post-emplacement alteration. LA-ICP-MS analyses on profiles across plagioclase phenocrysts are in progress to examine the behaviour of the trace elements during the different stages of anorthosite formation.
Exhumation histories of high-pressure rocks: New insights from Rb-Sr geochronology

J. GLODNY
GFZ Potsdam, Telegrafenberg C2, 14473 Potsdam, Germany (glodnyj@gfz-potsdam.de)

High-pressure (HP) rocks can be considered as 'flight recorders', potentially recording their individual P-T-time-deformation path through evolving orogens. Reading the flight recorder requires both deciphering of the geochronological information, and correlating it with data on pressure, temperature and tectonometamorphic processes. Isotopic signatures of minerals, like the Rb-Sr system of white mica, has long been considered as particularly sensitive to temperature. This often prompted direct translation of sets of mineral ages into cooling histories, with inference of exhumation paths from thermal histories. However, this approach is problematic because microscale spatial correlations of isotopic ages with mineral growth zonation and recrystallization fronts (Vance et al. 2003) indicate that factors like availability of fluids, mineral recrystallization, and the modal rock composition similarly play vital roles in determining whether an isotopic system remains closed.

As an alternative approach, assemblages which remained closed for intermineral isotope exchange can be used to generate Rb-Sr 'event ages' for specific metamorphic processes. It is shown that the Rb-Sr system of white mica in eclogite may persist unchanged even through very high temperatures (>650°C). Key requirements for this high thermal stability are a) absence of free aqueous fluids after crystallization, evidenced from absence of fluid-mediated retrogression reactions, and b) modally controlled closed system behaviour, i.e., presence of white mica in an assemblage solely of phases like garnet and omphacite which do not allow for significant diffusional Sr isotope exchange even at the highest temperatures reached. A valid Rb-Sr multimineral isochron comprising all phases of an eclogite assemblage can be interpreted as dating eclogitization (cf. Glodny et al. 2005), and directly linked to PT data from the same sample to constrain eclogitization conditions.

The same concept applies to assemblages formed later in a HP rocks’ history. Veins, precipitated from fluids during exhumation, may be used to determine age and PT conditions of amphibolite- or greenschist facies overprints. Different event ages combine to an exhumation history, established beyond the pitfalls of closure temperature theory. Using examples from the Tauern Window (Austria) and the Bergen Arcs (Norway), the potential of this approach to precisely constrain contrasting exhumation histories is demonstrated.

Miocene calc-alkaline (CA) volcanic suites – more or less parallel with the Carpathian Mt. range – suggest a southwest-westward subduction process. Indeed, composition of the CA volcanic rocks shows typical subduction-related features, such as elevated LILE and relatively depleted HFSE. Boron, a fluid-mobile, incompatible trace element can be effectively used to monitor the subduction influence along the arc. In general, the boron concentration of the CA volcanic rocks of the region is typical of subduction-related magmas; however, it shows both significant spatial and temporal variations.

In the western segment of the arc, we cannot see a clear variation in the B content, nor in the B/Nb ratio towards the back-arc region, such as was found in other arcs (e.g., Japan and Kurile, Kamchatka). However, a gradual temporal decrease of these values can be observed. These features can be explained by the strong connection of the CA volcanism in this segment to the lithospheric extension of the Pannonian Basin, more than to the southward dipping subduction.

In the eastern segment of the region, the volcanic arc is narrower. Here, volcanism is getting to be younger towards the southeast. The boron content is increasing to the south along the arc; however, a sharp decrease can be observed at South Harghita. This is consistent with the change in the overall composition of the volcanic rocks and the position of the Trotus fault, which divides two main lithospheric domains.

In the northeastern part of the arc, a kind of transition is observed. At first sight, no correlation can be recognized between the B content and the spatial and temporal distribution of the volcanics. But separately, in the more basic and in the more silica rich rocks, we observe a B content decrease towards SSE. The present volcanological information is too incomplete to understand this. It may indicate the influence of the subduction-related fluids originating from a previously existing subducting slab under the Tokaj region.

Electrodynamic disaggregation of geologic material

E. GNOS1, D. KURZ2, I. LEYA3 AND U. EGGENBERGER2

1Muséum d’histoire naturelle, Route de Malagnou 1, CP 6434, 1211 Genève 6, Switzerland (edwin.gnos@ville-ge.ch)
2Institut für Geologie, Universität Bern, Baltzerstrasse 1 + 3, 3012 Bern, Switzerland (geoscience@swissonline.ch, usse@geo.unibe.ch)
3Physikalisches Institut, Universität Bern, Sidlerstrasse 5, 3012 Bern, Switzerland (ingo.leya@phim.unibe.ch)

A series of tests were run on a selfFrag Lab electrodynamic disaggregation machine produced by selfFrag AG, Langenthal, Switzerland. The operation principle is an electrical discharge passing trough a non-conductive material (e.g., rock) immersed in a dielectric liquid. The electrical pulses are of very short duration (<500 ns). In this case, the solid material becomes the better conductor, and hence the electrical “discharge channel” will pass through the solid material. High amounts of energy are deposited along this discharge channel leading to local temperature of up to 10000 °K and pressures of up to 1010 Pa (Rudashevsky et al., 1995; Andres and Timoshkin, 1997), thus conditions reached by using conventional explosives.

The tests using different geologic material immersed in deionised water showed that electrical discharges as low as 80 kV and a few hundred pulses at a frequency of 1-5 Hz are commonly sufficient to disintegrate rocks or other mineral aggregates. Accessory minerals separated at voltages of 80 – 100 kV retain their original shape (e.g. zircon, apatite, magnetite); the minerals may break under increased energy input. Sieves replacing the reactor vessel bottom allow small enough material to be removed during operation, and hence to prevent further grain size reduction. Major rock constituents generally disaggregate mainly along internal impurities or fissures, leading to a grain size reduction. However, the minerals contain fewer inclusions. Rare artefacts of the method are formation of melt films, and contamination by very small particles derived from the electrode material. The amount of contamination from the electrode material is much lower than by using conventional crushing methods. A closed disposable microcontainer allows to disaggregate sub-gram samples for microanalysis minimizing loss. Preliminary result did not show negative effects on isotopic systems.

Major advantages in comparison with conventional methods (jaw crusher, vibration disk mill, ball mill) lie in the reduction of fines, the omission of dust, the production of inclusion-free and/or isometrically shaped products, and the reduction of cross contamination.

From phosphors to ceramic magnets
stability, crystal chemistry and
applications of hexa-aluminitates
and -ferrites

MATTHIAS GÖBBELS
University of Erlangen-Nuremberg, Institute for Geology and
Mineralogy, Applied Mineralogy, Schloßgarten 5a.
D-91054 Erlangen, Germany

The groups of hexa-aluminates and -ferrites exhibit a wide
range of applications. From lamp phosphors in the case of Ba-
aluminates (Eu & Mn doped – green, Eu doped – blue
luminescence) to ceramic magnets such as Sr-ferrites doped
with Co and La a wide range of daily applications can be
presented.

In the group of hexa-phases compounds exhibiting
magnetoplumbite- and beta-alumina structures are stable. A
wide crystal chemical variety gives rise to numerous
properties with large potential for chemical fine tuning.

Phase relations and crystal chemical aspects like solid
solution series in the multicomponent systems
CaO/SrO/BaO/EuO/La2O3 – Al2O3/Fe2O3 – MgO/CoO are
presented and discussed. The crystal structures present can be
explained as mixed layer structures. Starting from the spinel
structural type modifications consisting of rock salt-units and
perovskite-units build up the different hexa-phases.

Furthermore shaping aspects like ceramic foams
consisting of Ca-aluminates aiming towards catalytic
applications will be presented.

Indications for pedogenic formation
of perylene in terrestrial soil:
First results from stable carbon
isotope ratios

TILMAN GOCHT, JOHANNES BARTH, MICHAELA EPP,
ILKA HERKLOTZ AND PETER GRATHWOHL
University of Tuebingen, Center for Applied Geosciences,
Sigwartstr. 10, 72076 Tuebingen, Germany
(johannes.barth@uni-tuebingen.de)

Concentrations and isotope compositions of polycyclic
aromatic hydrocarbons (PAHs) were determined in natural
soils of Southern Germany. Surprisingly, perylene
concentrations increased with soil depth when compared to the
other PAH compounds present, but only in specific profiles.
Its low solubility made vertical transport by seepage water
unlikely. We therefore stipulate atmospheric deposition of
combustion-derived perylene in the top-soil and in-situ
generation in the sub-soil of these selected profiles. This could
have been caused by microbial activities or other catalytic
processes yet unknown. In order to distinguish between
pyrogenic and natural generation we compared compound-
specific \[^{13}C/^{12}C\] ratios (\(\delta^{13}C\)) between perylene and other
PAHs in samples from the top-soil and from the sub-soil.
Despite high amounts of co-extracted non-target compounds
and low perylene concentrations relative to other PAHs
(benzo(e)pyrene and benzo(a)pyrene) successful clean-up of
the extracts led to determination of a unique \(\delta^{13}C\) value for
perylene in the upper horizon. The \(\delta^{13}C\) value of perylene in
the sub-soil was 3.4 permille more negative than for top-soil
perylene, and 5.2 permille more negative than other equal-
mass PAHs (with m/z of 252) in the top-soil. Future work will
include isotopic characterization of atmospheric input and in
situ synthesis of PAHs.
Modelling continental weathering: from the lab to the field

Y. GODDERIS¹, J. SCHOTT¹, L.M. FRANÇOIS², C. DESSERT³ AND B. DUPRE¹

CO₂ consumption through continental silicate weathering at the watershed scale has been generally described as a parametric function of mean annual continental runoff and temperature, based on river chemistry. These mathematical expressions have been successfully used in numerical modelling of the evolution of the past geochemical cycles and climate. They have the advantage of integrating numerous processes (hydrologic, biogeochemical, and kinetic) and to rely directly upon field constraints, but they leave us without any access to the intimate processes of chemical weathering, and do not allow a hierarchization of its controlling factors. Here we present sensitivity tests performed with the WITCH numerical model which describes weathering in soil profiles through vertical multiple box modelling based on a rigorous description of mineral-water interactions. This model is coupled to a vegetation productivity model, and we explore the response of continental vegetation on weathering. We also test the impact of using laboratory-based kinetic weathering rates to estimate the main cation fluxes exported from the soil profile. We show that such method does not lead to any large overestimation of the CO₂ consumption, if the chemical affinity of reactions, and secondary minerals precipitation rates in soils are accurately accounted for. Sensitivity of the kinetic model WITCH to drainage and annual mean temperature is compared to the sensitivity expected from field parametric laws. Particularly, we show that parametric laws underestimate by one to two order of magnitude the weathering rates at low runoff (below 100 mm/yr), while the agreement is good at higher runoff. Although the specific contribution of the low runoff areas to the CO₂ consumption is low, they are typical of the weathering regime of 44 % of the total continental surface.

Interaction of calcite with Cr(III) and evidence for direct inorganic formation of vaterite

A. GODELITAS¹, J.M. ASTILLEROS², K. HALLAM¹, K. WRIGHT³, F. TOMASCHEK² AND A. PUTNIS³

⁵Universität Münster, Institut für Mineralogie, Münster, Germany (flom@nwz.uni-muenster.de, putnis@nwz.uni-muenster.de)

The interaction of freshly cleaved \{10 \bar{1} 4\} calcite surfaces with 100 mg/L (~2 mmol/L) Cr(III) solutions was investigated at room temperature under atmospheric conditions using in-situ AFM for a time-period of up to 20 min. It was observed that the initial typical nanoscale dissolution features (rhombohedral etch pits) are successively filled with matter up until the final overgrowth of spheroidal-like particle aggregates. Ex-situ experiments with variable time exposures (1 min, 20 min and 1 month) were also carried out in order to study the surface of the interacted calcite crystals using a combination of techniques. A detailed SEM-EDS, XRD and FTIR study of the experimental products revealed that the surface precipitates consist of amorphous Cr(III) hydroxide/oxyhydroxide phases. EPMA (WDS) elemental maps on polished-thin sections of teeth-like material removed from the solid interface after long-term interaction (1 month) indicated the formation of a peculiar carbonate phase containing both Ca and Cr in variable concentrations. It should be noted that distinct Ca carbonate (or even hydroxycarbonate) solid phases containing Cr(III) are rather unknown in nature, except maybe the case of a meteorite. Preliminary computational investigations showed a difficulty of Cr³⁺ ions to be hosted in the calcite surface structure.

On the other hand, detailed XPS and Laser µ-Raman studies of \{10 \bar{1} 4\} calcite surfaces interacted for 20 min with Cr(III) solutions indicated the presence of vaterite. In this case, the thickness of the Cr(III)-modified carbonate surface was investigated using accelerator-based techniques, namely ¹²C-RBS. The formation of vaterite on the surface of calcite, and in general the direct inorganic formation of vaterite in the presence of Cr(III)₉⁺, was also confirmed by means of macroscopic experiments aiming at crystal growth of CaCO₃ into appropriate glass tubes filled with Cr(III)-doped hydrogel.
Extreme Hf isotope signals from basement weathering and its influence on the seawater Hf-Nd isotope array

L.V. GODFREY1, R.L. KING2, B. ZIMMERMANN3, J.D. VERVOORT2 and A. HALLIDAY4

4Dept. of Earth Sci., Oxford Univ., Oxford OX1 3PR, UK

Differential weathering of Lu and Hf host minerals in rocks leads to Hf isotope composition of river water with a more radiogenic composition than the bulk rock that they drain [1]. In contrast, the Nd isotope composition of river water is very similar to that of bulk rock due to congruent weathering of Sm and Nd from their shared mineral hosts. We measured Hf and Nd isotope ratios in seawater and from the Hudson River in NY. The Hf isotopic composition of the upper Hudson draining Grenville-aged metamorphic rocks is extreme, with εHf values of +24 to +128. Associated marble and amphibolite bedrock have normal crustal εHf values (0 to –11), whereas apatite and garnet from these rocks have εHf values as high as +2250 and +103 [2,3]. In contrast, Nd compositions of the upper Hudson are similar to bulk rocks (εNd = –8). After the Mohawk River, which drains Orдовician-Devonian limestone and shale, joins the main stem of the Hudson, river water εHf and εNd decrease to +6 and -10. On the New Jersey Bight, εHf and εNd are +3 and -8.

The Hf and Nd isotope composition of filtered seawater in the Atlantic overlap data for ferromanganese nodule crusts. Vertical profiles exhibit almost negligible εHf gradients suggesting rapid vertical, but little lateral, transport. Surface water εHf is less radiogenic close to the Saharan dust plume suggesting an eolian source of Hf with a signal that is not fractionated through weathering processes.

We suggest that the radiogenic Hf character of the seawater Hf-Nd array is due to the preferential weathering of high Lu/Hf phases in basement rocks such as apatite. When this source rock is old evolved crust, dissolution of these high Lu/Hf phases contributes a very radiogenic Hf isotope composition, as evidenced by the upper Hudson river water samples. This differential chemical weathering will be prominent at times when there are no glaciers, and particularly prominent when glacial action has exposed fresh surfaces containing less resistant minerals to weathering [4].

Cosmogenic nuclide intercalibration and erosion rate study on fault scarps of the Bishop Tuff, CA, USA

M.M. Goethals1,2, S. Niedermann2, R. Hetzel1 and C.R. Fenton2

1Westfälische Wilhelms-Universität Münster, Germany, (goethals@uni-muenster.de)
2GeoForschungsZentrum, Potsdam, Germany

The Bishop Tuff in eastern California is a welded ignimbrite deposit that erupted 760 ± 2 ka ago from the Long Valley Caldera, as dated with 40Ar/39Ar on sanidines [1]. Surface samples from the Bishop Tuff were collected for comparing the production rates of cosmogenic nuclides (3He, 21Ne, 10Be, 26Al) in various minerals available in the sampled ignimbrite unit, like quartz, pyroxene, magnetite and sanidine. Although the Bishop Tuff has experienced erosion and absolute calibration is thus not possible, still production rate ratios can be assessed. So far, 20 samples have been analyzed for the 21Ne concentration in quartz. For one of those samples, 3He and 21Ne have been determined in coexisting clino- and orthopyroxene. The concentrations of cosmogenic 3He are difficult to assess due to possible contributions of both magmatic and nucleogenic 3He. However, the ratios of cosmogenic 21Ne(ox)/21Ne(qz) and 21Ne(ox)/21Ne(qz) are ~1.23 and ~1.45 respectively. In comparison, using the elemental production rates of Kober et al. [2005] [2], would imply ratios of 21Ne(ox)/21Ne(qz) 1.38 (cpx) and 1.50 (opx) for the chemical composition of these analyzed pyroxenes. In the near future we would also like to determine the production rate ratios 21Ne/10Be and 21Ne/26Al in the same quartz samples.

In addition to the production rate nuclide intercalibration, we performed an erosion rate study at the Bishop Tuff. We sampled the footwalls of 3 normal fault scarps, extending from the fault center to the tapering end, that run N-S through the SW of the Bishop Tuff due to tectonic extension of the area. 18 preliminary exposure ages – calculated from 21Ne concentration in quartz – range from 260 to 505 ka, i.e. ~35 – 70 percent lower than the eruption age of the Bishop Tuff. The discrepancy shows that about 1.0 to 1.8 m of material has been removed since the eruption. The 21Ne ages vary rather systematically with the oldest ages mostly at the tapering ends of the scarps and the youngest ages at the fault centers where the vertical displacement is maximal. As the faults are active and they propagate [3] our data indicates that the process of erosion is more pronounced on the fault centers compared to the lower fault tips. In general, ages from bedrock samples (n = 14) show more variation than desert pavement samples (n = 4).

Crystal orientation selection during growth of brachiopod shell calcite

A. Goetz1, E. Griesshaber1, W.W. Schmahl1 and C. Lueter2

1Department for Earth and Environment, LMU Munich, Germany (andrgoetz@gmx.de, e.griesshaber@lrz.uni-muenchen.de, wolfgang.schmahl@lrz.uni-muenchen.de)
2Museum für Naturkunde Berlin, Germany

The progresses in the technique of electron backscatter diffraction (EBSD) in combination with SEM provides an ideal set of imaging and diffraction methods to reveal the architecture of calcitic brachiopod shells. Usually calcitic brachiopods show a two-layered shell with a hard nanocrystalline primary layer and a fibrous secondary layer where the fibers are single crystals with the morphological fiber axis perpendicular to the crystallographic c-axis.

The investigated species, *Kakanuiella chathamensis* and *Liothyrella neozelanica* differ from this assembly: the former one is built entirely of hard nano- to microcrystalline calcite whereas the latter one shows a usual primary layer, but a secondary layer which is prismatic and a fibrous tertiary layer. Our observations on the interface between the primary and the secondary layer in *L. neozelanica* suggest a mechanism how the unusual crystallographic texture may arise.

Even though *Kakanuiella chathamensis* consists only of primary layer material we observe some textural features and a pattern in the distribution of hardness within the shell.

Figure 1: EBSD-Map of the three layered shell of *L. neozelanica* (black bar down left: 500 µm).

Earth’s core formation aided by flow channelling induced by Rayleigh-Taylor instabilities

G. GOLABEK AND H. SCHMELING
Institute of Geosciences, Section Geophysics, J. W. Goethe University Frankfurt am Main, Germany (golabek@geophysik.uni-frankfurt.de)

The core formation mechanism remains poorly known. Geochemical constraints by Hf/W systematics indicate a fast process which was largely completed within 33 Ma for the Earth. An unstable gravitational configuration of a dense molten metallic layer overlying a cold chondritic protocore is predicted by most studies, which leads to the formation of a Rayleigh-Taylor instability. We propose the application of Stevenson’s (1989) stress-induced melt channelling mechanism in the region surrounding an incipient iron diapir. We therefore perform numerical experiments solving the two-phase, two composition flow equations within a 2D rectangular box with symmetrical boundary conditions. We apply the Compaction Boussinesq Approximation (CBA) and include a depth-dependent gravity. For simplicity we use a constant viscosity for the solid phase and melt-fraction dependent rheology for the partially molten region around the diapir. A systematic investigation of the physical conditions under which the melt channels can form in comparison with the time scale of core formation and whether they are applicable to the early Earth is in progress. As a result, for sufficiently small melt retention numbers iron-melt focussing channels develop within a region of approximately twice the diapir’s size. This could lead to effective draining of the surrounding region and might initiate cascading daughter diapirs or the formation of dykes. The mechanism could effectively enhance melt accumulation in the protocore and accelerate the process of core formation.

Tracing oceanic sulphate with phosphorite geochemistry

TATIANA GOLDBERG1 AND GRAHAM SHIELDS2
1James Cook University, Townsville, Australia (tatiana.goldberg@jcu.edu.au)
2Westfälische Wilhelms-Universität, Münster, Germany (gshields@uni-muenster.de)

Sedimentary phosphorites contain francolite (carbonate fluorapatite) as the major mineral phase. Francolite is thought to incorporate $SO_4^{2-}$ in proportion to its concentration in ambient pore fluids (Jarvis et al., 1994) and thus could be a potential indicator of past seawater sulphate concentrations. This is attempted by relating $SO_4/P_2O_5$ ratios of recent and ancient phosphorite rocks to ocean sulphate levels.

Phosphorite can form under diverse redox conditions, which can lead to variations in incorporated $SO_4^{2-}$. By comparing francolite-bound sulphate $\delta^{34}S$ and $\delta^{18}O$ and carbonate $\delta^{13}C$, the impact of sulphate reduction and sulphide reoxidation on sulphate concentrations can be better constrained. Weathering is also considered to lead to the loss of $SO_4^{2-}$ in francolite, and this can be partially evaluated by CO$_2$ concentrations in francolite. However, our study suggests that sulphate is only lost from associated organics and pyrite during weathering.

The sulphate concentration and $\delta^{34}S$ of phosphorites do not correlate with Ce-anomaly, which is a redox-dependent parameter. The decoupling of REE from $SO_4^{2-}$ and $\delta^{34}S$ may result from the different timings and mechanisms of incorporation of REE and sulphate into the francolite lattice. Therefore, REE do not provide reliable constraints on the degree of preservation of francolite sulphur systematics.

Francolite $SO_4^{2-}$ is found to be lower than previously reported in Miocene phosphorites. This could relate to the removal of all non-francolite S during sample preparation in our study. $SO_4^{2-}$ levels in Neoproterozoic and Cambrian francolites are also low. Uppermost $SO_4^{2-}/P_2O_5$ ratios from the best preserved samples (from the Miocene, Cambrian and Ediacaran) in our study can be used to constrain minimum $SO_4^{2-}$ concentrations in the ocean.

Bistability of atmospheric oxygen and the Great Oxidation

COLIN GOLDBLATT, TIMOTHY M. LENTON AND ANDREW J. WATSON

School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, U.K. (c.goldblatt@uea.ac.uk; t.lenton@uea.ac.uk; a.watson@uea.ac.uk)

Earth history has been characterized by a series of major transitions separated by long periods of relative stability. The largest chemical transition was the ‘Great Oxidation’, approximately 2.4 billion years ago, when atmospheric oxygen concentrations rose from less than $10^{-5}$ of the present atmospheric level (PAL) to more than 0.01 PAL, and possibly to more than 0.1 PAL. This transition took place long after oxygenic photosynthesis is thought to have evolved, but the causes of this delay and of the Great Oxidation itself have been unclear. We show that the origin of oxygenic photosynthesis gave rise to two simultaneously stable steady states for atmospheric oxygen. The existence of a low oxygen (less than $10^{-5}$ PAL) steady state explains how a reducing atmosphere could persist for at least 300 million years after the onset of oxygenic photosynthesis. The Great Oxidation can be understood as a switch to the high-oxygen (more than $5 \times 10^{-3}$ PAL) steady state. The bistability arises because ultraviolet shielding of the troposphere by ozone becomes effective once oxygen levels exceed $10^{-5}$ PAL, causing a nonlinear increase in the lifetime of atmospheric oxygen (Goldblatt et al. 2006). The long term redox forcing of the surface system was probably a decrease in reductant input due to a progressive oxidation of the crust (Claire et al. 2006). Once the system was in a bistable regime, the Great Oxidation could have been triggered by a perturbation to the carbon cycle too small to leave a carbon isotope signal. Our results indicate that the existence of oxygenic photosynthesis is not a sufficient condition for either an oxygen-rich atmosphere or the presence of an ozone layer, which has implications for detecting life on other planets by remote sensing and for the evolution of multicellular life.

A coordinated continental and regional soil geochemical survey of North America

USGS, MS 973 Denver Federal Center. Denver CO 80225 (mgold@usgs.gov; dsmith@usgs.gov; jmorrison@usgs.gov; rwanty@usgs.gov; jholloway@usgs.gov)

The U.S. Geological Survey and collaborating partners in Canada and Mexico, have initiated a project that will produce a soil geochemical survey of North America. Pilot phase sampling and analyses have been completed along two continental transects, one of which extends from the west to east coasts of the United States along the 38th parallel. The data for a number of elements in this east-west transect reveal geochemical patterns that correlate with bedrock and glacial deposit composition.

One example of soil-bedrock correlation is elevated Cr concentrations in some California soils, which contain 2000-8000 ppm Cr compared to a median of 27 ppm for all samples across the east-west transect. The origin of this Cr anomaly is revealed by a more detailed regional-scale pilot study north of the San Francisco Bay extending from the Pacific Ocean to the California-Nevada border. This regional study incorporates geochemical data from nearly 2000 soil samples. Cr and Ni in these samples display patterns reflecting the underlying geology.

Elevated concentrations of soil Cr (2000-8000 ppm) and Ni (1000-5000 ppm) overlie serpentinite rocks in the foothills of the Sierra Nevada Mountains and in the Coast Ranges west of the Sacramento Valley. Chromium in these serpentinite-derived soil samples is predominantly in a refractory form, as chromite (FeCr$_2$O$_4$). Soils with Tertiary volcanic and granitic parent material located at higher elevation in the Sierra Nevada Mountains, as well as alluvial soil in the eastern Sacramento Valley, have much lower Cr and Ni concentrations relative to serpentinite soil (less than 100 and 50 ppm, respectively). Surprisingly, soil with elevated Cr and Ni content (150-400 ppm and 60-300, respectively) occurs in Sacramento Valley soil west of the Sacramento River. Chromium in this western valley geographic setting is in a less refractory form than that in soil overlying serpentinite, is more easily mobilized from soil into groundwater, and spatially correlates with the elevated groundwater Cr levels.

The geochemical studies at national and regional scales complement each other. The former targets areas of interest and the latter provides more detailed process insights.
Tracking microbial life in the marine subsurface

TOBIAS GOLDHAMMER AND MATTHIAS ZABEL
Research Center Ocean Margins, FB5 Geosciences, University of Bremen, PBox 330440, 28334 Bremen, Germany
(goldhammer@uni-bremen.de, mzabel@uni-bremen.de)

Evidence has grown that deeply buried marine sediments are habitats to living communities of microorganisms, even under scarcity of nutrients and terminal electron acceptors and apparently hostile environmental conditions. The contribution of such communities to element cycling remains elusive, but direct microbiological assays are difficult to conduct due to extreme in situ conditions. We suggest to make use of anorganic, cell-independent proxies to bypass this hassle and propose the application of oxygen stable isotopes of dissolved inorganic phosphate (DIP) in marine pore waters.

The \(^{18}\text{O}/^{16}\text{O}\) ratio of pore water DIP is significantly affected by active microbial phosphate (PO\(_4\)) metabolism. The exchange of oxygen atoms between water and phosphate is enhanced by extra- and intrazellular hydrolase enzymes in living cell PO\(_4\) uptake and processing, and can be distinguished from abiotic fractionations during sediment diagenesis (Blake et al. 2005). Therefore we consider the \(^{18}\text{O}\) of pore water DIP a fairly robust and feasible parameter for the identification and profiling of microbial activity in deep sediment cores.

We here present a modified microextraction technique for marine pore water PO\(_4\). DIP is concentrated by magnesium induced coprecipitation, separated from interferring anions by a preparative ion chromatography using anion exchange resin, and subsequently precipitated as silver phosphate (Ag\(_3\)PO\(_4\), Colman 2002). Ag\(_3\)PO\(_4\) is finally combusted in an elemental analyzer, and transferred online via continuous flow to an isotope ratio mass spectrometer. The amount of DIP required for the precipitation of crystal Ag\(_3\)PO\(_4\) can thereby be reduced to less than 1mg, making an analysis of pore water samples which are limited in sample volume and DIP content possible.

On research cruise MSM04-4a with German vessel Maria S. Merian we recovered four sediment cores up to 42m below sea floor offshore Morocco using a remotely operated seafloor drill rig, and took pore water samples with an average depth resolution of 0.5m for the application of the novel technique described above.

Chemical weathering of Taranaki volcanics, North Island, New Zealand

STEVEN T. GOLDSMITH, ANNE E. CAREY AND W. BERRY LYONS

School of Earth Sciences and Byrd Polar Research Center, The Ohio State University, Columbus, Ohio, USA (goldsmith.35@osu.edu; carey.145@osu.edu; lyons.142@osu.edu)

New Zealand’s North Island watersheds in the Taranaki and Manawatu-Wanganui regions have been subject to volcanism since the Miocene. We sampled water and sediments from watersheds that contain both volcanic and sedimentary rocks. Water and sediment samples were collected and analyzed for major, minor and trace elements, in order to quantify the weathering intensities in the watersheds and to establish the relationship between physical and chemical weathering yields in volcanic lithologies.

Results reveal distinct chemical signatures, with waters draining the Taranaki region volcanics significantly enriched in K+ and depleted in Sr2+ compared to those draining the Manawatu-Wanganui region volcanics, which also traverse expanses of sedimentary siltstones and mudstones. These depletions may reflect the relative absence of CaCO3 in the Taranaki region watersheds. In addition, sediment samples from the Taranaki Region show significant enrichment in Ti, Al, Ca, Fe, Mg, Mn, Mg, Ca, and P and depletion in Si and Rb compared to those of the Manawatu-Wanganui region.

Mineral stability diagrams for streamwater samples show that primary feldspar minerals present would weather to kaolinite while clay minerals would likely be present as kaolinite, illite, or Mg-montmorillonite. Normalized sediment values for the Taranaki region exhibited a best fit pattern to average Mt. Egmont andesite values with relative soluble alkali and alkaline earth elements Na, K, Rb, Sr, and Ba and insoluble elements Ti, Al, and Fe, while normalized values for the Manawatu-Wanganui region exhibited a best fit pattern to near shore mud.

From total dissolved solids concentrations and annual volumetric water discharge, chemical weathering yields of 60–238 tons km⁻² a⁻¹ are obtained. These weathering yields fall within the middle to upper range of those previously reported for New Zealand’s Southern Alps (93–480 tons km⁻² a⁻¹) and East Cape (62–400 tons km⁻² a⁻¹). Calculated silicate weathering yields of 12–33.6 tons km⁻² a⁻¹ and CO2 consumption of 852–2390×10⁶ moles km⁻² a⁻¹ for the rivers draining the Taranaki volcanic region are higher than those previously reported for watersheds hosted in sedimentary and metamorphosed rock terrains on HSIs. CO2 consumption is found to be within the range which others have reported for the basaltic terrains of the Deccan Traps (580–2450×10⁶ moles km⁻² a⁻¹) and Réunion Island (1300–4400×10⁶ moles km⁻² a⁻¹). Calculated chemical weathering yields demonstrate the importance of taking into account weathering on high-standing oceanic islands, particularly those with volcanic terrains, when considering global geochemical fluxes.

The nature of the mantle source of Archean ferropicrites

SHOSHANA GOLDSTEIN AND DON FRANCIS

Department of Earth & Planetary Sciences, McGill University, 3450 University Street, Montreal, Quebec, Canada, H3A 2A7 (shoshana@eps.mcgill.ca; donf@eps.mcgill.ca)

Although ferropicrites have been recognized as an unusually Fe-rich mafic igneous rock for some time, the nature of their mantle source remains unclear. Ferropicrites are most common in Archean terranes and four occurrences from the Superior craton form the basis of this study: the Taconic, Lusby Lake, Grassy Portage Bay, and Dayohessarah Lake greenstone belts. Ferropicrites from the first three belts occur as ash to lapilli tuffs, while those from the latter belt occur as coarse-grained intrusive rocks cutting basalts and komatite flows. These ferropicrites are mafic to ultramafic rocks (15-23 wt% MgO) characterized by low Al₂O₃ (<8 wt%), high FeO* (15-21 wt%), and relatively high TiO₂ contents (1-2 wt%). They have fractionated REE profiles (La/Yb = 8-20; Gd/Yb = 3-4.5) and relatively high contents of HFSE (Nb = 10-18 ppm; Nb/La = 0.8-3.0). In contrast, coexisting komatitites from Dayohessarah have higher Al₂O₃ (9-11wt%) and lower contents of FeO* (~11 wt%), TiO₂ (~0.5 wt%), HFSE, and LREE, despite having similar MgO contents; they also exhibit flat REE profiles (La/Yb = 1-2).

These geochemical differences require that the two magma types have different mantle sources. Peridotite-basalt mixtures that have been proposed as possible ferropicrite mantle sources fail to reproduce ferropicrite Fe contents. A garnet pyroxenite mantle source does not have sufficient Mg to produce liquids with up to 20 wt% MgO, and an olivine-dominated source seems to be required. Melting experiments on model mantle compositions (KLB-1, Mg # = 89.6) suggest that komatiitic liquids like those at Dayohessarah can be produced at 45 kbar, but do not reproduce the Fe contents of ferropicritic liquids under any conditions. Experimental melts of a model Martian mantle composition (Mg # ~80) at 15 kbar have nearly identical Fe contents to our ferropicrites, and melts produced at 50 kbar have Fe contents significantly higher than our ferropicrites. Interpolation of these data shows that the mantle source of our ferropicrites would have a Mg # of ~80 at 15 kbar, which would require large degrees of partial melting, or a Mg # of ~85 at 50 kbar. In the latter scenario, these ferropicritic liquids would be the result of smaller degrees of partial melting, consistent with their fractionated trace element profiles and lower Al contents relative to komatitites, if garnet were not completely consumed during ferropicrite petrogenesis.
Hf isotopes as the key for distinguishing slab melting in arcs: 
The case of the Mexican Volcanic Belt

STEVEN L. GOLDSTEIN1, YUE CAI1, CHARLES H. LANGMUIR2, ALEXANDRA LAGATTA1, SUSANNE M. STROUB1, ARTURO GOMEZ-TUENA1 and ANA-LILLIAN MARTIN DEL POZZO1

1Lamont-Doherty Earth Observatory, Palisades, NY USA (steveg@ldeo.columbia.edu)
2Harvard University, Cambridge, MA USA
3UNAM, Querétaro, Mexico.
4UNAM, Coyoacan, DF, Mexico

Convergent margins are important as the global setting 
where crust is recycled into the mantle and new continent is 
made. Despite major advances in delineating the processes 
that control arc magma generation, the problem persists of 
distinguishing slab, mantle wedge, and crustal contributions, 
along with the question of whether there is significant melting of 
subducted ocean crust. Especially in thick crust regions, the 
importance of crustal versus mantle contributions to lavas 
represents a long-standing fundamental issue in arc magma 
geochemistry. We show, based on evidence from Hf isotopes, 
that frontal arc magmas from the Central Mexican Volcanic 
Belt (CMVB), including the large andesitic stratovolcanoes 
Popocatepetl and Nevado de Toluca, display negligible crustal 
contamination, and contain a component derived from melting 
of regional subducted oceanic crust plus sediments.

Despite thick continental crust, the CMVB erupts near 
primitive lavas including “high-Nb” alkaline basalts that show 
negligible trace element “subduction signatures”. The “high 
 Nb” basalts define the regional mantle wedge composition in 
isotope-trace element space, and show well-defined Hf-Nd-
Pb-Sr isotope “arrays”. In “normal” CMVB lavas with 
“subduction signatures”, a key feature is that they form trends 
from the “high-Nb” lavas toward even higher Hf isotope 
ratios, thus their sources are more “depleted mantle-like” than 
the regional mantle wedge. Of prime importance here is that 
higher Hf isotopes in these “normal” lavas correlate with low 
Lu/Hf and Pb isotope ratios.

These negative correlations can be simply modeled as 
mixtures of the regional mantle wedge, represented by “high-
 Nb” basalts, with a low degree composite melt of the 
subducted slab represented by altered Pacific ocean crust plus 
DSDPSite 487 sediment, located near the trench. Neither 
altered Pacific crust nor sediment by themselves explain the 
“normal” CMVB data, but the ocean crust component 
predominates. Thus, the integrated data allow us to clearly 
distinguish between mantle and crustal sources and point to 
substantial subducted slab melt contributions to these lavas.

It is fitting for a symposium that asks what have we 
learned from Hf isotopes that we don’t know already from Nd, 
that Lu-Hf provides key evidence identifying mantle 
signatures in a thick crust arc, and for distinguishing the slab 
melt contribution from other possibilities. These observations 
are also significant in the context of global arc data.

Relationships between magnetic properties and heavy metals in 
*Nerium oleander* leaves and soils 
(Viseu, Central Portugal)

C. R. GOMES1,4, J. DIAS5, L. NEVES2,4, A. ROCHA4 and 
E. GOMES1,4

1CGUC, 2 IMAR, 3CentroGeociênciasUC 
4Department of Earth Sciences, University of Coimbra, 
Portugal (romualdo@ci.uc.pt)

Magnetic parameters (χ, ARM, IRM) and selected 
heavy metals concentration (Cu, Fe, Mn, Zn, Pb, and Cr) of 
*Nerium oleander* leaves and topsoils were determined for 24 
samples sites in the urban area of Viseu (Central Portugal). 
The purpose of this study is to relate magnetic properties to 
heavy metals concentrations and to assess the urban pollution 
levels. The table bellow presents some statistical information 
on the results obtained.

Significant correlations were found between most 
chemical elements and magnetic parameters determined in 
leaves. This is confirmed by a factor analysis, where the 
dominant factor (60% of the total variance) shows only 
positive contributions including both physical and chemical 
parameters (Cu, Fe, Mn, Pb, Zn, magnetic susceptibility, and 
IRM). The second factor (18% of the total variance) shows 
positive contributions of Fe and Cr and negative of IRM and 
magnetic susceptibility. Communalities are higher than 0.82, 
with the exception of Mn (0.44) and Pb (0.65). The same 
pattern was observed for topsoils. Again, chemical and 
magnetic parameters are related with significant correlations 
and a factor analysis shows positive contributions of all of 
them to the most important factor (49% of the total variance). 
The second factor (25% of the total variance) shows positive 
contributions of ARM and Fe and negative contributions of Pb 
and Zn. Communalities are all higher than 0.55 and most 
are exceed 0.75.

These results indicate that factor 1 in both cases is clearly 
related to contamination induced by anthropogenic activities 
and that magnetic parameters of leaves and soils can be used 
as an indicator of the degree of chemical contamination and 
pollution levels. Factor 2 is probably related to natural 
variations of the composition of leaves and topsoils.
Remediation of azo dyes by natural manganese oxides

I.C. Goncalves1, C. Dowding2, K. Johnson2 and A. Brown3

1Chemistry Department, University of Beira Interior, Covilha, Portugal (imscg@ubi.pt)
2School of Engineering, University of Durham, South Road, Durham, England (karen.johnson@durham.ac.uk)
3School of Civil Engineering & Geosciences, University of Newcastle, Newcastle, England (angela.brown1@ncl.ac.uk)

In the present work, the degradation of azo dyes (60 mg/L) and aromatic amines (60 mg/L) in the presence of natural Mn oxides was investigated in batch experiments. A 1/10 (w/v) solid/solution ratio was used.

Discussion

Dyes Acid Orange 7 and Acid Yellow 36 were decolourised by the manganese oxide (natural pH of 8-9), indicating that they were either being degraded or adsorbed onto the mineral surface[1]. As no sterilised Mn oxide samples were used, the possibility of the reactions being solely biologically mediated cannot be discounted. Experiments performed in the absence and presence of nutrients also gave different results.

The biological activity of these systems was assessed by using molecular biological techniques such as DNA extraction followed by Polymerase Chain Reaction (PCR) [2]. Results indicate the presence of microorganisms in all samples analysed.

Conclusions

The ability of natural ‘waste’ Mn oxide compounds to undergo oxidation and reduction reactions makes them suitable to be used as redox mediators (electron shuttles) in the degradation of azo dyes and aromatic amines in natural environments. It is not clear from these experiments whether this process is either a chemically and/or a biologically mediated processes.

Biogeochemical and mineralogical characteristics of the acid mine drainage system in Aljustrel and S. Domingos mines, Iberian Pyrite Belt

M.A. Gonçalves1, J. Figueiras1, C. Pinto1, N. Neng2, P. Sá-Pereira3 and M.J. Batista4,

1Dep. Geologia, FCUL and CREMINER, Ed C6, Piso 4, Campo Grande, 1749-016 Lisboa, Portugal (mgoncalves@fc.ul.pt; jmvf@fc.ul.pt; geoclaudia@sapo.pt)

4INETI, Apt 7586, 2721-866 Alfragide, Portugal (joao.batista@ineti.pt)

Aljustrel and S. Domingos are important mines of the Iberian Pyrite Belt, the former currently active and the latter closed since the sixties. Both systems were sampled and analysed. Samples included old and recent mine taillings, stream sediments, surface waters, and biological material (algae). Acid drainage is very similar in both areas but acid waters in Aljustrel have 7 to 8 times higher metal concentrations than in S. Domingos. However, in S. Domingos the system is much more contained.

Aljustrel: Água Forte stream drains the major taillings. This stream receives domestic waste-waters 2 Km away, which act as a neutralizing agent to the acid waters (pH 2). Waste-waters pH is ≈8, and drops to values near 4 upon mixing with the acid waters. In Summer, acid drainage stops but waters down-stream maintain their pH close to 4. The ubiquitous presence of gypsum and jarosite in sediments and crusts provide a source for acidity due to their dissolution. Sediments down-stream have iron-rich surface layers and dark coloured material in the deeper layers (sulphides?). Modelling results show that such pH values may be attained only if precipitation of iron oxides and sulphides occur during mixing of waters. Water samples from sites with abundant iron-oxide sediments present the association Acidithiobacillus ferrooxidans, Leptospirillum ferrooxidans, Acidithiobacillus albertensis, and Leptospirillum ferriphilum.

S. Domingos: Has a much more complex secondary mineral assemblage: gypsum, jarosite, schulenbergite, natrojarosite, szomolnokite, and coquimbite. Along the major flow path from the dams and pits, both water chemistry and parameters do not change appreciably.

Algae from both mining areas were centrifuged to extract part of their water content, and their tissues were dissolved. Concentrations of Cu and Zn in the organic material were 3 to 4 times lower than in the liquid extracts, whose concentrations were about half the corresponding concentrations in the flowing waters. Pb, Co, and Cd have only trace concentrations.

H-O isotopes and water content in nominally anhydrous minerals from UHP eclogite in the Dabie orogen

B. GONG, Y.-F. ZHENG AND R.-X. CHEN
School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (gongb@ustc.edu.cn)

Fluid activity during subduction-zone metamorphism is an important issue with respect to chemical geodynamics of continental collision. In particular, it has been intriguing where retrograde fluid comes from during exhumation of deeply subducted continental crust. Mineral water concentration and stable isotope analyses are a powerful means to decipher the origin and nature of aqueous fluid in UHP metamorphic minerals. Using a stepwise heating procedure, a number of FTIR analyses demonstrate that only molecule H_2O is removed from garnet from eclogite, without significant loss of structural OH. A TC/EA-MS online method, together with the stepwise heating procedure, is used to determine both H isotope ratios and concentrations of total water and structural hydroxyl in nominally anhydrous minerals from UHP eclogite at Bixiling in the Dabie orogen, China. The results show total H_2O concentrations of 1791 to 2997 ppm in omphacite and 522 to 981 ppm in garnet, and hydroxyl concentrations of 1242 to 2808 ppm H_2O in omphacite and 279 to 747 ppm in garnet. Except for quartz which has a higher concentration of molecule H_2O (189 ppm) than structural hydroxyl (117 ppm), all of the other minerals have much higher concentrations of structural hydroxyl than molecule H_2O. The eclogite has total water δD values of −112 to −92‰ for omphacite and −98 to −94‰ for garnet; structural hydroxyl δD values of −91 to −85‰ for omphacite and −87 to −72‰ for garnet. It appears that the total H_2O is depleted in D relative the structural OH in the nominally anhydrous minerals. The nominally anhydrous minerals have similar δD values to each other, but are lower than δD values of −59 to −58‰ for muscovite. On the other hand, hydroxyl δD values for the nominally anhydrous minerals are close to hydroxyl δD values for hydrous minerals. Laser fluorination analysis obtained that the eclogite has an δ^{18}O value of 2.5‰ for zircon, 2.7 to 3.7‰ for garnet and 3.3 to 4.5‰ for omphacite. They are lower than normal mantle zircon δ^{18}O values. Both O and H isotope equilibrium and disequilibrium occur between coexisting omphacite and garnet, but retrograde metamorphism occurred with internal buffering of stable isotope compositions. Thus both O and H isotope signatures of minerals from the eclogite indicate incorporation of meteoric water into eclogite protolith by high-T hydrothermal alteration and subsequent magmatism. The meteoric signature was preserved in the UHP minerals during the subduction of continental slab, with only limited activity of fluid within the slab. Nevertheless, fluid became available during exhumation due to a decrease in water solubility with pressure decrease. Therefore, exsolution of structural hydroxyl and molecular water from the minerals is the most plausible source for the retrograde fluid.

A fractal concentration-mass method for geochemical anomaly separation in Shizhuyuan tungsten deposit area

QINGJIE GONG1,2, JUN DENG1,2, YUNCHUAN XIANG3, QINGFEI WANG1,2 AND LIQIANG YANG1,2
1Faculty of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China (qjiegong@163.com; djun@cugb.edu.cn)
2State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China
3Center for Development and Research, China Geologic Survey, Beijing, 100037, China

Anomaly separation plays an important role in mineral exploration. A fractal concentration-mass (C-M) method was presented for separating geochemical anomalies from background. The method is derived from Mandelbrot's coastline length-ruler model by replacing the length with mass and ruler with concentration. In log-log plot, the concentration-mass pattern follows the fractal distribution with uni-scale or multi-scale, which was used to discriminate geochemical processes and to separate geochemical anomaly from background.

The C-M method was tested on stream sediment geochemical data in Shizhuyuan tungsten deposit area, Hunan province in China. The stream sediments were sampled using grid method by 31 multiply 31 kilometers with one sample per square kilometer (n=961). Six elements, W, Sn, Pb, Ag, Ni and Ba, were selected to test the C-M method in this area, in which W, Sn, Pb, Ag with mineralization and Ni, Ba without. The results indicated that multi-scale fractal or mixing-dominant geochemical processes was occurred in this area and the anomaly can be separated from background efficiently. Compared with the typical method (anomaly determined by average plus double standard deviation), the anomaly area of W, Sn, Pb, Ag determined by C-M method is evidently smaller (with larger anomaly value) and more coincident with known deposit sites, and the anomaly area of Ni, Ba is distinctly larger (with smaller anomaly value) and more consistent with the Devonian and pre-Cambrian strata area respectively. Therefore, the C-M fractal method is efficiently in separating geochemical anomaly from background with good qualities in aiming at deposit target promptly or in avoiding losing weak anomaly information.
Geochemical features of the basic-ultrabasic rocks of the Udokan-Chiney region (Siberia, Russia)

B.I. GONGALSKY¹, N.A. KRIVOLUTSKAYA² AND M. GONGALSKY¹

¹IGEM RAS, Moscow, Russia (gon@igem.ru)
²Vernadsky Institute RAS, Moscow, Russia (nakriv@mail.ru)

The problem and the main goal of the study

Mantle magma’s intrusions inside the Southern framework of the Siberian platform reflect the main destruction episodes on the Earth. They are the Paleopangea falling to pieces in the Early proterozoic époque and the tectonic activity in Kz. To understand the magmatic evolution and the associated ore-forming processes in the Udokan-Chiney region it is necessary to study geochemical features of the basic-ultrabasic rocks from numerous massifs located inside this area.

Results

The composition of the rocks (main and trace elements) from different Paleoproterozoic massifs – Chiney, Luktur, Mylove, and Neoproterozoic massifs – Doros, Udokan Great Dyke, so as the Mz and Kz basalts have been studied by XRF and ICP-MS. In this range (from ancient to modern rocks) there is an evolution of its compositions: close to N-MORB – E-MORB – OIB. La/Yb and Th/Ta ratios of the studied massifs change significantly (fig.1) and demonstrate the role of the different sources in their magma generation.

Figure 1: La/Yb vs. Th/Ta diagram for the studied complexes from Udokan-Chiney region.

Nothing paradoxical about Helium concentrations in OIBs

H.M. GONNERMANN¹ AND S. MUKHOPADHYAY²

¹Department of Geology and Geophysics, SOEST, University of Hawaii, Honolulu, Hawaii, 96822, USA (helge@hawaii.edu)
²Department of Earth and Planetary Sciences, Harvard University, Cambridge, Massachusetts, 02138, USA (sujoy@eps.harvard.edu)

We show that the He concentration paradox, as well as the full range of noble gas concentrations observed in mid-ocean ridge basalt (MORB) and ocean island basalt (OIB) glasses, can self-consistently be explained by disequilibrium, open-system degassing of the erupting magma. We demonstrate that a higher CO₂ and H₂O content of OIBs, compared to MORBs, leads to more extensive degassing of He in OIB lavas.

Outgassing during melt production at mid-ocean ridges has led to a volatile depleted upper-mantle MORB source with low ³He/⁴He ratios. Consequently, ³He/⁴He ratios in OIBs, often a factor of 4-6 higher than in MORBs, are conventionally viewed as evidence for an undegassed, primitive mantle source. However, this conventional model provides no viable explanation for why noble gas abundances in OIBs are an order of magnitude lower than in MORBs. This has been called the “He concentration paradox”, which has contributed to a long-standing controversy about the structure and dynamics of Earth’s mantle.

If, during magma eruption there is insufficient time for all volatiles to diffuse from the melt into gaseous bubbles, the abundance of dissolved volatile species is controlled by both solubility and diffusivity. Because of its relatively high diffusivity, He degassing of OIB and MORB magmas is not significantly limited by diffusion and is predominantly controlled by solubility. On-average higher CO₂ content of OIBs relative to MORBs dilutes He in the exsolved gas phase, thereby lowering partial pressures and decreasing absolute He solubility. This explains why OIB lavas have lower He abundances than MORBs, even though the OIB parental magma is more He rich. On the other hand, degassing of Ne and Ar is limited by diffusion during eruption of both MORB and OIB magmas. When combined with higher He loss in OIBs, this explains the low He/Ne and He/Ar ratios of OIBs relative to MORBs.

The observed noble gas content in OIBs is entirely consistent with degassing of a parental magma derived from a mantle source with a primordial component and total ³He, ²²Ne, and ³⁶Ar abundances of approximately 4×10⁻⁹, 1×10⁻⁹, and 3×10⁻⁹ cm³ STP g⁻¹, respectively. The percentage of primitive mantle component in the OIB source is on average less than 20%, but our present calculations do not constrain the size nor the location of the primitive reservoir. Regardless of whole mantle convection, it appears that part of the Earth’s mantle has remained relatively undegassed and primordial in volatile content over Earth’s history.
Mud-breccia clasts and sediments as nucleation sites for hydrocarbon-derived ferromanganese nodules in carbonate-mud mounds from the Gulf of Cadiz

F.J. GONZÁLEZ1, L. SOMOZA1, R. LUNAR2, J. MARTÍNEZ-FRÍAS3, J.A. MARTÍN RUBÍ4, T. TORRES4, J.E. ORTIZ4 AND V. DÍAZ DEL RÍO5

1Geological Survey of Spain (IGME). Madrid, Spain (fj.gonzalez@igme.es)
2Dpto de Cristalografía y Mineralogía (UCM). Madrid, Spain
3Centro de Astrobiología (CSIC/INTA). Madrid, Spain

5Centro Oceanográfico de Málaga (IEO). Málaga, Spain

During the Anastasya-01 cruise (TASYO project), extensive nodule fields were discovered and sampled for the first time at water depths ranging from 850 to 1000 m, associated with hydrocarbon-derived carbonate chimneys and crusts in the Guadalquivir Diapiric Ridge area (eastern Central Atlantic) [1]. Nodules show a wide range of sizes and predominantly tabular shapes. They are formed of multiple millimetre-thick layers of Fe and Mn oxides surrounding the nucleus composed of Early-Middle Miocene plastic marls and mud-breccia sediment, which were derived from underlying units by fluid venting. Fe-Mn layers and carbonated cores display the same microtextural features, composed by zoned rhombohedral crystals (authigenic Fe-Mn oxides in layers, and siderite to rhodochrosite in the nuclei) surrounded by detrital grains (silicates) and frambooidal associations (fresh pyrite or totally pseudomorphised by goethite). The center of the rhombohedral crystals are enriched in manganese and their exterior edges are iron enriched for both, Fe-Mn oxides and Fe-Mn carbonates. Nodules show a high mean abundance of Fe (38.6%) moderate Mn (6.0%), and low contents of trace metals and REEs compared to the average content of deep-seabed polymetallic nodules [2]. The studied nodules hold in their oxide layers and cores hydrocarbons (n-alkanes), with a first concentration maximum at n–C18, derived from marine bacterial activity, also with presence of aromatic hydrocarbons such as phenanthrene, characteristic of mature petroleum. Bacteria-mediated oxidation of hydrocarbons through Mn4+ and Fe3+ reduction, could be related to the precipitation of Fe-Mn carbonates and sulphides, forming siderite-rhodochrosite concretions bellow the redox boundary within the sediment, that later were transformed into ferromanganese-oxide nodules by exhumation and exposition to the sea bottom oxidising waters.

Slab-mantle interaction and petrogenesis of interplate basalts

N.S. GORBACHEV, D.M. SULTANOV AND A.I. NEKRASOV
Institute of Experimental Mineralogy of RAS (gor@iem.ac.ru)

Interplate basalts have been produced from mantle reservoirs which content of protholiths of former oceanic crust. The peculiarity melting of these sources were studied experimentally at temperature range 1250-1400°C and pressure 1.5-4.0 GPa by using the peridotite ampoule method. In peridotite-basalt-volatile (H₂O or H₂O+CO₂) systems (PBV) as the model such reservoirs high magnesian melts (14-18 % MgO) in equilibrium with Opx+Cpx formed by react slab-derived liquids with mantle peridotite (“reaction” melts). Their volume depend on volume basalt of slab. In the some experiments during partial melting of peridotite formed 3-5 % "filmy" andesitic or more high siliceous (up to 60 % SiO₂) liquids.

Figure 1: Photo of experimental sample in the backscattered electrons. T=1250 C, P=2.5 GPa, 5% H₂O+CO₂

Make allowance of volume slab basalts my proposed, that the slab-mantle sources would be produced more bigger volumes of magnesian basalts at comparatively lover temperatures to compare with normal partial melting of peridotite. All these observations, based on experimental study PBV systems, probably may extent to petrogenesis of interplate basalts.

Bacterial nanowires: Extracellular electron transfer and mineral transformation

YURI A. GORBY
J. Craig Venter Institute, La Jolla, CA 92035
(ygorby@jcvi.org)

Dissimilatory metal reducing bacteria use solid phase iron and manganese oxides as electron acceptors and couple this enzymatic reduction to growth. This mode of anaerobic respiration profoundly influences mineralogical transformation in diverse natural environments. But the use of metal oxides as electron acceptors presents challenges to bacteria that must coordinate transfer of electrons from bacteria to the mineral surfaces. Recent results demonstrate that metal reducing bacteria, such as Geobacter and Shewanella spp., produce electrically conductive appendages called bacterial nanowires under conditions that limit availability of electron acceptor (Reguera et al., 2005; Gorby et al., 2006). A combination of scanning electron microscopy (SEM) and scanning tunneling microscopy (STM) confirmed that wild type S. oneidensis MR-1 produced electrically conductive nanowires that connected cells together into an electrically integrated cellular network. Conductivity of Shewanella nanowires requires the presence of cytochromes, which were previously shown to enzymatically reduce solid phase Fe(III) and Mn(IV) minerals (e.g. Beliaev et al., 2001). Mutants lacking these electron transport proteins produced appendages resembling nanowires that were not conductive. These mutants did not reduce Fe(III) (hydr)oxides, produce electricity in microbial fuel cells, or form thick biofilms (Gorby et al., 2006).

Nanowires are not exclusive to dissimilatory metal reducing bacteria. Organisms ranging from oxygenic cyanobacteria to thermophilic syntrophic bacteria produce electrically conductive nanowires (Gorby et al., 2006). Structure ressembling nanowires are commonly observed in iron oxidizing environments. This presentation will provide our current understanding of the diversity, distribution, and implication of bacterial nanowires in a variety of microorganisms.

Melting and mixing processes in mantle wedges

WERONIKA GORCZYK¹, TARAS V. GERYA¹, JAMES A.D. CONNOLLY¹, JEAN-PIERRE BURG¹ AND DAVID A. YUEN²

¹ Department of Geosciences, Swiss Federal Institute of Technology (ETH - Zürich), CH-8092 Zurich, Switzerland (weronika.gorczyk@erdw.ethz.ch, james.connolly@erdw.ethz.ch, taras.gerya@erdw.ethz.ch, jean-pierre.burg@erdw.ethz.ch)
² Department of Geology and Geophysics, University of Minnesota, Minneapolis, Minnesota 55455-0219, USA (davey@krissy.geo.umn.edu)

Partial melting of mantle and subducting slab material is one of the crucial mechanisms of mass transfer in subduction zones. To study the dynamics of this phenomenon we used 2-D coupled petrological-thermomechanical model with different tectonic setups (i.e. intra-oceanic subduction and active continental margin). To simulate water propagation and magmatic processes we implemented slab dehydration, partial melting and hydration of mantle wedge. We studied mantle wedge processes in various resolutions (form 0.5 million to 10 billion markers) to resolve complexity of theses processes.

Hydrated and partially molten material (plumes) rise through the mantle wedge along trajectories determined by the balance between buoyancy force and mantle flow. Their geometries differ depending on physical properties of mantle and diapir as well the dynamics of the system. Variations in plume development have influence on surface processes like slab retreat and speed of back-arc opening or rotation of fore-arc.

Slab plumes material can be homogenous (only mantle material) or heterogeneous (mantle and slab material). In case of heterogeneous plume during its growth materials mix chaotically resulting in attenuation and duplication of the original layering on scales of 1–1000 m. This process may verify marble cake theory and explain existence of complex peridotitic structures exhumed to the surface.

The use of overbank sediments data for geochemical mapping and contamination assessment: Results from selected floodplains of Serbia

V. GORDANIC, A. CIRIC AND D. JOVANOVIC

Geological Institute of Serbia, Rovinjska 12, Belgrade, Serbia (geochemija@sezampro.yu)

Introduction

Profiles made from the data of the overbank sediments from the flood plains of Serbia contain the geochemical inscription of the depositional milieu of the preindustrial era. Taking into consideration that they represent wider drainage areas together with the stream sediments, they were used to create regional geochemical map. Contents of the certain chemical elements from the overbank and stream sediments along with anthropogenic influence on the certain localities were represented on the map.

Discussion and results

Geochemical prospecting and mapping were done in accordance with the criteria of the West European Geochemical Surveys (WEGS). The area of the East Serbia drained by the river Timok with its tributaries was selected for investigations. Differences in Pb, Zn, Cu, Au, Sb, As, Cd, Cr, Ni, Co, V and other elements were noted in overbank and stream sediments of the main flow and its tributaries. The contents of certain elements are presented in the table below:

Lifetime of the active solar nebula
J.N. GOSWAMI
Physical Research Laboratory, Ahmedabad 380009, India
(goswami@prl.res.in)

The duration of formation of the very early solar system objects, such as the Ca-Al-rich Inclusions (CAIs) and chondrules, that are considered to be products of high temperature nebular processes, effectively defines the lifetime of the active solar nebula. Most of the CAIs host radiogenic isotopic anomalies from in-situ decay of short-lived now extinct nuclides, while a subset of CAIs are devoid of such anomalies but host large magnitude stable isotope anomalies. The latter group appears to have formed in the solar nebula within the first $10^5$ years, prior to the injection of freshly synthesized short-lived nuclide into it [1]. The formation of the CAIs hosting radiogenic isotope anomalies spread over a time scale of a few times $10^5$ years [2], although recent data suggest that this could be as short as $5\times10^4$ years [see, e.g., 3]. There is a general consensus at present that formation of chondrules started about a million years after the formation of the CAIs, and the inferred duration of chondrule formation, based on study of $^{26}$Al records, varies from less than a million years to three million years [3]. A detail study of chondrules from unequilibrated ordinary chondrites (UOCs) belonging to the L group and representing various petrologic types, show that the major episode of chondrule formation started $\sim1.5$ Ma after CAI formation and lasted $\sim1$ Ma [4]. The longer duration of formation for UOC chondrules, inferred in earlier studies, appears to be an artifact caused by thermal metamorphism affecting some of the chondrules belonging to low petrologic type. In contrast, data for chondrules from carbonaceous chondrites, obtained by us [5] and others, suggest that chondrule formation in the outer region of the inner solar system persisted for a much longer duration of $\sim3$ Ma. Plausible scenarios that may accommodate these observations relevant to the lifetime of an active solar nebula will be presented.

Sulfur K-edge X-ray absorption spectroscopy as a tool to investigate microbial triggered sulfate reduction
J. GÖTTLICHER AND S. MANGOLD
Forschungszentrum Karlsruhe GmbH, Institute for Synchrotron Radiation, Karlsruhe, Germany (joerg.goettlicher@iss.fzk.de)

Investigation on the chemical states of sulfur is essential to characterize reaction products from microbial catalyzed neutralization of acidic mine waters and from laboratory experiments carried out with the iron and sulfate containing mineral jarosite (KFe$_4$(SO$_4$)$_2$(OH)$_6$) exposed to sulfate reducing bacteria as a model system. With an element specific technique like the x-ray absorption spectroscopy (XAS), and therein from the near edge structure (XANES) information on the chemical binding form of sulfur can be obtained. XANES spectra at the sulfur K edge (around 2.48 keV) have been recorded at the XAS beamline of the synchrotron radiation source ANKA at the Forschungszentrum Karlsruhe.

Due to the oxidation of metal sulfides (e.g. FeS$_2$) in coal mining sites metal ions and sulfuric acid are released in the adjacent waters. Thus, the acidic pit lakes that form in abandoned mining sites are an environmental hazard. A stimulation of sulfate reducing bacteria (SRBs) at the sediment water interface might act as a starting point to neutralize such lakes by transforming dissolved iron, metal and sulfate ions as well as the iron sulfate minerals of the lake sediment (e.g. jarosite) back into iron sulfides. Analysis of the sulfur K edge XANES shows in near surface samples of the sediment that was locally covered with calcium carbonate and organic carbon to increase bacterial activity reduced sulfur species (monosulfide). To understand the processes at the sediment water interface synthetic jarosite has been exposed to SRBs in the laboratory. Resonances in the spectra were assigned to monosulfide and disulfide sulfur besides the sulfate of the remaining reactant jarosite. Re-oxidation experiments indicate a similar behavior as for the lake sediments: the decrease of monosulfides to sulfur and to sulfate (Göttlicher and Mangold, 2005).

Samples required to solve Earth and environmental questions are often complex (e.g., weathered minerals and rocks, contaminated soils, lake and dump sediments). They consist of mixtures of mineral phases (often with micrometer particle sizes), microbes, and in some cases living tissues or are only available in scarce amounts of tiny particles (exhaust particles, precipitations in extreme environments). Elemental distribution, spatially resolved chemical speciation and mineral phase identification are helpful to uncover relationships between mineral phases, main and trace elements and finally to comprehensively understand natural and anthropogenic affected systems. Such problems can be addressed by a combination of microfocused synchrotron X-ray techniques as they have been setup with the Synchrotron Radiation Laboratory for Environmental Studies at ANKA. The lab consists of a microfocus X-ray beamline (SUL-X) that enable elemental mapping using X-ray fluorescence analysis (XRF), chemical speciation with X-ray absorption spectroscopy (XAS) and mineral phase determination by X-ray diffraction (XRD), successively at the same sample position. Moreover, the laboratory is supplemented with an infrared microscope (SUL-IR) at an edge radiation IR beamline.

First measurements during the commissioning period of SUL-X comprise localization and speciation of arsenic in natural iron minerals for water treatment and in weathering rims of sulfides in tailing impoundments by microfocused XRF analysis and X-ray absorption near edge structure (µ-XANES) spectroscopy. Selected area XRD has been used to identify mineral formations in sea water ice. µ-XRD and µ-XANES spectroscopy is applied to characterize lead in human bone junctions.

To meet the demand of speciation of low Z elements like Al, Si, P, S for environmental questions, it is planned to offer XAS at energies down to the Al K edge (1.5keV).

Microstrain and structural defects in the magnesian calcite skeleton of the Crown of Thorns starfish

HERIBERT A. GRAETSC
Institut für Geologie, Mineralogie und Geophysik, Ruhr-Universität Bochum, D-44780 Bochum, Germany (heribert.graetsch@rub.de)

Sea stars have a magnesium calcite (Ca_{1-x}Mg_{x}CO_3) skeleton made up of small ossicles which form an open meshwork supporting the body. In spite of their spongy morphology, the skeletal parts are single crystals as in other echinoderms (sea urchins, sea lilies, sea cucumbers and brittle stars). The skeletons are metastable formations as their composition often lies within the miscibility gap between calcite and dolomite. The Crown of Thorns starfish (CoT) was chosen for this x-ray diffraction study for its extraordinary high magnesium content of x = 0.17. The name is for the large number of long spikes. The high Mg content indicates an average water temperature of the habitat of about 29°C.

The x-ray powder reflections of CoT are slightly broadened with respect to those of quartz which was used as internal standard. A Williamson Hall plot indicates that the broadening is almost entirely due to microscopic strain caused by lattice imperfections rather than to small crystallite size. Annealing experiments suggest that the microstrain can only partly be explained by the different sizes of Mg^{2+} and Ca^{2+} cations incorporated in the calcite lattice. A single crystal structure refinement revealed the presence of vacancies on cation sites and misoriented CO_3 groups.

After annealing at 300°C, the appearance of few weak extra reflections indicate the beginning of the exsolution of high-magnesium calcite to low-magnesium calcite and calcian dolomite.

Annealing at lower temperatures (100 - 200°C) causes some changes of the microstructure which show up in the diffraction patterns. The lattice parameters expand slightly on increasing temperature of the heat treatment [1]. Simultaneously, the broadening of the x-ray powder reflections is reduced indicating less microstrain. Single crystal structure refinements show a reduction of vacancies and smaller atomic displacement parameters suggesting some healing of structural defects.

Annealing at about 250°C, however, causes an increase of the reflection broadening indicating larger microstrain introduced by newly formed lattice imperfections. Additional weak diffuse intensity was found close to the strongest reflections which can be ascribed to Huang scattering caused by the occupation of interstitial lattice sites. The formation of interstitials seems to be an intermediate step before at higher temperatures unmixing of the solid solution begins.

Mobile fission and activation products in nuclear waste disposal

BERND GRAMBOW

SUBATECH, Ecole des Mines de Nantes, Université de Nantes, IN2P3/CNRS, 4, rue Alfred Kastler, 44307 Nantes, France

When disposing nuclear waste in clay formations it is expected that the most radiotoxic elements like Pu, Np or Am do move only few centimetres to meters before they decay. Only a few radionuclides are able to reach biosphere and contribute to their long-term exposure risks, mainly $^{129}$I, $^{36}$Cl, $^{79}$Se and in some cases $^{14}$C and $^{99}$Tc, whatever the scenario considered. The recent OECD/NEA cosponsored international MOFAP workshop focussed on transport and chemical behaviour of these less toxic radionuclides. New research themes have been addressed, such as how to translate molecular level information to large migration distances. Diffusion studies need to face mineralogical heterogeneities over tens to hundreds of meters. The large volume of traversed rock will provide so many retention sites that despite weak retention, even these “mobile” nuclides may show significant retardation. The question however has been posed how to measure reliably very low retenion parameters. Additionally, the radioactivity of some of the nuclides in the waste is so low that sophisticated techniques must be employed to measure them. An important issue is whether redox states or organic/inorganic speciation change from its initial state at the moment of release from the waste during long term contact with surfaces, hydrogen saturated environments etc.

Changes in soil reactive aluminium fractions following logging in podzols of British Columbia, Canada

S. GRAND1 AND L. M. LAVKULICH2

1Resource Management and Environmental Studies, University of British Columbia, Vancouver, Canada (sgrand@interchange.ubc.ca)
2Land and Food Systems, University of British Columbia, Vancouver, Canada (lml@interchange.ubc.ca)

The potential for aluminium stress in ecosystems

Al is the 3rd most abundant crustal element, and in soluble forms is toxic to most organisms. The potential for acidic soils to be Al toxic is considerable. Ecosystems stressed by human interventions such as forest harvesting are particularly at risk. This study investigates the effects of clear-cut logging on soil reactive Al fractions, including exchangeable Al ($\text{Al}_{\text{exch}}$), organically bound Al ($\text{Al}_{\text{org}}$), and Al associated with poorly crystalline minerals. The study soils are humo-ferric podzols located in the coastal mountains of southern British Columbia, Canada. These soils are strongly acidic and are at risk for Al stress. We collected soil samples from undisturbed plots (control), and compared them to samples from neighbouring plots that were clear-cut 1 to 15 years prior to sampling.

Results and discussion

$\text{Al}_{\text{exch}}$ and $\text{Al}_{\text{org}}$ are influenced similarly by logging. These Al pools are unaffected in plots logged 1 - 2 years ago, show an increase in plots logged 3 - 10 years ago, then decrease to control levels or below at 12 - 15 years after logging. This pattern matches closely the observed variation in the organic matter content. Organic matter provides exchange sites as well as sites for specific Al adsorption.

The increase in $\text{Al}_{\text{exch}}$ is mitigated by a concomitant increase in exchangeable calcium. The Ca/Al ratio, a valuable ecological indicator used for the identification of the risk of adverse effects due to Al stress, was remarkably constant in control and logged plots.

Poorly crystalline mineral fractions consist mainly in imogolite-type material (ITM). Control soils average 23g/kg ITM in the B and C horizons. Logged soils exhibit highly variable ITM content, indicating a possible disruption of the podzolization process. With an Al/Si ratio around 2, ITM stores a significant fraction of the reactive Al in these soils.

Conclusion

All reactive Al pools in these soils are affected by logging. The impacts of these changes on the ecosystem are under investigation.

Modelling of denitrification plumes induced by organic matter injection in aquifers

F. GRANDIA, C. DOMÉNECH, S. JORDANA, G. COSCERA, D. ARCOS, L. DURO, J. GUIMERA AND J. BRUNO
ENVIROS-Spain S.L., Passeig de Rubí, 29-31, 08197 Valldoreix, Barcelona, Spain (fgrandia@enviros.biz)

Injection of organic matter can be an effective method for the remediation of nitrate-polluted aquifers. Microbial activity mediates the reduction of nitrate to N₂ by organic matter what can be exemplified by the following reaction:

\[ 5CH_4O + 4NO_3^- \rightarrow N_2 + HCO_3^- + H^+ + H_2O \]

Nitrate pollution is of special concern in many areas of Catalonia (NE Spain). Although the accepted limit for drinking waters is 50 mg·L⁻¹, many aquifers in the region contain \([NO_3^-]>75 \text{ mg·L}^-1\], reaching in some cases up to 400 mg·L⁻¹. The Catalan Water Agency is presently designing an in situ experiment of organic matter-doped water injection in a selected aquifer with high nitrate concentration (~75 mg·L⁻¹ NO₃⁻). The extent and intensity of an aquifer denitrification plume is controlled by geochemical and hydrological parameters and variables (initial injected organic matter concentration, aquifer redox conditions, hydraulic conductivity, dispersivity and porosity).

The denitrifying capacity of the selected aquifer under study was tested in batch experiments in laboratory. From these experiments, a rate law of denitrification was determined and implemented in a series of 3-D reactive transport simulations aimed at selecting the optimal injection conditions, namely the injection rate of the reactive solution, organic matter concentration and injection pulse frequency.

Main parameters controlling the rate law were initial nitrate content, organic matter concentration and temperature.

In the numerical simulations, the total mass of organic matter to be injected (1.74 Kg CH₂O·day⁻¹) and total injection time (23 days) were kept constant while different organic matter concentrations and water injection rates were considered. The results show that solutions with organic matter concentration higher than 80 mg·L⁻¹ at injection rates from 5000 to 20,000 L·day⁻¹ generate a durable denitrification plume (>50 days under the maximum limit of nitrate concentration). Injection of water with lower CH₂O concentrations and higher injection rates leads to larger plumes but with lower denitrification intensity. The in situ test will also characterise aquifer properties such as depth-related redox conditions and the aquifer parameters given that the injection rate and the extent of the denitrification plume does not only depend on the geochemical variables but also on the ground water velocity.

U-series isotopes in suspended sediments of the Himalayan rivers

M. GRANET AND F. CHABAUX
Centre de Géochimie de la Surface, CGS-EOST UMR 7517, 1 rue Blessig, 67084 Strasbourg Cedex, France (mгранет@illus.ustrasbg.fr; fchabaux@illus.ustrasbg.fr)

Geochemical analysis of river sediments allows to study and quantify the parameters which control erosion and weathering processes at the scale of the watershed. In particular, \(^{238}\text{U}-^{234}\text{U}-^{230}\text{Th}-^{226}\text{Ra}\) disequilibria are useful in supplying constraints on the time-scales of erosion and weathering processes (Granet et al., subm.; Chabaux et al., 2003).

Previous studies were carried out on different kind of sediments: bedloads and river bank sediments (i.e. Granet et al., subm.), and suspended materials (i.e. Dosseto et al., 2006). These works highlight quite different U-Th-Ra values for coarse sediments and suspended materials, which still need to be explained in order to propose robust time-scales of erosion and weathering processes.

Here we analysed U-Th-Ra disequilibria for all the solid phases carried by the Ganges river and its tributaries to understand the relationships among the different kind of sediments: river coarse sediments (Granet et al., subm.) and suspended materials sampled at different depths in the water column.

U-Th-Ra analyses of samples collected at the same location highlight a wide range of values from the coarse sediments to the surface suspended materials. The chemical heterogeneity is explained by the fact that the U-Th-Ra composition of the suspended materials is the result of a mixing between coarse sediments and fine materials collected at the same sampling location but which have different origins at the scale of the Ganges basin. The data allow to conclude that the fine materials originate from the Ganges alluvial plain where they have been trapped before to be reworked and carried by the rivers.

The chemical differences observed between suspended materials and river coarse sediments are due to their different origin and history. This certainly accounts for the different time-scales of transfer proposed for these solid phases: long times of about 100’s ka for the coarse sediments (Granet et al., subm.), and, in agreement with the mixing scenario, short times for the suspended materials.

Time-space migration of melting within the E-Atlantic plume and magmatism in Portugal: U-Pb ages and Pb-Sr-Hf isotopes

M. GRANGE1, U. SCHARER1, J. GIRARDEAU2 AND G. CORNEN2

1 Université de Nice - Sophia Antipolis, Geosciences Azur (UMR 6526), parc Valrose, F-06108 Nice, France (grange@unice.fr; scharer@unice.fr)
2 Université de Nantes, Laboratoire de Planétologie et Géodynamique (UMR 6112), 2 rue de la Houssinière, F-44322 Nantes cedex 3, France (vpcs@univ-nantes.fr; guy.cornen@univ-nantes.fr)

To examine time-space relations between gabbroic to granitic anorogenic magmatism in Portugal and seamount formation in the central east Atlantic region we have undertaken (1) U-Pb dating on zircon and titanite, (2) U-Pb and Rb-Sr isotope analyses on grain-by-grain selected feldspars and (3) Hf isotope analyses of the dated zircons. Ages are 68.9 ± 0.3 (2σ) and 70.0 ± 1.0 Ma for the Monchique complex, and 77.1 ± 0.4 and 75.8 ± 0.2 Ma for the Sines massif. For the Sintra magmatic complex four ages of 82.1 ± 0.2, 83.4 ± 0.7, 80.2 ± 0.6, and 81.7 ± 0.4 Ma are obtained. An older age of 88.2 ± 0.5 Ma is defined for the Ribamar complex. These ages define a period of at least 19 million years for alkalic magmatism showing a systematic increase in ages from south to north. For intrusional-subvolcanic rocks exposes more than 100 km to the north, much older ages of 146.5 ± 1.6, 142.3 ± 1.0, and 145.3 ± 1.4 Ma were determined.

Corrected for in-situ decay of U and Rb (isotope dilution) Pb, in the Cretaceous rocks lies at 18.522-19.299 for 206Pb/204Pb; at 15.555-16.007 for 207Pb/204Pb, and at 38.482-39.350 for 208Pb/204Pb, and Sr are 0.70274 to 0.70481. For Hf isotopes, εHf range from +4.3 to +9.6. Most sources are less radiogenic in 206Pb than the Cretaceous seamounts but they partly overlap with data from younger seamounts and the Madeira Archipelago. Examined in the Pb vs. εHf correlation diagrams all data plot in or adjacent to the field of worldwide OIB sources, being significantly different from any Atlantic MORB source. Cretaceous anorogenic alkaline magmatism in Portugal therefore requires melting of OIB-like mantle sources possibly followed by melting of the Iberian subcontinental mantle, as well as small contributions from old crust. The large spectra of lithologies seems to reflect differences in degrees of melting in possibly both, the plume and the subcontinental mantle. Emplacement of the 88 to 69 Ma alkaline complexes including the 77 Ma old Ormonde seamount is younger than Cretaceous seamount formation along the continent-ocean transition in the central east Atlantic. On the other hand, it is much older than Oligo-Miocene and Quaternary seamount emplacement. This pattern allows to establish that melting within the plume migrated in time from West (104-81 Ma) to East (88-69 Ma) and South (< 69 Ma).

Lithium incorporation in olivine

K.J. GRANT AND B.J. WOOD

GEMOC, Macquarie University, Sydney, Australia (kgrant@els.mq.edu.au; bwood@els.mq.edu.au)

The relative concentrations of the two stable isotopes of lithium are increasingly being used to investigate chemical homogeneity and evolution of the upper mantle. The principal host for lithium in the mantle is olivine, but how univalent species, such as Li and Na, are incorporated into the crystal structure remains poorly understood. Here, we describe the results of isobaric crystal-melt partitioning experiments which, together with thermodynamic modelling, provide insight into the mechanisms of incorporation of Li in forsterite and natural olivine of mantle composition.

The results of partitioning experiments conducted on end-member forsterite doped with varying concentrations of lithium and trivalent cations show that the dominant substitution mechanism depends strongly on the concentrations of dopant elements. At relatively high concentrations (>20 ppm Li in the crystal), lithium is principally incorporated into near end member forsterite via coupled substitution with trivalent cations such as Al and Fe³⁺. At <20 ppm Li in the crystal, however, there is no correlation between Li partitioning and trivalent element concentration and results indicate charge-balance via vacancy or interstitial defect formation.

The lithium contents of natural olivine from the spinel stability field were measured using LA-ICPMS. The amount of Li in olivine is low (<5 ppm) and, unlike Na, does not correlate with the concentration of any trivalent cation species. We therefore conducted a series of additional experiments in order to investigate Li incorporation in natural, Fe-bearing olivine. In these experiments, crystals were grown at 1 atm from a natural basanite melt, at a range of oxygen fugacities. The results demonstrate that the partitioning of lithium between iron-bearing olivine (approximately Fo89) and melt is strongly dependent on oxygen fugacity (fO₂). The concentrations of lithium in mineral-melt pairs from our experiments show that DLi olivine-melt decreases from 0.3 at IW to 0.15 at NNO. This negative dependence on fO₂ suggests that lithium is incorporated into Fe-bearing olivine either through formation of oxygen vacancies or coupled to tetrahedral Fe²⁺. The consequences are that partitioning and diffusion of Li in natural materials is strongly dependent on the activities of major components in the medium.
A chondritic and nonchondritic Earth: What would the dynamists say?

AMARA L. GRAPS¹,² AND ALESSANDRO MORBIDELLI³

¹INAF Istituto di Fisica dello Spazio Interplanetario, Rome, Italy (amara.graps@ifs-roma.inaf.it)
²Planetary Science Institute, Tucson, Arizona, USA.
³Observatoire de la Côte d’Azur, BP 4229, F-06304 Nice cedex 4, France.

The question of the origin of water on Earth is as pure as SMOW: it can be reduced to endogenic or an exogenic sources, however the reduction problem is anything but simple. This complex question must be probed via theoretical, physical, isotopic, and geochemical arguments, each of which require highly specialized skills. Many of the physical arguments can be numerically probed via n-body simulations that build terrestrial planets from smaller bodies in the inner solar system during its formation period, while many of the isotopic and geochemical arguments can be explored via sample collections and remote measurements of terrestrial and extraterrestrial materials. To properly address the question of the origin of water on Earth requires that each of these approaches use the other approach as a constraint.

For example, upon building their planets, the dynamists will negate or affirm the simulated planets with constraints including (D/H) ratios, water abundances, noble gas isotopic ratios and abundances, and nitrogen, oxygen, and HSE isotopic compositions. And, upon collecting their samples, the geochemists will negate or affirm the samples’ origins using physical models of solar nebula gas temperatures, time for core formation, dates of chondrules and zircons and mixes of solar elements to construct a body with plausible elemental compositions. However, their tasks are not finished, until a synthesis of the two approaches is attempted.

In this work I will present the second approach from the geochemical angle with a first synthesis between the two approaches. While a chondritic Earth is often assumed by geochemists, the implications for a nonchondritic Earth are: 1) the heat-4He paradox [1]. Which type of Earth better meets the dynamical constraints?

2.7-2.6 Ga Archaean ecology determined by microbial activities: A view from C and S isotopes

N.V. GRASSINEAU AND E.G. NISBET

Dept. of Geology, Royal Holloway University of London, Egham TW20 0EX, UK (nathalie@gl.rhul.ac.uk)

The well-preserved Belingwe Greenstone Belt (2.7-2.6Ga) in Southern Zimbabwe was deposited in a sub-continental basin upon a basement gneiss. The isotopic study from drill-cores was based on clastic sedimentary units of two formations: Manjeri Fm. (2.7Ga) and Cheshire Fm. (2.6Ga). The most interesting sections of the Manjeri Fm. are two carbon- and sulphur-rich black shale layers, Shavi and Jimmy Members, with reduced carbon contents up to 20wt%. The very wide δ13C range of 40‰ obtained on pyrite separates (from −23.7 to +16.7‰) and the similarly wide δ34S range of nearly 32‰ (from −38.4 to −7.0‰) indicate primary bacterial matter. Such variations are in favour of biological fractionation that indicate various co-existing metabolic pathways: an oxygenic photosynthesis signature and anoxicogenic processes. There is also strong evidence for sulphate-reducing activity and even for S-oxidizers in various sections of the core. Some results associated with δ13C measured in carbonate clumps suggest the existence of a methane seep environment, emphasizing that complex microbial communities existed at 2.7Ga, based on well represented C and S biological cycles.

The Jimmy Member has been sampled from three different cores. The isotopic results suggest variations in the biological activities between the three localities. There is evidence of changing processes in the microbial mats, which allows an overview of the ecology of the Belingwe basin at this specific period. In fact, these changes are caused by changing biotopes in the environment, most likely due to the subsidence of the basin shifting sedimentation for shallow water to a deeper setting.

In the Cheshire black shales, δ13C values with between −44 and −32‰ suggest that methanogenic and even methanotrophic processes were present in the basin too. In addition to this study, δ13C for carbonate and reduced carbon have been measured on different stromatolitic sequences (Abell et al., 1985) from the two formations. The isotopic fractionations obtained are in favour of the Rubisco I signature indicating cyanobacterial activity.

All these information allow the re-constitution of the ecosystems that were present between 2.7 and 2.6Ga in the Belingwe basin. Multiple biological activities and various ecologies were needed to colonize the entire planet and to allow the evolution of the Archaean life.

Natural pigments as enamel opacifiers on ancient glass: Raman study of lazurite colour decoration on 1st to 2nd century glass vessels from Lubieszewo (Lübsow), Poland

Susanne Greiff and Jan Schuster

1Römisch-Germanisches Zentralmuseum Mainz, Kompetenzzentrum für Mineralogische Archäometrie und Konservierungsforschung des Landes Rheinland-Pfalz, (greiff@rgzm.de)
2Rheinische Friedrich-Wilhelms-Universität Bonn, Vor- u. Frühgeschichtliche Archäologie, (jan.grazyna.schuster@web.de)

Glass vessels decorated with colourful designs either by application of pigments or a low melting coloured glass flux were highly estimated by the Germanic population along the Northern and Eastern borders of the Roman Empire in the 1st and 2nd century AD. Despite the fact that a number of splendid examples with depictions of birds, fishes and plants has survived in high ranking tombs of the barbaric elite, investigations either of the glass composition or the decoration technique employed are still quite limited.

In the case of the Lübsow glasses the basic pattern is scratched on the glass body before the coloured glass flux layers carrying the pigments are applied. The presence of lazurite grains as colouring and opacifying agent was confirmed by Raman micro-spectroscopy of a pale grey ornament with a more vivid blue colour visible from the back side of the sherd.

The use of Lapis Lazuli as decorative inlay or as pigment for wall paintings in Mesopotamia, Egypt, Greece and the Roman Empire is a well known fact (see e.g. Derakhshani 1999). The as yet earliest evidence for its application in a high temperature process seems to fall into the 13th century with a high pressure phase Mg5Al5Si6O21(OH)7 named MgMgAl-pumpellyite in analogy to the phase MgAl-pumpellyite (Schiffman & Liou 1980) that was identified in experiments in the system MgO-Al2O3-SiO2-H2O for the first time (Schreyer et al. 1986). Due to its close chemical similarity to pyrope and the high-pressure, low-temperature stability delineated by Fockenberg (1998) up to 10 GPa, this phase was proposed to be an important water reservoir in cold subducting slabs (e.g. Schreyer et al. 1991; Fockenberg 1998). Gottschalk et al. (2000) found strong evidence that Mg5Al5Si6O21(OH)7 is isostructural to natural sursassite, Mn2Al5Si6O22(OH)6. Therefore, they suggested calling this high-pressure phase Mg-sursassite.

Calorimetric and P-V-T data for Mg-sursassite have been obtained by Grevel et al. (2001). The enthalpy of drop-solution was measured by high-temperature oxide melt calorimetry using lead borate as solvent. The resulting values were used to calculate the enthalpy of formation from different thermodynamic data sets; they range from -13892.2 kJ mol⁻¹ to -13927.9 kJ mol⁻¹ (formation from the elements). The heat capacity of the phase has been measured at T = 50 °C to T = 500 °C by differential scanning calorimetry. A Berman & Brown (1985) type four-term equation represents the heat capacity over the entire temperature range to within the experimental uncertainty: $C_p(T) = (1571.104 - 10560.89 \times T^{-3} + 26217890.0 \times T - 1798861000.0) \times 10^{-5} \times T^4 (J K^{-1} mol^{-1})$ (T in K).

The P-V-T behaviour of Mg-sursassite has been determined under high pressures and high temperatures up to 8 GPa and 800 °C using a MAX 80 cubic anvil high-pressure apparatus. By fitting a Birch-Murnaghan EOS to the data, the bulk modulus was determined as $116.0 \pm 1.3 \text{ GPa}$, K = 4, $V_{TO} = 446.49 \text{ Å}^3 \exp\left\{[(0.33 \pm 0.05) \times 10^{-4} + (0.65 \pm 0.85) \times 10^{-8} T dT]/(cK_f/\partial T)_{T=50} = -0.014 \pm 0.002 \text{ GPa K}^{-1}\right\}$. The thermodynamic data obtained are consistent with the phase equilibrium data (Fockenberg 1998) and included into the internally consistent dataset of Grevel (2004); the best agreement was obtained with $\Delta_f H_{298} = -13907.33 \text{ kJ mol}^{-1}$, and $S_f^{298} = 608.39 \text{ JK}^{-1} \text{ mol}^{-1}$.

The most significant pulses of evolution throughout Earth’s history have coincided with abrupt extinction events (e.g. Benton & Twitchett 2003). The most pronounced extinction of the Phanerozoic occurred near to the Permian-Triassic (P/Tr) boundary. Many trigger mechanisms have been proposed for the P/Tr event and include bolide impact, Siberian flood basalt volcanism, ocean anoxia, H2S emissions and catastrophic release of methane from the collapse of gas hydrates, all leading to the loss of many marine organisms and land plants. Biomarkers derived from pigments of photosynthetic green sulfur bacteria have been reported in sections from W. Australia and S. China, indicating the presence of toxic H2S in the zone of light penetration (PZE) of the Tethys Ocean during the P/Tr extinction (Grice et al., 2005). Similar observations were made in a section from W. Canada (Hays et al., 2007) suggesting that the Panthalassic Ocean was also prone to periodic euxinia. Any H2S reaching the atmosphere would have been both toxic and persistent (Kump et al., 2005). The significance and value of biogeochemical markers for identifying changes at the P/Tr and F/F will be presented. In particular, the pervasiveness of PZE conditions and the origin and importance of the biomarker crocetane, generally associated with the anaerobic oxidation of methane, will also be presented.

Amorphous components in the shell material of the brachiopod *Megerlia truncata*

E. GRIESSHABER1, K. KELM2, W.W. SCHMAHL1 AND A. SEHRBROCK3

1Department for Earth and Environment, LMU Munich, Munich, Germany (E.Griesshaber@lrz.uni-muenchen.de, W.Schmahl@lrz.uni-muenchen.de)
2CAESAR Research Institute, Bonn, Germany, (K.Kelm@caesar.de, A.Sehrbrock@caesar.de)

Brachiopods have existed throughout the phanerozoic and they developed shell materials employing the two principal mineral groups of hard biologic tissue: calcium carbonate and calcium phosphate, each with distinct hierarchical architecture [1, 2, 3]. We have observed a large domain filled with amorphous calcium carbonate in the shell of the modern brachiopod *Megerlia Truncata* by transmission electron microscopy. The domain has the typical outer shape and size of calcite crystals composing the fibrous secondary layer shell. It is adjacent to a large solid inclusion incorporated into the shell, suggesting that the amorphous material is related to a repair mechanism. The fibres of the secondary shell layer are surrounded by an an organic sheath. Along the innermost segment of the secondary layer, in addition to the organic sheaths, thick organic membranes are present. The amorphous domain is located between two thick organic membranes. In the outer nanocrystalline (primary) layer we do not observe any organic material between the crystallites. Under TEM imaging conditions the amorphous carbonate crystallized in situ to vaterite. Our observations indicate that brachiopod shell formation may occur via an amorphous calcium carbonate precursor that is produced in an initial stage prior to the crystallization of calcite.

Non-monotonic scenarios for the Earth’s thermal history
C. GRIGNÉ AND P.J. TACKLEY
Geophysical Fluid Dynamics, Institut für Geophysik, ETH Hönggerberg, CH8049, Zürich, Switzerland
(grigne@erdw.ethz.ch)

Expected variations of heat loss out of the Earth’s mantle with the cycle of aggregation and separation of supercontinents and the consequent variations of the wavelength of mantle flow are important, of the order of 20 TW on a timescale of a few hundreds million years [Grigné et al. 2005]. Monotonic models of planetary thermal evolution do not account for those variations and thus, may not be relevant for the Earth. The observed variations obtained in numerical models of mantle convection including continents are presented.

On a longer timescale, an event that may influence the heat loss of a terrestrial planet in a more dramatic way is the possible cessation of plate tectonics [e.g. Lenardic et al., 2004, Sleep 2000]. This possibility is studied here using models of thermal convection including a temperature-dependent viscosity and plastic yielding, which leads to either a stagnant lid or a plate-like regime, depending on the chosen parameters for plastic yielding, on the vigour of convection, on the thermal state of the mantle and on the geometry of the flow. We discuss the consequences of switching between the two regimes on the thermal state of the mantle, particularly on the temperature and heat flux at the core-mantle boundary, and on the thermal evolution of terrestrial planets.

The non-existence of the SEP noble gas component – Implications for geo- and cosmochemistry from Genesis samples
A. GRIMBERG1,2 AND R. WIENER2
1Physikalisches Institut, University of Bern, Sidlerstrasse 5, CH-3012 Bern, Switzerland (grimberg@erdw.ethz.ch)
2Isotope Geochemistry and Mineral Resources, NW C84, ETH, 8092 Zürich, Switzerland (wieler@erdw.ethz.ch)

Dust grains from the lunar regolith appear to contain a solar noble gas component isotopically heavier than the solar wind that is trapped at larger depths. This component was attributed to solar particles implanted at considerably higher energies than the solar wind and dubbed "SEP" for Solar Energetic Particles. Though it has been impossible to reconcile the high apparent abundance of the “SEP” component in lunar samples with the very low flux of solar energetic particles measured in-situ in space, the “SEP” component also found wide acceptance for the interpretation of N and O data in cosmo- and geochemistry.

Ne and Ar data from a metallic glass exposed on the Genesis mission now have clarified this conundrum. The isotopic and elemental depth profiles in the glass are very similar to those predicted for a solar wind uniform in composition implanted with the velocity distribution as measured by Genesis instruments. Thus, the gases at larger depths do not represent an isotopically distinct component but are solar wind particles that got fractionated with implantation depth as a function of their mass (Grimberg et al., 2006).

In this contribution we will discuss some implications of this finding for noble gas geo- and cosmochemistry. The interpretation of solar Ne in the Earth’s mantle being due to accretion of grains irradiated by an early solar corpuscular radiation (Trieloff et al., 2000) may be maintained, except that the observed Ne composition in this case would not be a result of large contributions of “SEP”-Ne but rather has to be implantation-fractionated SW-Ne. Similarly, the inferred isotopic composition of solar O in lunar dust reported by Hashizume and Chaussidon (2005) with a $\Delta^{17}O$ value less than -20% needs not to be revised, though the O measured by these authors has now to be viewed as fractionated SW-O rather than as “SEP”-O. On the other hand, the proposed inverse trend between the isotopic composition of Ne and N from SW to “SEP” (Mathew et al., 1998) needs to be reinterpreted in the light of our results.

Modelling of radium-barium sulphate co-precipitation in the near field of a HLNW repository

M. GRIVÉ, F. GRANDIA, J. MERINO, L. DURO AND J. BRUNO
ENVIROS-Spain S.L., Passeig de Rubí, 29-31, 08197 Valldoreix, Barcelona, Spain (mgrive@enviros.biz)

The solubility limit of radium is one of the main uncertainties remaining in the safety assessment of high-level nuclear waste repositories. Previous evaluations have commonly considered RaSO₄ as the solubility limiting phase, although observations in Nature indicate that this phase never occurs. Since the pioneering laboratory work of Germann (1921) and Doerner and Hoskins (1925), which showed a readily incorporation of radium into the barium sulphate (barite) lattice, most studies have concluded that the fate of radium in waters is intimately linked to barite precipitation. Both radium and barium are present in spent nuclear fuel. Most of the barium will be created during fuel irradiation, but some will also be generated shortly after the fuel is discharged from the reactor through decay of the short-lived isotopes of caesium, namely ¹³⁴Cs and ¹³⁷Cs. About 5 kg of Ba are estimated for each waste canister (SKB, 2006). On the other hand, radium is progressively generated by U-Th isotope decay chain, and maximum Ra inventory is going to be produced from the spent fuel after 100,000 years. The coexistence of both, Ba and Ra, in the fuel makes feasible the formation of (Ba,Ra)SO₄ solid solution, and, therefore, there is a great potential for reducing the calculated releases of ²²⁶Ra if co-precipitation effects are considered. These solid solution would occur at the interface between canister and clay-based barrier when, as a consequence of failure of canister integrity, a sulphate-rich water from the barrier leaches Ba and Ra from the spent fuel. In this conceptual model, the supply of sulphate is a key parameter to ensure (Ba,Ra)SO₄ formation. Calcium sulphate is a common accessory mineral in many bentonite rocks used in the barriers, although it can be easily leached by inflowing groundwaters, especially in ice-melting water intrusion.

In this study, we have calculated the effect of solid solution formation on the radium solubility limit in wide ranges of radium, barium and sulphate concentrations. The results obtained show that radium solubility limit can be reduced up to 4-5 orders of magnitude, mainly in those cases in which initial barium concentration is higher.

Single particle sampling and analysis

B. GROBETY¹, M.G.C. VERNOOIJ¹,² AND R. LORENZO²
¹Dep. of Geosciences, University of Fribourg, 1700 Fribourg, Switzerland (bernard.grobety@unifr.ch)
²Empa, Swiss Federal Laboratories for Materials Testing and Research, 8600 Dübendorf, Switzerland

The ability to sample and analyse individual particles is paramount for the determination of their sources, their distribution and to understand their interaction with the environment. Electromagnetic and thermophoretic sampler have been designed for collecting the ultrafine fraction (< 0.5PM) directly onto TEM grids. The results from numerical modelling of the deposition patterns and the sampling efficiency compared well with the experimentally determined performance of the samplers. Particle counts and chemical analysis (SEM, TEM) of individual particles sampled on a TEM grid can, therefore, easily be translated into quantitative information about the sampled aerosol.

Different sources of ultrafine particles have been studied using the new collectors. Particle emission from railway traffic and welding workplaces have been investigated by conventional EDS-based single particle analysis. Synchrotron based scanning transmission X-ray microscopy (STXM) and carbon(1s) near edge xray adsorption fine structure (NEXAFS) spectroscopy have been used to analyse soot particles produced by diesel engines and wood fires. First results show clear differences in the chemical structure of the particles from the two sources. NEXAFS may, therefore, be used as tool for the source apportionment of soot particles, but also to follow their evolution with time.
An improved single-step distillation of chromium-reducible sulfur

J. GRÖGER, K. HAMER AND H.D. SCHULZ
University of Bremen, Department of Geosciences, Bremen, Germany (jgroeger@uni-bremen.de)

The determination of elemental sulfur by chromium distillation is a controversial subject. Since elemental sulfur is an important intermediate in sulfur transformations in natural environments, a reliable method for quantitative recovery is required. Especially in the assessment of risks from acid sulfate soils a quantitative determination of all reduced inorganic sulfur compounds (RIS) is essential. In this field the chromium distillation has already been shown to be superior to other methods (e.g. Sullivan et al., 1999).

In the analysis of elemental sulfur Canfield et al. (1986) found a recovery of 92 % but did not specify any further the form of elemental sulfur deployed. Wieder et al. (1985) observed 94.4 % recovery by using powdered elemental sulfur but only in minor amounts. Fossing and Jørgensen (1989) and Kallmeyer et al. (2004) proved that the recovery of elemental sulfur is clearly limited. In their experiments only in dissolved state a quantitative recovery could be obtained. Neither granular nor colloidal sulfur showed recoveries >50%. Our experiments carried out with the procedure according to Canfield et al. (1986) yielded recoveries of less than 50% in the analysis of powdered elemental sulfur.

Our modified method provides recoveries >90% (mean value: 94 %) for powdered, colloidal and dissolved elemental sulfur up to at least 16 mg S (approx. 3.2% of a 0.5 g sample). Nevertheless all other reduced inorganic sulfur species are quantitatively recovered. The modified method is selective towards RIS. It does not affect organosulfur compounds or sulfates. The selectivity was verified with methionine, cystine, cysteine, taurine, gypsum and barite.

The obvious advantage of this method is the ensured quantitative recovery of elemental sulfur. Furthermore no additional toxic solvents, e.g. dimethylformamide (DMF) (Kallmeyer et al., 2004), are required. Besides that the selectivity of procedures involving DMF has not been tested with organosulfur compounds.

Determining mineral solubilities at high pressures: A new method combining weight-loss and in situ approaches

J. GROSS, W.V. MARESCH AND T. FOCKENBERG
Ruhr-Universitaet Bochum, Institut fuer Geologie, Mineralogie und Geophysik, D-44780 Bochum, Germany (juliane.gross@rub.de, walter.maresch@rub.de, thomas.fockenberg@rub.de)

Although a fairly extensive dataset is now available on the solubility of minerals in aqueous fluids at high pressure and temperature, almost all of the data above 0.5 GPa have been obtained by ex situ quench methods in piston-cylinder apparatus. A few comparative studies between such indirect weight-loss techniques and direct disappearance-of-phase, in situ methods are available, but only for trace elements (e.g. Ayers and Watson, 1993; Audetat and Keppler, 2006; Tropper and Manning, 2005). The results show huge differences, which are not yet satisfactorily explained. Here we introduce a new approach for determining solubilities of dissolved components using a hydrothermal diamond anvil cell (HDAC). We propose to exploit the tendency of crystals to approach an idiomorphic habit during HDAC runs, as observed by Wang et al. (2004), and also in our own HDAC studies. By defining the habit of a crystal before the run, its changing geometry can be modeled at various stages of the experiment. Knowing its original volume and mass, absolute solubilities can be determined. By comparing masses at various PT conditions, relative changes in solubility can be calculated. Our specially designed HDAC (Burchard et al., 2003) allows fluid pressures up to 4.0 GPa to be reached. The results should allow a more fundamental and objective comparison between in situ and ex situ experiments. The initial focus is on quartz solubility in pure water, in order to assess the voluminous published data at hand, most of which has been obtained by ex situ methods. However, important rock-forming minerals such as feldspar and mica appear viable targets for this approach.

Processes controlling the relationship between volcanic fronts and the subducting slab revisited

TIMOTHY L. GROVE AND CHRISTY B. TILL
Dept. of Earth, Atmos. and Planet. Sci., Mass. Inst. of Tech.,
54-1220, Cambridge, MA 02139, USA (tlgrove@mit.edu,
till@mit.edu)

Thus far a thorough understanding of the controls on the position of the arc volcanoes above the subducted slab has remained elusive. Recent work by England et al. (2004, GJI, 156, 377) and Syracuse and Abers (2006, G3, 7, 5) explores global variations in depth to the slab below the volcanic front. England et al. find a systematic variation in depth to the slab, which they attribute to the product of the convergence rate of the slab and the angle of descent (Vsinδ). They conclude the downdip velocity (Vsinδ) likely controls the temperature structure in the wedge because as the downdip velocity increases, the rate at which hotter mantle is sucked into the nose of the mantle wedge increases. This observation, when combined with new experimental results on the H2O-saturated melting of peridotite (Grove et al., 2006, EPSL 249, 74), provides a model to explain the location of arcs above the subducted slab. Grove et al. found the vapor-saturated melting curve for peridotite has a negative slope. Therefore as pressure decreases, temperature increases and the minimum depth of melting is limited by the maximum temperature in the shallowest - hottest part of the wedge nose. Thus, the negative slope of the H2O-saturated peridotite solidus controls the minimum depth where melting can occur. Following this model, as the downdip velocity decreases: 1) the depth to the hottest point on the wedge nose is increased, 2) the volcanic arc is shifted away from the trench and 3) the depth to the slab is increased. The H2O-saturated phase relations also predict that there should be a maximum cut-off depth for hydrous flux melting at ~135 - 150 km depth because the hydrous phases (chlorite and serpentine) present in the mantle wedge above the slab and within the slab have dehydrated by this depth. Arc volcanoes >150 km above the slab are therefore likely the product of adiabatic decompression melting, not hydrous flux melting.

DuneXpress, in situ analysis of interstellar dust

EBERHARD GRÜN1, RALF SRAMA1,2 AND THE DUNEXPRESS SCIENCE TEAM

1Max-Planck-Institut für Kernphysik, Heidelberg
(eberhard.gruen@mpi-hd.mpg.de)
2Institut für Raumfahrtsysteme, Univ. Stuttgart
(ralf.srama@mpi-hd.mpg.de)

Interstellar grains are messengers through space and time from the remote sites in which they formed and traversed in their journeys. Born as stardust with the elemental and isotopic compositions characteristic of the cool atmospheres of giant stars or of novae and supernovae explosions, they are subsequently modified in the interstellar medium. Interplanetary dust represents more processed material from comets and asteroids at different stages of Solar System evolution. DuneXpress will provide the capability to intercompare between epochs of our cosmological history and our planetary history, via the study of the compositional variation and differences between interplanetary and interstellar dust particles.

The key to this treasure is dust astronomy. Dust astronomy requires a dust telescope in space to detect particles while accurately distinguishing their origins via their interstellar and interplanetary trajectories. Trajectory sensors utilize the electric charge signals induced when charged dust grains fly through the detector. These sensors, in combination with state-of-the-art in-situ dust impact detectors, are capable of determining mass, speed, physical properties and the chemical composition of individual dust grains in space.

The detailed objectives of DuneXpress are: 1. Mapping the seasonal interstellar and interplanetary dust flow. 2. Identification of the chemical and isotopic classes of cosmic dust grains. 3. Determination of the size distribution of interstellar dust. 4. To study the differences between interplanetary dust of cometary and asteroidal origin.

The DuneXpress spacecraft will be placed in a halo orbit at the L2 libration point of the Sun-Earth system, outside the Earth’s debris belts. The spacecraft is three-axes stabilized and provides pointing of the dust telescope to better than one degree. The payload consists of dust telescopes, dust cameras and a plasma monitor. The total sensitive area of the dust instruments will be 1 m². The newly developed dust telescope consists of a Dust Trajectory Sensor (DTS) and a Large-Area Mass Analyzer (LAMA). LAMA consists of an impact target of 0.1 m² sensitive area. It performs time-of-flight measurements of ions generated by hypervelocity dust impacts onto the target. The device employs a reflectron in order to reach a mass resolution M/ΔM ≥ 150.

The mission costs less than 100 M€ and could be launched as early as 2013.
Potential remobilization of phosphorus from acid mining lake sediments

BJÖRN GRÜNEBERG\textsuperscript{1} AND ANDREAS KLEEBERG\textsuperscript{2}

\textsuperscript{1}Brandenburg University of Technology Cottbus, Chair of Freshwater Conservation, Seestraße 45, 15526 Bad Saarow, Germany (grueneberg@limno-tu-cottbus.de)

\textsuperscript{2}Leibniz Institute of Freshwater Ecology and Inland Fisheries, Müggelseedamm 301, 12587 Berlin, Germany (kleeberg@igb-berlin.de)

Introduction and methods

Natural maturation or artificial neutralization measures will lead to an accumulation of organic carbon (C\textsubscript{org}) and phosphorus (P) in acid mining lakes. Concurrently, a reduction of Fe-imports into these lakes is foreseeable (Kleeberg and Grüneberg 2005). Consequently, due to low redox potential and the neutral pH conditions in the sediment, reductive dissolution of Fe-hydroxides and the formation of sulfides might lead to P-remobilization and higher trophy.

This hypothesis was tested by studying the response of undisturbed sediment cores from the mining lake 117 (pelagic pH 3, age 35 a, z\textsubscript{max} 14.4 m, Plessa mining area, Lusatia, Germany) to C\textsubscript{org}- and P-additions. Glucose and dried Chlorella algae where added at rates between 0.2 and 3.5 g C m\textsuperscript{-2} d\textsuperscript{-1}.

Results

Only the columns with high sulfur (S) and relatively low Fe content (Fe:S ratio molar 1.4 – 2.0) showed P release with a flux between 0.15 and 0.46 mg m\textsuperscript{-2} d\textsuperscript{-1}, which is in a range comparable to oligotrophic lakes. The resulting concentration of soluble reactive P (SRP) in the pore water was approximately calculated in adsorption equilibrium with the fraction of Fe which is not immobilized as FeS using PHREEQC (Parkhurst and Appelo 1999). Vivianite formation is probably inhibited as high SRP-concentrations in the pore water up to 0.63 mg l\textsuperscript{-1} can not be explained in equilibrium with Vivianite.

Column experiments proved that P-sorption capacity becomes very low (< 1 mg P m\textsuperscript{-2} d\textsuperscript{-1}) under the influence of FeS\textsubscript{x}-formation in the sediment and without constant supply of Fe(OH)\textsubscript{3}, and that a mobilization of sediment P is possible despite high Fe content. The future P-sorption capacity might be approximated from the ratio of Fe- and S-input into the lake, provided that the supply of C\textsubscript{org} is adequate for intensive sulfate reduction.

Estimation of ferromanganese concretions growth rates using \textsuperscript{210}Pb

K. GRUZDOV, A. GRIGORIEV, V. ZHAMOIDA AND R. KRYMSKY

VSEGEI, St.Petersburg, Russia (gruzdov@hiex.phys.spbu.ru)

The present investigations are devoted to dating of ferromanganese concretions from Gulf of Finland using \textsuperscript{210}Pb. About 90\% of \textsuperscript{210}Pb detected in the concretions are generated directly inside concretions as a result of \textsuperscript{222}Rn decay formed from \textsuperscript{226}Ra. The content of \textsuperscript{228}Ra in the concretions are 10-50 times higher than in all types of bottom sediments irrespective of the morphology of the concretions (Grigoriev et al., 2004).

For the study of \textsuperscript{210}Pb concentrations one spheroidal concretion (20 mm in diameter) sampled in the eastern Gulf of Finland was selected. Four probes for \textsuperscript{210}Pb determination were sampled: 1 – from the centre of the concretion (distance from the centre 0-2.5 mm); 2 – 2.5-5 mm; 3 – 5-8 mm; 4 – 8-9 mm. Analysis of \textsuperscript{210}Pb concentrations was fulfilled in the Center of Isotopic Research of VSEGEI. The radioactive decay spectra of \textsuperscript{210}Pb and its daughter elements were detected with liquid-scintillation spectrometer Quantulus 1220.

The first model does not take into account \textsuperscript{222}Rn emanation. Composing equations set and solving it we got the minimal value of concretion age 670±50 yr. Accordingly the rate of concretions radial growth is within the range 0.013 – 0.042 mm/yr.

For the second model we tried to take into account \textsuperscript{222}Rn emanation. For this purpose we applied parameter \(\phi\), which defines emanation process. After solution of the equations set we obtained the age of studied spheroidal concretion is within the range 260 – 490 yr or its radial growth rate is within the range 0.018-0.034 mm/yr.

Remobilisation experiment of sulphides from massive Sulphide ore at 350°C and a differential stress without exotic fluid

L.X. GU¹, Y.C. ZHENG¹, X.Q. TANG¹, Z.J. WANG², C.Z. WU¹ AND X.Y. WU²

¹State Key Laboratory of Endogenic Metal Deposits Research (Nanjing University), Nanjing 210093, China (lxgu@nju.edu.cn)
²Guiyang Institute of Geochemistry, Academica Sinica, Guiyang 550002, China

The sample for the experiment is massive sulphide ore free of intense deformation textures, and is composed mainly of pyrite (32%), pyrrhotite (8%), chalcopyrite (9%), sphalerite (7%), quartz (25%) and silicates (14%). Fluid inclusions in quartz have salinities in the range of 15.96~22.98 wt% NaCl equiv.

A sample cylinder 17 mm in diameter and 40 mm in length was dried in an oven at 100°C for 24 hours before being mounted in a 3-axes rock stress machine with piston-cylinder equipment. After the experiment for 13 hours at temperature of 350°C, confining pressure of 414 MPa and axial pressure of 1276 MPa, the sample was cooled at room temperatures for 24 hours.

In the experimental product, pyrite has been intensely cataclastically deformed, resulting in numerous cracks and angular fragments. By contrast, pyrrhotite, chalcopyrite, and sphalerite are dominated by plastic deformation. Remobilised chalcopyrite and pyrrhotite occur as veinlets cutting pyrite porphyroclasts or as cementing materials of pyrite fragments, whereas remobilised sphalerite is only seen in minor amount in a few veinlets. The sulphides in the veinlets and breccia matrix are not connected to the same minerals outside the pyrite porphyroclast, indicating that remobilisation was not in solid state due to mineral plasticity, but driven by fluid. Under transmitted light, no dehydration textures of hydrous minerals have been observed, indicating that, the fluid for sulphide remobilisation in this experiment was derived mainly by breakdown of fluid inclusions.

The results of this experiment have lead to the following conclusions: 1) Deformation without exotic fluid can induce remobilisation of ore components. 2) Apart from metamorphic dewatering of hydrous minerals, breakdown of fluid inclusions due to deformation is capable to provide sufficient fluid for metal remobilisation. 3) Deformed pyrite is the best substrate for the precipitation of remobilised sulphides. 4) Sphalerite shows less strong tendency to remobilise than chalcopyrite under condition of the present experiment.

Petrography and Geochemistry Features of the Yoncayolu Metamorphics in Erzincan, NE Turkey

M. A. GUCER, Z. ASLAN AND O. BEKTAS

KTU, GMF, Department of Geological Engineering, Gumushane/Turkey (maligucer@ktu.edu.tr; aslan@ktu.edu.tr)

The study area is located of between transitional zone Pontide and Anatolide tectonic units, on the eastern of Erzincan (NE, Turkey). The aim of this study to explain mineralogy, petrography and geochemical characteristics of Yoncayolu Metamorphics. Permo-Triassic aged these metamorphics extend almost parallel to North Anatolian Fault and have lenses of phyllite, schist, calc-schist, quartzite, orthogneiss and metabasics of very-low grade, low-grade and often medium grade metamorphic rocks. These metamorphics are overlaid by Lias-Dogger aged Cayderesi Limestones. The Refahiye Ophiolite Melange cover both of these units tectonically [1].

In the study area, sericite+chlorite+quartz+muscovite-mineral assemblaged schists, amphibole+albite+K-feldspar+quartz+chlorite-mineral assemblaged gneisses, and quartz+sericite+calkite+chlorite-mineral assemblaged calc-schist are determined. Metabasics are characterized with light schistosity rather than formation of new minerals. Metamorphics are cut often by quartz veins and dense epidotization is observed at their contacts.

Metamorphics have a composition of 50-77% SiO₂, 9-21% Al₂O₃, 2-12% Fe₂O₃, 1-7% MgO, 2-5% Na₂O, 0-1,2,2% K₂O. Comparing to SiO₂ with major element values, a negative correlation between SiO₂- Al₂O₃, SiO₂- Fe₂O₃, SiO₂- MgO, SiO₂-CaO are seen whereas, there is a positive correlation between SiO₂-Na₂O. Similarly a negative correlation exist between SiO₂-Ga, SiO₂-Sr, SiO₂-Ni and a positive correlation between SiO₂-Nb, SiO₂-Zr, SiO₂-Y. Phyllite, schist and calc-silicate rocks fall in the within the calc-alkaline field on an AFM plot but metabasic rocks fall within the tholeiitic field. On the Ni-Zr/TiO₂ diagram all of the samples values point a igneous origin [2]. On the diagrams a positive correlation of K₂O versus Th, Ba, Rb are exists that are related to clay minerals within metamorphics.

Metamorphics exhibit an increase from very low grade to medium grade metamorphism along south to north.

4Okayama University of Science, RINS, Okayama, Japan (okumura@rins.ous.ac.jp)

Introduction
The purpose of this study is to identify and microcharacterize the phosphates in Martian meteorites.

Samples and Experimental Procedures
Standard polished geological thin sections were prepared from the Nakhla, ALH84001 and Y-000593 nakhlites for WDS analysis and CL spectral investigation. Details on the CL equipments, methods, sample preparation and samples can be found in [1-3].

Discussion of results
Various phosphates such as β-Ca-phosphate (ALH84001), chloroapatite (Nakhla) and apatite (Y-000593-nakhlite) have been identified in these samples (Fig. 1), indicating the mineralogical information on the fluid-rock-atmospheric interactions in the Martian environment.

Micro-Raman spectroscopy and optical reflectance studies of coals with different rank

A. GUEDES, B. VALENTIM, S. RODRIGUES, A. COSTA, M. MARQUES AND D. FLORES

Centro and Departamento de Geologia da Faculdade de Ciências da Universidade do Porto, Porto, Portugal (aguedes@fc.up.pt)

Powerfull techniques for studying changes in the structure of organic matter during coalification and graphitisation processes include micro-Raman spectroscopy and optical reflectance.

Since coal is a heterogeneous rock with different maceral composition, the coalification studies should include the properties of each individualized component and not the average samples. Therefore, micro-Raman spectroscopy and optical reflectance analysis were performed on collotelinite and fusinite macerals from a set of coals with increasing rank.

The Raman analysis indicates the presence of bands at 1580 cm⁻¹ (G), 1470 cm⁻¹, 1350 cm⁻¹ (D₁) and 1170 cm⁻¹ on the first-order Raman spectrum on both macerals from the different coal samples. From table 1 several differences between both macerals can be observed, lower values of FWHMₕ and higher values of reflectance, vₕ and D₁/G were obtained on fusinite in all samples with the exception of sample 3153 (anthracite). With increasing reflectance a narrowing of the G band and its shift toward higher wavenumbers occur on both macerals. However the D₁/G intensity area show a slight decrease on collotelinite (except for sample 3153) and a rather constant values on fusinite. The results show that within the same coal sample the Raman parameters and reflectance in collotelinite and fusinite are different and their evolution with increasing of coal rank is also different.

Table 1: Raman parameters and reflectance of collotelinite and fusinite macerals from a set of coals of increasing rank.

Stable isotope fingerprinting of iron metabolism in higher plants

M. GUELKE1, E. SCHEUERMANN2, F. VON BLANCKENBURG1, N. VON WIREN2 AND R. SCHOENBERG1

1Institute for Mineralogy, University of Hannover, D-30167 Hannover (m.guelke@mineralogie.uni-hannover.de)
2Institute for Plant Nutrition, University of Hohenheim, D-70599 Stuttgart (scheuerm@uni-hohenheim.de)

The fractionation of stable iron isotopes by biological processes is currently a matter of intense debate. Our study is the first to show that higher plants fractionate stable iron isotopes during Fe acquisition and translocation in a significant and plant-specific manner [1].

To maintain an optimal iron supply plants have adopted two different strategies to acquire iron from the soil [2]. Strategy I plants reduce Fe(III) in the rhizosphere, as only Fe(II) can be transported across the plasma membrane of root cells. Strategy II plants acquire Fe(III) by complexation with phytosiderophores. In which form iron is translocated from roots to shoots is so far unclear [3].

Stable iron isotope compositions reflect these two uptake strategies when soils are Fe sufficient [1]. Reduction of Fe(III) in soils by strategy I plants results in the uptake of light iron compared to the available Fe in soils; complexation with siderophores by strategy II plants results in only minor fractionation. Furthermore, younger parts of strategy I plants get increasingly depleted in heavy isotopes from the first to the fourth leaf, while strategy II plants incorporate Fe of virtually uniform isotope composition throughout [1].

Here we report new results of changes in Fe isotopic compositions of strategy I (tomato, bean) and strategy II plants (oat) during growth in a nutrient solution environment under Fe-sufficient conditions. Older leaves of strategy I plants get increasingly enriched in heavy Fe isotopes whereas younger leaves become lighter while the plant grows (δ56Fe = up to -3 ± 0.05 (2SD) ‰). In strategy II plants all parts of the plant incorporate similar isotope compositions during growth. These results now show that indeed younger leaves of strategy I plants receive a substantial proportion of their Fe from older leaves. Apparently differences in iron translocation mechanisms between strategy I and II plants exist. Inside the plant Fe is scavenged by complexing agents, e.g. nicotianamine in the cells or citrate in the xylem. Nicotianamine has the ability to bind ferrous and ferric iron. The current hypothesis is that strategy I plants change the Fe redox state during translocation. In contrast, Fe in strategy II plants remains in the ferric state but changes its ligands.

Under Fe deficiency plants mobilize Fe from phytoferritin in older leaves, which includes a reduction step. The challenge is now to assign Fe isotope labels to these redox changes during re-/translocation.

Further evidence for a two stage magmatic underplating event in the Ivrea-Verbano Zone, Italy

Z. GÜNES1, U. KLÖTZLI1 AND S. SINIGOI2

1Center of Earth Sciences, University of Vienna, Austria (zekeriya.gunes@univie.ac.at)
2Dipt. di Scienze della Terra, Universita’ di Trieste, Italy (sinigoi@units.it)

Magmatites of the continental crust are essentially formed by two tectono-magmatic processes: In the course of subduction and by the way of “magmatic underplating”. While subduction processes can be studied at many different places world-wide, the process of “magmatic underplating” can only be studied directly in the Ivrea-Verbano Zone (IVZ) of the Southern Alps (Italy). So our understanding of this not less important mechanism of crustal growth is still unsatisfactory inasmuch as reliable age data providing tight time constraints on the duration of the underplating processes are still missing. One of the major open questions still is, for instance, whether magma formation and emplacement is a discrete or a continuous event. The IVZ is interpreted as being a slice of the South-Alpine lower crust intruded by mantle magmas. Rocks of this zone have been grouped in two major units, the voluminous composite Mafic Complex (=Mafic Formation) and the high-grade paragneiss Kinzigite Formation. For the main intrusive body of the Mafic Complex in the Val Sesia and Val Sessera sections an intrusion age of 288 ± 4 Ma is postulated [1]. This speaks in favour of a short, discrete main underplating event in the Lower Permian. In addition, the age data indicate that a significant thermal event affected the country rock of the Mafic Complex around 310 Ma, the significance of which is not yet clear. “Strati-graphically” this thermal event seems to be most prominent in the lower most parts of the crust. We have investigated the Campello Monti and Monte Capio area (Val Strona). Here the Mafic Complex forms a composite intrusion which only in parts can be paralleled with the main intrusive body in the Val Sesia. Especially an amphibole-garnet-bearing gabbro strongly resembles the amphibole-gabbro of the lower mafic complex in the Val Sessera [1]. From the former a zircon LA-MC-ICP-MS U-Pb intrusion age of 331.5 ± 3.8 Ma could be determined. This new age is the first unequivocal evidence that an older magmatic event occurred in the lower part of the IVZ crust in the Middle Carboniferous. This substantiates that the underplating event in the IVZ indeed was a long lasting process with a duration of ca. 50 Ma but comprising a number of discrete intrusive phases of only a few million years duration. The geodynamic implications of this new aspect in the evolution of the IVZ in the framework of the Variscan orogeny, mainly the onset of crustal thinning already in the Carboniferous, remain to be investigated.

Silica polymerization. Rate constants at 23° to 80°C as a function of pH

I. GUNNARSSON AND S. ARNÓRSSON

Earth Science Institute, University of Iceland, Sturlugata 7, 101 Reykjavík, Iceland.
(ingvig@hi.is; stefanar@raunvis.hi.is)

When monomeric silica concentration exceeds the solubility of amorphous silica, monomeric silica reacts to form polymeric silica. It is generally agreed that the polymerization proceeds until the concentration of monomeric silica is equal to the solubility of amorphous silica. Much work has been done over the years to determine the rate of silica polymerization but to date there is no general agreement on rate laws. Rate orders of 1 to 8 and rate maximum between pH 6 to 9 have been reported. Part of the discrepancies is probably due to failures to recognize things like induction periods and failure to account for higher amorphous silica solubility at high pH values.

After the initial stages of silica polymerization, where silica is forming nuclei of critical size, the polymers have a tendency to maximize the number of siloxane bonds (Si-O-Si) and minimize the number uncondensed SiOH groups and they become spherical units. These polymers grow with addition of monomeric silica on their surfaces. At this stage of silica polymerization there is equilibrium between the silica polymers and monomeric silica in solution. As polymerization continues the polymers increase in size and the area, to which the monomers are added, is continuously changing affecting the polymerization rate. Silica polymerization stops when the polymers are so big that surface energy does not contribute much to the total energy of the polymers. Polymers of that size have similar solubility as amorphous silica.

In this contribution are presented the results of silica polymerization experiments in the pH range 5.66-9.18 at 23°, 2.48-8.50 at 58° and 2.18-8.75 at 80°C. Ionic strength was 0.11±0.02M in all cases. Rate of silica polymerization was monitored by analyzing concentration of molybdate active silica. Results indicate that the rate of silica polymerization is greatly affected by the pH value of the solution and there is no maximum in polymerization rates over the pH range of this study. The calculated rate constants increase with rising pH value over the whole pH range of the experiments at all experimental temperatures.

The sulphur isotopic evolution of late Neoarchean and early Paleoproterozoic seawater

Q. GUO1,2, H. STRAUSS2, S. SCHRÖDER3 AND J. GUTZMER1

1State Key Laboratory for Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (guoqingjun@vip.skleg.cn)
2Geologisch-Paläontologisches Institut, Westfälische Wilhelms-Universität Münster, 48149 Münster, Germany
3Paleoproterozoic Mineralization Research Group, Department of Geology, University of Johannesburg, Johannesburg, South Africa

Despite its well accepted importance for reconstructing the redox evolution of Earth’s ocean-atmosphere system, our knowledge of the abundance and isotopic composition of seawater sulphate decreases substantially with increasing time. This is most apparent for the Precambrian. In particular, the proposed rise in atmospheric oxygen abundance (Great Oxidation Event) around 2.3 Ga ago and an assumed parallel increase in the abundance of dissolved oceanic sulphate is not documented at all.

Here, we report abundances for sulphate sulphur as well as sulphur and oxygen isotopic compositions for the Neoarchean-Paleoproterozoic succession deposited on the Kaapvaal Craton between 2.65 and 1.92 Ga, i.e. the Transvaal Supergroup of eastern Transvaal and correlative units in the Griqualand West Subbasin.

Trace sulphate extracted from 16 carbonates of the Koegas, Duitschland, Mooidraai, Silverton and Lucknow formations gradually increase from less than 0.1 to 23.5nmol/kg. The respective sulphate sulphur isotopic composition varies between +4.6 and +34.6‰ with a distinct stratigraphic trend being discernible. The oxygen isotope values for the trace sulphate displays a range between +6.1 to +21.1‰.

Individual stratigraphic units are well constrained in their isotopic composition. Yet, the truly global significance of the isotope record needs to be verified with additional analyses. So far, respective host carbonates have provided a carbonate carbon isotopic composition that includes pertinent features considered characteristic for this time interval, such as the globally recorded 13C maximum (the Lomagundi-Jatulian event).

**Trace element and Ca isotope ratios in calcareous dinoflagellate cysts of** *Thoracosphaera heimii*

N. Guccione 1, K. Zonneveld 2 and H. Kuhnert 3

1Institut für Mineralogie, Universität Münster, Correnstr. 24, 48149 Münster (nikolaus.guccione@uni-muenster.de)
2Universität Bremen, Klagenfurter Str., 28159 Bremen (zonnev@uni-bremen.de)
3RCOM, Klagenfurter Str., 28159 Bremen (hkuhnert@uni-bremen.de)

Dinoflagellates are important marine primary producers, which significantly contribute to the global carbon cycle. They can form cysts, composed of organic-material, silicate or calcium carbonate, which are used as stratigraphic and paleoenvironmental indicators.

The export flux of calcareous dinoflagellate cysts is of particular importance in temperate to tropical waters and is dominated by the species *Thoracosphaera heimii*. Providing a significant calcium sink, their Ca isotope fractionation is an important factor for the Ca isotope ratios of the locally deposited carbonate oozes, but might also be important for defining the isotopic Ca budget of the ocean. In addition, *T. heimii* cysts provide the potential to record long-term changes in the ocean chemistry, because their first occurrence dates at the K/T boundary [1].

The CaCO₃ cysts of *T. heimii* might be particularly useful as proxy archive recording ocean surface conditions (e.g. temperature, pH) due to their formation at the deep chlorophyll maximum depth in the water column and the ease in which a monospecific assemblage can be isolated from sediments [2]. Furthermore, they are comparatively insensitive to dissolution.

The dominant calcareous dinoflagellate *T. heimii* was grown in lab cultures at varying temperatures ranging from 12 to 30 °C as described earlier [3]. Trace element to Ca and Ca isotope ratios were analysed on the CaCO₃ cysts, previously cleaned from organic components.

The Ca isotope fractionation for *T. heimii* cysts resembles previous calibrations of other marine calcifiers, including coccolithophores [4], foraminifers and corals [5], in respect to absolute fractionation and temperature sensitivity. In contrast, trace element to Ca ratios and their temperature dependence differ from trends observed for coccolithophores and planktonic foraminifera. These results will be discussed in terms of bimineralisation of *T. heimii* and potential use for paleoceanographic applications.

**Mechanisms of iron(III) binding to organic matter and its competitive effect on trace metals**

J.P. Gustafsson 1, J.W.J. van Schaik 2, D. Berggren Kleja 3 and I. Persson 4

1Department of Land and Water Resources Engineering, KTH (Royal Institute of Technology), Stockholm, Sweden (gustafp@kth.se)
2Department of Soil Sciences, SLU (Swedish University of Agricultural Sciences), Uppsala, Sweden (joris.van.schaik@mv.slu.se)
3Department of Chemistry, SLU (Swedish University of Agricultural Sciences), Uppsala, Sweden (ingmar.persson@kemi.slu.se)

Organic complexation of iron(III) is important for the binding of trace metals in natural environments because of competition effects. We have investigated the binding mode of iron(III) in the presence of O horizon soil material and isolated fulvic acid by means of EXAFS spectroscopy. The spectra for the O horizon samples showed Fe-O/N interactions at 2.02(2) Å, second-shell Fe-C interactions at 3.00(4) Å, and a mean Fe-Fe distance at 3.37(3) Å (Gustafsson et al., 2007). This showed that the major part of the organically complexed iron(III) was hydrolyzed, and comparisons with literature data revealed that iron(III) had formed a mixture of di- and trimeric complexes with soil organic matter. The results were used to constrain a model for organic complexation, the Stockholm Humic Model. Observed competition effects on Cd ²⁺, Cu ²⁺, Ni ²⁺ and VO ³⁻ were well described with a single dimeric iron(III) complex in the model. In another set of experiments iron(III) was equilibrated with isolated fulvic acid at different initial pH:s, and the mixtures were analyzed with EXAFS spectroscopy after different time periods. These spectra lacked the Fe–Fe distance at 3.37 Å, instead Fe formed a monomeric iron(III) complex with FA or was reduced to Fe(II) after prolonged equilibration times. Our results indicate that the iron(III) binding modes to organic matter need not be identical in soils and aquatic environments. In soil suspensions any added iron(III) is quickly polymerized, whereas in solutions significant amounts of iron(III) complexes may remain as monomeric organic complexes. This shows that much remains to be done before the aquatic geochemistry of iron(III) is fully understood.

Identifying processes and rates of incipient chemical weathering using Pb and U isotopes

M. GUTJAH1, M. B. ANDERSEN1 and B. BOURDON2
1Bristol Isotope Group, Department of Earth Sciences, Queens Road, Bristol, BS8 1RJ, UK
2ETH Zürich, Institute for Isotope Geology and Mineral Resources, 8092 Zürich, Switzerland

This study focused on the role of incipient chemical weathering on combined U and Pb isotope systematics. Understanding the effect of incipient weathering is particularly relevant for interpreting the marine Pb isotope record during glacial-interglacial transitions. Here, we investigate whether the preferential release of radiogenic Pb, displaced through alpha recoil, could explain Pb isotope variations during the recent deglaciation. Soil samples from a granite chronosequence at the forefield of the Damma glacier were sampled for an experimental study of chemical weathering. A sequential leaching technique was employed on the <1mm grain size fraction (0.05M, 0.1M HBr; 0.05M, 0.6M HCl; leaching each fraction for 24 hours in a shaker) and the residue dissolved by pressure digestion. In order to distinguish the effects of preferential dissolution of U- and Th-rich minerals (Harlavan et al., 1998) and release of alpha-recoiled Pb, we measured both the Pb isotope compositions and $\delta^{234}$U (expressed as the per mil $234U/238U$ variation from secular equilibrium). Most strikingly, even the moraine samples with a maximum of hundreds of years, as opposed to much longer timescales suggested in earlier studies.

Dissolution of magnetite in hydrothermal solutions: Kinetics and speciation by in situ X-ray absorption spectroscopy

F. GUYOT1,2, D. DAVA1, F. DUFAUD1, D. TESTEMALE3 and I. MARTINEZ3.
1IPGP, Paris (guyot@impmc.jussieu.fr; daval@ipgp.jussieu.fr; dufaud@ipgp.jussieu.fr; martinez@ipgp.jussieu.fr)
2IMPMC, Paris
3Institut Néel, Grenoble (denis.testemale@grenoble.cnrs.fr)

In the research program on mineral sequestration of CO$_2$, time-resolved studies dedicated to fluid-rock interactions are essential. Magnetite (Fe$^{III}$)O$_4$ is an accessory host solid phase (the most reactive host candidates are basic and ultra-basic rocks), but is likely to release critical amounts of dissolved iron in the fluid, iron which is a reactant for the carbonation of carbon dioxide. Furthermore, magnetite may play a major role in the redox control of the system. For those reasons, we studied the dissolution of magnetite in hydrothermal conditions, as a function of pH, temperature and the nature of ligands in presence (the roles of sulfate and chloride ligands were quantitatively compared).

Our methodology is based on in situ x-ray absorption spectroscopy (XAS) on synchrotron sources. For that purpose, we use an high-pressure/high-temperature cell (Testemale et al.) that allows, in the same run, the determination of iron speciation and the measurement of X-ray absorption spectra at the iron K-edge (see Figure 1). The latter is a strong point of this method: the speciation and oxidation state of dissolved iron can be inferred from these x-ray absorption spectra.

We will present a kinetics model for the dissolution of magnetite, in the conditions investigated (300 bar, [30-300°C]), to be compared with literature data. In particular, the role of iron speciation and the stoechiometric nature of the dissolution will be discussed.

Figure 1: Total iron molality (Fe$^{II}$ and Fe$^{III}$), as a function of time, in a 2.5M sulfuric acid solution. For each point, we acquired a XAS spectrum from which the speciation is determined.

Apatite- and K feldspar-hosted primary carbonatite melt inclusions from mantle xenoliths, Hungary

T. GUZMICS1, Z. ZAJACZ2,1, C. SZABÓ1, AND W. HALTER2

1Lithosphere Fluid Research Laboratory, Eötvös University
Budapest, 1117 Pázmány P. s. 1/C, Budapest, Hungary
(cszabo@elte.hu)
2Department of Earth Sciences, Institute of Isotope Geochemistry and Mineral Resources, ETH Zürich, 8092 Zürich, Switzerland (zajacz@erdw.ethz.ch)

Samples

We studied metasomatic mantle xenoliths, consisting of clinopyroxene, apatite, K feldspar and phlogopite, were found in lamprophyre dikes in central Hungary. A large number of multiphase primary carbonatite melt inclusions (CMI) were observed in apatite and K feldspar, but clinopyroxene and phlogopite are barren. Average PM normalized REE distribution of apatite and K feldspar hosted CMI (n=60 and n=20, respectively) are shown on Fig. 1. Both CMI in apatite (Ap) and K feldspar (Kfs) are extremely enriched in LREEs relative to HREEs analyzed by LA-ICP-MS.

Discussion

It is a characteristic geochemical feature that CMI in Kfs contain small amount of P and that in Ap do small amount of K. The REE distribution of CMI in both host minerals show similar pattern (Fig. 1), suggesting common origin of their melts. It is also supported by some unique CMI hosted in Ap having trace element composition and pattern similar to CMI of K feldspar. All of these indicate that there was a liquid-liquid separation between a P-bearing carbonatite melt and a carbonate-bearing silicate melt before crystallization of the host minerals. It seems that the liquid-liquid separation was caused by dramatic compositional change in the continuously migrating “initial” carbonatite melt. This change was linked with an open-system metasomatic interaction between the “initial” melt and the peridotite mantle.

Conclusion

The studied xenoliths were formed by metasomatic interaction between the peridotite mantle and the P-bearing, Mg-calcitic “initial” carbonatite melt.

Fluid composition, density and viscosity changes along terrestrial Pressure-Temperature paths associated with particular tectonic processes

A.C. HACK AND A.B. THOMPSON

Clausiusstrasse 25, NW-E78.2, CH-8092 Zürich
(alistair.hack@erdw.ethz.ch; alan.thompson@erdw.ethz.ch)

Physical properties determine how buoyant fluids rise (density) and how fast they flow (viscosity). Such physical properties will also depend on fluid composition, especially where mineral solubility is high. We have modeled the thermal and chemical behavior of dehydration fluids with dissolved constituents generated in and above subduction zones, and also along burial and exhumation paths in the crust. Silica solubility has been used as an example (e.g., Gerya et al. 2005). SiO2–H2O fluid viscosities at quartz-saturation have been modeled following Audétat & Keppler (2004). Silicate-bearing fluid densities have not yet been measured, so in the interim, we have modeled SiO2–H2O fluid densities at quartz-saturation. We assumed an ideal mixture and combined solubility data with properties of the end-member liquids. The results show that fluid-rock interactions are likely to follow distinct patterns along different PT paths. For example, buoyant fluid flow into the overlying hot mantle wedge is up T (while down P) and follows a dissolution path, whereby fluids may create permeability, facilitating higher fluxes. Fluids flowing along the slab-mantle interface move to lower T and P and precipitate dissolved matter, which acts to decrease porosity and probably permeability and reduce flow rates in that direction. Our analysis reveals that subtle differences in fluid PT ascent paths, strongly influence both solubility and fluid density-viscosity evolution along paths and thus also the efficiency and rate of mass transport. Low-viscosity and low-density fluids have the greatest chance of moving at higher velocities. With increases in density, solute concentration increases, buoyancy decreases and viscosity increases. Increased solubility of mineral in fluid thus decreases ease of ascent, but tends to work in the opposite PT direction. So fluids related to rock burial become increasingly dense and more viscose, and thus less mobile. In contrast, rising fluids tend increase their buoyancy and decrease their viscosity but because solute concentrations also decrease, fluid ascent can become restricted by precipitation.

Genesis and rates of fluid flow at the Mercator mud volcano, Gulf of Cadiz

M. HAECKEL1, C. BERNDT2, V. LIEBETRAU1, P. LINKE1, A. REITZ1, J. SCHÖNFELD1 AND H. VANNESTE2

1IFM-GEOMAR, Kiel, Germany (mhaeckel@ifm-geomar.de; areitz@ifm-geomar.de; vliebetrau@ifm-geomar.de; jschoenfeld@ifm-geomar.de; plinke@ifm-geomar.de)
2NOC, Southampton, UK (cbe@noc.soton.ac.uk; hlaev105@soton.ac.uk; hlaev105@soton.ac.uk)

Mud volcanism is a widespread phenomenon in the Gulf of Cadiz (GoC) and provides a window into deep structural and diagenetic processes [1]. Sediment pore fluids from the Mercator mud volcano (MMV), located in the El Arraiche mud volcano field offshore Morocco, are extremely enriched in chloride reaching up to 5.3 M (thus, exceeding normal seawater values by a factor of 9). Na/Cl ratios are close to 1 suggesting halite dissolution by the ascending fluid. This is corroborated by 3D seismic data that shows an active anticline below the eastern flank of the MMV, which can only be explained by a rising salt diapir. Additionally, the fluids are highly enriched in Li and B indicating a deep fluid source from mineral dewatering reactions at elevated temperatures (>100 °C). A deep fluid source is also supported by a radiogenic 87Sr/86Sr porewater signal of 0.7106 as well as the morphology of quartz and gypsum crystals transported within the ascending mud matrix. These crystals are probably of Triassic origin. Hence, the geochemical and the 3D seismic data suggest that the Triassic salt province 500 km further south on the Moroccan Margin might extend further north than previously known and that halokinesis has to be considered as a driving force for mud volcanism in the GoC.

Finally, a 1-D transport-reaction model has been applied to constrain the fluid advection rates. The numerical simulations of conservative porewater compounds Cl, Li, and B reveal upward fluid flow rates of ~6 cm/a at the top of the MMV, gradually decreasing to 0.3 cm/a towards the rim. In addition, a CTD mounted onto a video sled system provided bottom water salinity and temperature information (about 2 m above the seafloor) from tracks crossing the MMV. In combination with the numerical porewater analysis, this unique spatial data set allows to constrain the overall budgets for the release of water, methane, and other porewater constituents as well as the heat flow of the MMV.

Arsenic mineralogy in high-As wastes at historic gold mine sites, New Zealand

L. HAFFERT AND D. CRAW

Geology Department, University of Otago, PO Box 56, Dunedin, New Zealand

The studied mine processing sites are part of the Phoenix Mine and the Blackwater Mine, which are historic gold mines hosted within the Otago schist and Greenland Group schist, respectively. The processing of arsenopyrite ore produced very arsenic rich residues (up to 40 wt% As) and no rehabilitation was undertaken after mine closure at either mine. Thus, the studied sites possess suitable conditions for the study of the physical and chemical characteristics of secondary arsenic minerals, especially with respect to time. At the Blackwater Mines all arsenic was originally present as arsenolite (arsenic trioxide polymorph, AsO3), which is a by-product of arsenopyrite roasting. At the Phoenix Battery, where roasting did not take place, arsenopyrite was the original arsenic phase. High dissolved arsenic concentrations derived from the processing residues are temporarily immobilized by the formation of hydrated iron arsenates in the downstream environment. At the Blackwater Mine the hydrated iron arsenate is in the form of scorodite (FeAsO4·2H2O), whereas at the Phoenix Battery it is in the form of kankite (FeAsO 4·3.5 H 2O). In the past the precipitation of hydrated iron arsenates, especially scorodite, has been mainly associated with acidic environments. The studied mine sites are, however, excellent examples for iron arsenate precipitation in a geological setting with high neutralizing capacity and predominant circum-neutral pH. The stability of the hydrated arsenates depends on dissolved arsenic concentrations and is, therefore, controlled by the solubility and availability of the original As phase. In addition, the stability of As is further enhanced by the inherent morphology of the hydrated iron arsenates which precipitates as an interstitial cement, thereby creating an impermeable surface crust and preventing further dissolution of underlying arsenic minerals.
Application of in situ cosmogenic nuclide analysis to landform evolution in (palaeo)-periglacial south-west Britain

J.H. HÄGG1, M.A. SUMMERFIELD1, C. SCHNABEL2, W.M. PHILLIPS3 AND S. FREEMAN2

1Institute of Geography, School of Geosciences, University of Edinburgh, UK (j.hagg@ed.ac.uk)
2Scottish Universities Environmental Research Centre, East Kilbride, UK
3Idaho Geological Survey, University of Idaho, Moscow, ID, USA

Located beyond the southern limit of glaciation in Britain, the upland granitic terrain of Dartmoor, south-west England, has been exposed to long intervals of intense periglacial activity during the Pleistocene. This region has been significant in debates about appropriate models of long-term landscape change, most notably two-phase versus single-phase models of landform evolution, and the development of tors (Linton, 1955; Palmer & Nielsen, 1962). However, given the previous lack of quantitative techniques capable of constraining denudation and specific process rates, and thereby testing developmental models, for these features there remains much uncertainty in the interpretation of the classic landforms of the region. Here we present the results of research utilising in-situ cosmogenic nuclides to evaluate geomorphological processes and report on three key aspects of landform development: (1) the formation of tors and models of outcrop emergence in non-glaciated regions; (2) the development of regolith and boulderfields under periglacial conditions; and (3) catchment-averaged denudation rates derived from alluvial sediments. This variety of landforms and scale of investigation facilitates an integrated approach to the understanding of catchment-scale erosional dynamics. In addition, the complex nature of landform development that is evident in the area provides challenges to the application of in-situ cosmogenic nuclides and highlights both the potential and limitations of the technique.

Origin of tungsten mineralization in the quartzdioritic unit of the Boroujerd Granitoid Complex (Western Iran) using geochemical evidences

M. HAGHNAZAR, D. ESMAEILY AND M.V. VALIZADEH

School of Geology, University College of Science, University of Tehran, Iran (haghnazar@khayam.ut.ac.ir; esmaili@khayam.ut.ac.ir; mvalizad@chamran.ut.ac.ir)

Boroujerd Granitoid Complex of the Sanandaj-Sirjan Zone consists of three main units: granodiorite, quartzdiorite and monzogranite. In Nezamabad area (SE of this complex), quartzdioritic unit has been cut by various quartz-tourmaline veins having NW-SE trending. Tungsten mineralization (scheelite) accompanying by arsenopyrite, pyrite, pyrrhotite, chalcopyrite, sphalerite, malachite, azurite and quartz and tourmaline as gangue are generally associated with the veins.

The geochemical signature of this unit is compared with the well known W-bearing and W-barren granites (Lemann et al., 1994; Srivastava and Sinha, 1997; Singh and Singh, 2001) in order to investigate their relationship with tungsten mineralization in the area.

The host quartzdioritic unit of the quartz-tourmaline veins is mostly depleted in silica (52-63%), total alkalis (4.6%), Rb (94 ppm), Nb (10 ppm), W (6 ppm) and Sn (3 ppm) with low DI and enriched in CaO (6.11%), MgO (4.19%), MnO (0.14%), Sr (285 ppm) and Ba (359 ppm). Compared with the W-barren granites, the K/Rb (211) and Ba/Rb (4) ratios of this granitoid are also higher than its Rb/Sr ratio (0.34). All these geochemical evidences as well as I-type characteristics of the quartzdiorite unit (Ahmadi-Khalaji et al., 2007) indicate that the unit behaves as a barren granite.

On the other hand, geochemical investigation on the metamorphosed sedimentary rocks (hornfels and spottedschist) existing in contact with the quartzdioritic unit demonstrates that the W-bearing fluid originated from the dehydration of the metamorphosed sedimentary rocks and it mixing with granitic fluids.

The quartzdioritic unit is a W-barren granite of a low differentiated magma and has no significant role in tungsten mineralization. In contrary, metamorphic rocks fluids can be considered as the main source for tungsten mineralization rather than granitic fluids.

**Reaction textures of allanite in metagranitoids: A sub-micrometer insight in REE-mobility**

A. HAHN¹, G. FRANZ² AND D. RHEDE¹

¹GeoForschungsZentrum Potsdam, Section 4.1 and 4.2, 14473 Potsdam, Germany (ahahn@gfz-potsdam.de; rhede@gfz-potsdam.de)
²TU Berlin, Fachgebiet Mineralogie-Petrologie, 13355 Berlin, Germany (gerhard.franz@tu-berlin.de)

Various reaction textures of accessory allanite in an orthogneiss from the Tauern Window (Austria), which experienced metamorphism (max. 500-550°C, 1.0 GPa; Selverstone 1993), and extensive metasomatism have been investigated by high-resolution BSE images (JEOL Hyperprobe JXA-8500 F, field-emission cathode).

Euhedral to anhedral (Ø 150 - 500 µm), partly zoned allanite crystals have corona-type textures with polycrystalline (REE+Y)-poor epidote/clinozoisite rims (type 1). Variable deformation stages resulted in regularly to sigmoid or irregularly shaped rims of 20 - 200 µm thickness. Anhedral titanite crystals (15 µm) mark the core-rim boundary along the epidote/clinozoisite site of the paragenesis. Micropores within allanite (type 2), partly filled with Th- or REE-silicates, are part of the core-rim zonation (relatively REE+Y+Th-rich to – poor) or scattered over allanite. Th-silicates on grain boundaries of newly formed (REE+Y)-poor epidote/clinozoisite (polycrystalline epidote/ clinozoisite rim of allanite) indicate decomposition and reprecipitation of that phase. Patchy aggregates of allanite and REE-poor epidote with intermediate compositions, changing in an irregular pattern on the µm and sub-µm scale, are the dominant feature in the intensely deformed orthogneiss (type 3). In addition to these well-known textures up to 1 µm wide mineral-filled channels within elongate textures (max. 80 µm) in an allanite of type (3) were found (type 4). The zoned channels pass perpendicular through the internal textures, which are orientated parallel and perpendicular to the long axis of the allanite and connect (REE+Y+Th)-poor with relatively (REE+Y+Th)-enriched parts of the unzoned crystals.

In a preliminary interpretation texture (1) was formed in late- to postmagmatic stage in the protolith, textures (2, 3, 4) indicate a simultaneous fluid-assisted decomposition of allanite and growth of (REE+Y)-poor epidote/clinozoisite in an open system during metamorphism. The Th-silicate on grain boundaries within the epidote/clinozoisite rims of allanite and sub-micrometer wide channels within allanite possibly indicate multistage grain boundary diffusion and a gradually changing composition of the fluid phase during the breakdown process.

**The bulk chemical composition of the upper Martian crust**

B. C. HAHN AND S. M. MCLENNAN

Department of Geosciences, Stony Brook University, Stony Brook, NY 11794-2100 (bhahn@mantle.geo.sunysb.edu; Scott.McLennan@sunysb.edu)

There is strong evidence that the Martian surface has been extensively chemically homogenized over time due to broad-scale impact gardening, an apparent lack of plate tectonic fractionation and evolution, long-term global eolian processes, and periodic fluvial transport. Despite wide geographic separation, soil chemistry from landing site analyses (MER, Pathfinder, and Viking) are remarkably similar with most variation attributed to the addition of some local rock components - strongly implying that the unconsolidated fraction of the Martian surface has been reasonably well-homogenized. Gamma-Ray Spectrometer (GRS) elemental abundance maps agree well with surface analyses and, with some notable exceptions, global GRS elemental abundance maps reveal less broad-scale chemical variation compared to the terrestrial or lunar surfaces.

Therefore, it has been suggested that the chemical composition of averaged Martian soil analyses reflect the bulk chemical composition of the Martian surface from which they are derived – much in the same way terrestrial sedimentary chemistry can be used as a proxy for the bulk terrestrial upper crust. Weathering, sedimentary transport, and deposition naturally sample a wide array of source rocks with the resultant chemistry being an efficient mixture of source terrains.

With carefully screened MER APXS data, we develop an estimate of major and trace element crustal chemistry based upon MER soil averages. GRS global chemical averages for certain elements are used to corroborate compositions calculated from the soil data and in some cases GRS global averages for a particular element are assumed to represent the bulk upper crust. Where applicable, SNC chemistry and canonical cosmochemical relationships are also incorporated into the bulk determination.
Petrogenesis of meta-peridotites in the Takab area, NW Iran

R. HAJIALIOGHLI1, M. MOAZZEN1, A. JAHANGIRI1, G. DROOP2, R. BOUSQUET3 AND R. OBERHÄNSLI3

1Department of Geology, University of Tabriz, 51664 Tabriz, Iran (r_hajialioghli@yahoo.co.uk)
2School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Oxford Road, Manchester, M13 9PL, UK
3Institut für Geowissenschaften, Universität Potsdam, Postfach 601553, D-14415 Potsdam, Germany

The Takab meta-ultramafic rocks of north western Iran crop out in association with a variety of metamorphic rocks including mafic granulites, amphibolites, calc-silicates, granitic gneisses and pelitic schists. The protoliths of the Takab meta-peridotites were mainly harzburgite and dunite with subordinate lherzolite. All peridotite varieties contain primary Cr,Al-spinel. The peridotites were modified by metasomatism under low-grade conditions and later amphibolite-facies metamorphism, the thermal peak of which occurred at temperature of 410-530ºC, corresponding to an orogenic setting.

Chemical compositions of the porphyroclastic olivine, pyroxene and spinel in the investigated meta-peridotites give temperature of 1000-1200ºC; clinopyroxene barometry yields a pressure of 24±2.7kbar, corresponding to a depth of ca. 72km.

The results are consistent with oceanic lithospheric upper mantle origin (i.e. in an ophiolitic setting) of the meta-ultramafic rocks in the Takab area. Similarities in the stratigraphy, lithology and age data (relative and isotopic ages) of the protoliths of the Takab complex and equivalent units from the Central Iran Zone suggest that the Takab complex has a Neooproterozoic-Early Cambrian age and experienced the Pan-African orogeny. The strips of the ultramafic rock in the study area are remnants of the Proto-Tethyan oceanic lithosphere.

Li isotope fractionation in the subducted slab – A case study from the Raspas complex, Ecuador

RALF HALAMA1, TIMM JOHN2, VOLKER SCHENK1, WILLIAM F. MCDONOUGH3 AND ROBERTA L. RUDNICK3

1Institut für Geowissenschaften & SFB 574, Universität Kiel, 24118 Kiel, Germany (rh@min.uni-kiel.de)
2Physics of Geological Processes, University of Oslo, 0316 Oslo, Norway (timm.john@fys.uio.no)
3Department of Geology, University of Maryland, College Park, MD, 20742, USA

Lithium isotopes are a potentially powerful geochemical tracer of subducted material due to significant isotopic fractionation on the Earth’s surface and the fluid-mobile behaviour of Li. To improve our ability to track recycled Li in the mantle, and to understand the transfer of Li from the slab through the mantle wedge to the volcanic arc, it is important to constrain the Li isotopic composition of subducted material and the isotopic changes that may occur during the subduction process.

Here, we report results from a detailed geochemical and Li isotope study on the now exhumed part of a subducted slab from the Raspas complex (Ecuador), which comprises serpentinites, eclogites, blueschists and high-pressure metapelites. Eclogites show MORB-like trace element signatures and are LREE-depleted. They are characterized by a light Li isotopic composition with δ7Li ranging from 0 to -13. These values are considerably lower than those of fresh and altered MORB (δ7Li = +3 to +14; Chan et al., 1992), but they overlap with those of Alpine eclogites (Zack et al., 2003). In contrast, blueschists and metapelites, as well as the serpentinites that are interpreted to represent the mantle portion of the subducted slab, have Li isotopic compositions in between the eclogites and MORB. A negative correlation between δ7Li and Li/Dy for the eclogites suggests that influx of Li from an external source may have been responsible for decrease in δ7Li in the eclogites. Moreover, the elevated Li concentrations in some of the eclogites (up to 94 ppm) are difficult to reconcile with Li loss during dehydration alone. Although none of the associated lithologies is particularly rich in Li, eclogite-facies fluids that may contain up to 438 ppm Li (Svensen et al., 2001) could provide a suitable source of Li. These results suggest that fluid-assisted kinetic isotope fractionation (Teng et al., 2006) may have played a role in causing the light Li isotope composition of the eclogites, as also suggested by Marschall et al. (2007).

The Pb isotope evolution of Arctic Ocean intermediate water over the past 16 million years

B.A. Haley¹, M. Frank¹, R. Spielhagen¹,2 and J. Fietzke¹

¹IFM-GEOMAR, Leibniz Institute of Marine Sciences at the University of Kiel, Germany, bhaley@ifm-geomar.de
²Academy of Sciences, Humanities and Literature, Mainz, Germany

We present the first record of the dissolved Pb isotope composition of Arctic intermediate water of the past 16 Myr. The data were obtained from leaches of sediments of IODP Leg 302 (“ACEX”) drill-cores and from a piston-core (PS2185), both located near the North Pole on the Lomonosov Ridge (~1200m water depth). Both the leaches and bulk dissolutions of the same sediments show similar Pb isotope compositions in the “Neogene” (>1 Ma) and in the “Pleistocene” (<1 Ma) sediments, although the median values differ slightly between the two sections (e.g. 206Pb/204Pb ~18.5 in the “Neogene” versus ~18.6 in the “Pleistocene”). These central Arctic isotope signatures are much less radiogenic compared with N. Atlantic records, and, although similar trends between these two basins are observable for the Pleistocene, they differed significantly during the Neogene.

From these observations and comparisons in Pb-Pb isotope space, we argue that the source of dissolved Pb in Arctic intermediate waters has primarily been derived locally from exchange with sinking ice transported sediment particles. These sediments originated from the Eurasian shelves and have continuously been carried to the North Pole region via the Transpolar Drift for the past 16 Ma.

On short millenial time scales of the Quaternary our Arctic records reflect isotopic changes in the Siberian continental sources of Pb. The most likely process driving these changes was incongruent weathering and soil formation during interglacial periods. These soils originated in the marine environment: corals (porites lutea and acropora), Cretaceous limestone (Judea Mt.); Cretaceous evaporitic aragonite (Dead Sea) yielded uniform δ86Sr value (-0.28±0.07 ‰) within the 1σ error of Red Sea and Atlantic seawater (-0.35±0.04 ‰). On the other hand, secondary materials (products of chemical weathering) from the terrestrial environment of the Judea Mt. such as speleothem calcite and terra rossa soil (airborne dust particles residual rock material) both yielded significantly higher δ86Sr value (0.17±0.03 ‰).

All rocks that originated in the marine environment: corals, Cretaceous limestone, and Pliocene epigenetic dolomite (Dead Sea rift margins); as well as lacustrine evaporitic aragonite (Dead Sea) yielded uniform δ86Sr value (~0.28±0.07 ‰). On the other hand, secondary materials (products of chemical weathering) from the terrestrial environment of the Judea Mt. such as speleothem calcite and terra rossa soil (airborne dust particles residual rock material) both yielded significantly higher δ86Sr value (0.17±0.03 ‰). It should be noted that both groups are distinctly different from the SRM987 standard that has by definition a value of 0 ‰. It appears that strontium isotopes are fractionated within the terrestrial environment by geochemical processes such as chemical weathering and genesis of soils and hence δ86Sr/88Sr ratio may be developed as a tracer for these processes.
Growth of the Earth’s core

Hafnium-tungsten chronometry provides evidence that some magmatic iron meteorite parent bodies formed relatively small cores within a million years of the start of the solar system. Similar timescales can be inferred from martian meteorites and ureilites. There is some evidence that the degree of siderophile element depletion, possibly reflecting relative core size, increased over the first 10⁷ years on Mars and the angrite parent body. How the Earth’s core started is less clear and some assume more efficient core growth under reducing conditions. The Si isotopic compositions of mantle-derived silicate rocks from the Earth and Moon are heavy relative to those from Mars and Vesta which in turn are identical to those of chondrites. A likely explanation for this is Si isotopic fractionation during high pressure and high temperature metal segregation. On this basis Si is one of the light elements in the Earth’s core. There is a hint of an analogous effect for oxygen. However, the heterogeneity within the circumstellar disk renders this interpretation less certain. Similarly, slightly heavy Fe in the bulk silicate Earth may reflect high pressure core formation in the presence of perovskite. The Moon does not have a high pressure core yet lunar basalts display O, Si and Fe isotopic compositions similar to those found on Earth. This can be reconciled with giant impact simulations provided there was efficient mixing between the silicate Earth and the protolunar disk as recently proposed (Pahlevan and Stevenson 2005). This being the case the Moon represents an important new archive for the composition of the early silicate Earth and demonstrates that Si and possibly O were already light elements in the core before the Giant Impact.

Molecular and isotopic study of acidic metabolites in the deep biosphere employing petroleum reservoirs as natural bioreactors

C. HALLMANN¹, K. GRICE¹ AND L. SCHWARK²

¹Isotope and Molecular Biogeochemistry Group, Curtin University, Perth, Western Australia
(C.Hallmann@curtin.edu.au, K.Grice@curtin.edu.au)
²Institute of Geology, University of Cologne, Germany
(Lorenz.Schwarc@uni-koeln.de)

Being systems that support a biologically active environment, petroleum reservoirs can be used as naturally occurring analogues to bioreactors in view of studying the anaerobic catabolic and metabolism of an extremophile deep-subsurface biosphere. Although living cells have been identified in deep sub-seafloor sediments (Schippers et al., 2004), cell organic matter is not preserved well in the aqueous environment. The hydrophobic oil matrix of petroleum reservoirs, in contrast, can act as an accumulator of in-situ produced metabolites and cell-wall lipids.

This presentation will examine the molecular distribution and stable carbon isotopic variation between carboxylic acids and their non-carboxylated hydrocarbon counterparts in oils that were biologically degraded to various extents and recovered from different non-communicating compartments of a reservoir. Oils were fractionated into compound classes and further analysed by gas chromatography (GC) and mass spectrometry (MS), as well as isotopic ratio monitoring (irm)GC-MS.

The lack of microbial petroleum degradation in reservoirs that were ever heated >80°C suggests that microbes have been present in the sediments since their deposition and possibly survive by the release of volatile organic acids from dispersed sedimentary organic matter (Wellsbury et al., 1997). Significant migration and recolonization of microbes in the subsurface does not appear to take place. The escape into the deep could be an ancestral evolutionary survival strategy that allows microbes to maintain their viability for extremely long periods, to the expense of pushing the physicochemical limits of life. Understanding the evolution of earth’s early biosphere is therefore closely related to understanding the biochemical adaptation of life to extreme environments, which can only be studied in present-day analogues, one of which are deep anaerobic petroleum reservoirs. This study focusses on the structural and isotopic analysis of carboxylic acids as indicators of deep biosphere processes.

In order to constrain the behavior of lithium isotopes in crystals during magma cooling, the study of a fresh pillow lava with large olivine crystals has been undertaken. An ion microprobe was used to measure lithium abundances and isotopic compositions both in olivine phenocrysts and in the pillow rim glass. Profiles in δ7Li conducted through olivines show very different patterns correlated with their cooling history. Olivines embedded in the pillow rim glass display no variation in Li abundance ([Li] = 1.2 μg.g⁻¹) and isotopic composition (δ7Li = +6 ‰). However, large Li isotopic zoning is found from crystal cores (δ7Li = +6 ‰, [Li] = 1.1 μg.g⁻¹) to rims (δ7Li = -11 ‰, [Li] = 1.4 μg.g⁻¹) for olivines set in microcrystalline groundmass. The cores of large olivine phenocrysts are equilibrated with the pillow rim glass (δ7Li = +6 ‰, [Li] = 3.4 μg.g⁻¹).

Recently, detailed investigation of the Li isotopic composition of large phenocrysts in various magmatic environments demonstrated that microscale δ7Li variations were due to fractionation of lithium isotopes during late stage chemical diffusion (Barrat et al., 2005; Beck et al., 2006; Jeffcoate et al., 2006). In our case, the diffusion-induced Li isotopes fractionation is the only process able to explain such diverse zoning in olivines from one single pillow lava. Our study brings new constraints on the Li fractionation during the diffusion process and suggests that the pristine δ7Li values can be completely erased in small phenocrysts, even in the case of rapidly cooled volcanics. The use of Li isotopes in crystals for tracking mantle heterogeneities should be taken with extreme caution.

δ7Li systematics of mantle xenoliths from Kilbourne Hole: Unraveling metasomatic & diffusional processes
S.J. HAMMOND1,2, I.J. PARKINSON1, R.H. JAMES1, N.W. ROGERS1 AND J. HARVEY3

1Dept. of Earth Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK. (s.hammond@open.ac.uk)
2Dept. of Earth Science and Eng., Imperial College London, South Kensington Campus, London, SW7 2AZ, UK.
3Boston University TIMS Facility, Department of Earth Sciences, 675 Commonwealth Avenue, Boston, MA 02215, USA.

We present a detailed Li isotopic study of spinel-peridotites from Kilbourne Hole, New Mexico, including whole rock and hand picked mineral separate δ7Li data (measured by MC-ICP-MS) and in-situ δ7Li data measured by ion microprobe. From this detailed approach the effects of mantle metasomatism and diffusion can be unravelled.

The xenolith suite can be divided into those which are in textural equilibrium, and those which have interacted with the host lava. Whole rock values for the sample suite range from +4.5 ‰ to -2.9 ‰. Of the samples which are in textural equilibrium, mineral separates reveal that olivine, orthopyroxene, and clinopyroxene are all in isotopic equilibrium, and grains analysed by ion microprobe are homogeneous in both Li and δ7Li across grains, with the exception of the outer 50 μm in some clinopyroxene grains. The two lightest δ7Li are found in equilibrated LREE enriched harzburgites, which is consistent with these samples having completely equilibrated with a melt with a slightly negative δ7Li (-3 ‰), possibly from a garnet pyroxenite/eclogite source (although partial equilibration with a heavy δ7Li melt can also explain these data).

Kilbourne Hole peridotite xenoliths have rapid transit times (~0.2 days), which is long enough to produce the Li isotope perturbation observed in the clinopyroxene grains by more rapid diffusion of δ7Li compared to δ6Li from the host lava.

The extent of clinopyroxene reaction correlates with a decrease in whole rock δ7Li, which can be explained by reaction driven diffusion with the host lava. Li diffusion in clinopyroxene is at least ten times faster than in olivine [1], and so interactions between peridotite and melt produce clinopyroxene with lighter δ7Li than co-existing mineral phases. Clinopyroxene data that have very light δ7Li values (e.g. [2]) have been used to argue a very light δ7Li component in the mantle. However, without evidence of Li isotopic equilibrium, the existence of such a component must be treated with caution.

Diagnosis of pollution state of the coasts in the vicinity of an oil terminal: Bioremediation effect

R. HAMOUDA, N. OUERTANI AND H. BÉLAYOUNI
Faculté des Sciences de Tunis, Département de Géologie, Laboratoire de Géochimie organique, (hamoudarym@yahoo.fr)

Coastal marine environments near the oil harbour installations can be the object of a chronic oil pollution coming from purging water of the storage tanks of oil, as well as water coming from ballast operations of tankers. In the oil terminal of the south of Tunisia, this water is collected in tanks before their discharge in a natural lagoon which communicates with the Mediterranean Sea. This lagoon is periodically flooded by sea water (tide phenomena). The objective of this work is the diagnosis of the pollution state of the lagoon. This study is based on the analysis of the COT and the technics of liquid and gas chromatography.

Analysis of TOC and TH (total hydrocarbon) in surface sediments of the lagoon permit to note that:
- TH varies between 200 and 4020 ppm.
- A positive correlation calculated between the TOC and TH, attest of the homogeneity of the organic matter contained in the sediments.
- % of saturated hydrocarbons vary between 6 and 12% and are classic of an organic matter inherited from original biomass;
- The organic matter presents a mixed origin terrestrial and marine. N-alkane distribution is bimodal: first mode characterized by n-alkanes from C21 to C33 with a CPI of 2,1 characterising organic matter from waxes plants, the second mode is centred on n-alkanes from C17 to C20 without odd to even prevalence and characterizes a marine organic matter. Presence of UCM with a hump developed under all the range of n-alkanes attest of an important microbial activity in sediments.
- Surface sediments of the lagoon seems not to be contaminated by water coming from the systems of water treatment of oil residues. These results show the role of these lagunar systems to manage and eliminate pollution: bioremediation effect.

Weathering processes in karst river, southwest China: Implication from riverine sulphur and strontium isotope

GUILIN HAN1, ZHIFANG XU2 AND YANG TANG1,3
1The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (hanguilin@vip.skleg.cn)
2The Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O.Box 9825, Beijing 100029, China
3Graduate School of Chinese Academy of Sciences, Beijing 100039, China

Geochemistry of river waters draining karst terrain in SW China has been studied in order to characterize the hydrogeochemistry of the rivers, to determine natural chemical and physical weathering rates in typical areas and anthropogenic contaminants. The studied area is impacted by serious sulphuric acid rain because of coal-mining and combustion and coal-formation strata in Guizhou Province. Another aim of the work is to study the effect of sulphuric acid on the carbonate weathering.

Results and Discussions
Water samples of karst river water from the Guizhou province (Wujiang River and Yuanjiang River) in karst-dominated regions were analyzed for dissolved major element concentrations (HCO3-, NO3-, SO42-, Cl-, Ca2+, Mg2+, K+, Na+), Sr2+ and 87Sr/86Sr and δ34S of dissolved sulfate (δ34SSO4) in summer. The waters of the Wujiang River have high Sr2+ concentrations and lower 87Sr/86Sr ratios (0.7074-0.7115), while those of Qingshuijiang River, one of two major tributaries of the Yuanjiang River system, show higher Sr isotopic ratios (0.7088-0.7155) and low Sr concentrations. Weathering rates of silicates and carbonates were determined from major element mass balance with Sr isotope.

The sulfur isotopic compositions (δ34S) in Wujiang River catchments range from -7.70‰ to 13.06‰ and have higher SO42- concentrations, which are inferred to be mainly derived from anthropogenic emissions and/or the oxidation of sulfide minerals in the coal-containing strata in the studied area. Samples from Yuanjiang River, which is dominated by clastic rocks, have relative enrich δ34S (-4.81‰ to 4.13‰) and lower SO42- concentrations, which appears to result from solution of gypsum and rainwater SO42-. The carbonate weathering of sulfuric acid may become an important CO2 source to atmosphere and can counteract the CO2 consumption by silicate weathering, so the presence of sulfuric acid should be seriously considered to calculated CO2 budget in this kind of area.

Source origin of the ultrapotassic lavas from the Leucite Hills, Wyoming: Hf isotope constraints

BARRY B HANAN1, JANNE BLICHERT-TOFT2, RICHARD H. KINGSLEY1 and JEAN-GUY SCHILLING3

1San Diego State University, San Diego, CA 92182-1020, USA (Barry.Hanan@sdsu.edu)
2Ecole Normale Supérieure de Lyon, 69364 Lyon Cedex 7, France (jblicher@ens-lyon.fr)
3University of Rhode Island, Narragansett, Rhode Island 02882, USA (kingsley@gso.uri.edu, jgs@gso.uri.edu)

The Leucite Hills of SW Wyoming consist of 22 volcanic outcrops that occur over an area of ~ 2,500 km². The lavas consist of 3 types of lamproite, basic to ultramafic madupite (M), and more silicic wyomingite and orendite (W/O), characterized by phlogopite phenocrysts in a groundmass of leucite, diopside, apatite, ±sanidine, ±glass. Volcanism spanned 3.0-0.89 Ma. 84% of the <0.7 km³ of magma was leucite, diopside, apatite, ±sanidine, ±glass. Volcanism characterized by phlogopite phenocrysts in a groundmass of

late-stage lavas formed by small degrees of melting can be used as high-resolution tracers of source components and heterogeneities in the Hawaiian mantle plume. This study presents high-precision isotopic ratios (Sr, Nd, Hf, Pb) and trace element concentrations of late- and post-shield lavas from four Hawaiian volcanoes: Mauna Kea and Kohala on the Kea-trend and their counterparts Hualalai and Mahukona on the Loa-trend. Mauna Kea and Hualalai demonstrate a systematic shift to distinctly less radiogenic Pb and Sr isotopic compositions as they evolve from the shield to post-shield stage. Post-shield lavas from both volcanoes deviate from the mixing trends (Sr-Pb, Nd-Pb, Hf-Pb) defined by Hawaiian shield-stage lavas, reflecting involvement of a more depleted source component similar to that sampled by rejuvenated lavas from other Hawaiian volcanoes. Interaction with oceanic crust and lithosphere (low 87Sr/86Sr, high 206Pb/204Pb) beneath Hawaii cannot explain the observed compositions of Hualalai post-shield lavas, which have some of the least radiogenic Pb isotopic compositions (206Pb/204Pb = 17.888-18.011) of recent Hawaiian volcanoes. In contrast, Kohala and Mahukona become more radiogenic with respect to Pb during the waning stages of volcanism. Post-shield lavas from these volcanoes remain within the Loa-Kea mixing hyperbola, but are shifted to more depleted Sr, Nd, and Hf isotopic compositions.

Despite their contrasting Pb isotope systematics, post-shield lavas from all four volcanoes preserve the striking Loa-Kea Pb bilateral asymmetry inferred for the Hawaiian plume over the past ~1.5 Myr [1]. However, post-shield lavas and tholeiites from Kohala form a Pb-Pb linear array that crosses the Loa-trend. The coupled isotopic systematics of both volcanic pairs indicates the successive sampling of isotopically distinct material intrinsic to the Hawaiian plume. The enriched trace element signatures of the post-shield lavas ([La/Yb]n = 6.0-16.3) further suggests that this material is not related to MORB. The isotopic similarities between the post-shield and rejuvenated lavas imply continuity of these heterogeneities on a million year timescale and have implications for models of Hawaiian plume structure.

Geochemistry of post-shield lavas from paired Loa- and Kea-trend Hawaiian volcanoes

DIANE HANANO1, DOMINIQUE WEIS1, SARAH ACIEGO2, JAMES S. SCOATES1 AND DONALD J. DEPAOLO2

1PCIGR, Dept. of Earth and Ocean Sciences, Univ. of British Columbia, 6339 Stores Road, Vancouver, BC, V6T 1Z4, Canada (dhanano@eos.ubc.ca)
2Center for Isotope Geochemistry, Earth and Planetary Science, Univ. of California, Berkeley, CA, 94720, USA

Late-stage lavas formed by small degrees of melting can be used as high-resolution tracers of source components and heterogeneities in the Hawaiian mantle plume. This study presents high-precision isotopic ratios (Sr, Nd, Hf, Pb) and trace element concentrations of late- and post-shield lavas from four Hawaiian volcanoes: Mauna Kea and Kohala on the Kea-trend and their counterparts Hualalai and Mahukona on the Loa-trend.

Mauna Kea and Hualalai demonstrate a systematic shift to distinctly less radiogenic Pb and Sr isotopic compositions as they evolve from the shield to post-shield stage. Post-shield lavas from both volcanoes deviate from the mixing trends (Sr-Pb, Nd-Pb, Hf-Pb) defined by Hawaiian shield-stage lavas, reflecting involvement of a more depleted source component similar to that sampled by rejuvenated lavas from other Hawaiian volcanoes. Interaction with oceanic crust and lithosphere (low 87Sr/86Sr, high 206Pb/204Pb) beneath Hawaii cannot explain the observed compositions of Hualalai post-shield lavas, which have some of the least radiogenic Pb isotopic compositions (206Pb/204Pb = 17.888-18.011) of recent Hawaiian volcanoes. In contrast, Kohala and Mahukona become more radiogenic with respect to Pb during the waning stages of volcanism. Post-shield lavas from these volcanoes remain within the Loa-Kea mixing hyperbola, but are shifted to more depleted Sr, Nd, and Hf isotopic compositions.

Despite their contrasting Pb isotope systematics, post-shield lavas from all four volcanoes preserve the striking Loa-Kea Pb bilateral asymmetry inferred for the Hawaiian plume over the past ~1.5 Myr [1]. However, post-shield lavas and tholeiites from Kohala form a Pb-Pb linear array that crosses the Loa-Kea isotopic division. The sampling of Loa-type heterogeneities has been observed at other Kea-trend volcanoes [e.g. 2] and may be related to structure within the plume conduit. The coupled isotopic systematics of both volcanic pairs indicates the successive sampling of isotopically distinct material intrinsic to the Hawaiian plume. The enriched trace element signatures of the post-shield lavas ([La/Yb]n = 6.0-16.3) further suggests that this material is not related to MORB. The isotopic similarities between the post-shield and rejuvenated lavas imply continuity of these heterogeneities on a million year timescale and have implications for models of Hawaiian plume structure.

Time scales of intracratonic orogeny

MARTIN HAND
Continental Evolution Research Group, School of Earth and Environmental Sciences University of Adelaide, SA, Australia

Intracratonic orogeny represents an intriguing endmember of the tectonic spectrum in that deformation is temporarily focused into regions of lithosphere that more generally exhibit plate-like behaviour. There is a general consensus that intracratonic orogeny is driven by stresses generated at plate boundaries. If this assertion is true, there should be a strong correspondence between the evolution of plate margin systems and events within mechanically coupled continental interiors. The intracratonic Petermann and Alice Springs orogens in central Australia form components of a shifting pattern of intraplate deformation whose duration spans the early stages of Gondwanan assembly (c. 600 Ma) to the establishment of a (c. 450-300 Ma) convergent margin along east Gondwana. These orogens have two important similarities. Firstly is the development of comparatively narrow deep foreland basins, which may be coupled with large-scale footwall depression beneath crustal-scale thrust sheets. These observations point to the involvement of weak lithosphere in the intraplate orogenesis. Secondly both record apparently long (> 70 Ma) durations of deformation. The 450-300 Ma Alice Springs Orogen terminated riftting and associated basaltic magmatism, providing an obvious thermal link for localizing the deformation. However an intriguing aspect of the Alice Springs Orogeny is the existence of a long-lived high-T thermal regime marked by the emplacement of crustally derived melts throughout the entire c. 100 Ma orogenic history. Simple calculations suggest that it would be difficult for the lower crust to remain above the solidus for c.100 Ma without significant inputs of heat from the mantle. The Alice Springs Orogeny coincided with the development of a long-lived convergent margin along eastern Gondwana. The development of the margin was characterised by upper plate extension punctuated by transient collision/accretion linked to the incorporation of buoyant colliders. A challenge in understanding the geodynamic evolution of the continental margin-interior system is to decipher event timing within the overall long-lived record of intracratonic deformation in comparison with events on the margin. Within the Alice Springs Orogen, phases of contractional deformation generally coincide with collisional events on the adjacent margin with the locus of most intense deformation coinciding with the footprint of pre-orogenic rifting and mantle-derived magmatism. This suggests that the mantle-driven thermal regime initially associated with rifting, played a central and on-going role in controlling the intracratonic response during the development of the adjacent east Gondwana plate margin.

Processes and timescales of magma genesis and differentiation at Lopevi Volcano, Vanuatu, SW Pacific

H.K. HANDLEY1, S.P. TURNER1, S.J. CRONIN2 AND I.E. M. SMITH3

1GEMOC, Dept. of Earth and Planetary Sciences, Macquarie University, Sydney, NSW 2109, Australia (hhandley@els.mq.edu.au; sturner@els.mq.edu.au).  
2Institute of Natural Resources, Massey University, Private Bag 11 222, Palmerston North, New Zealand (s.j.cronin@massey.ac.nz).  
3Department of Geology, University of Auckland, Private Bag 92019, Auckland, New Zealand (ie.smith@auckland.ac.nz).

Recently erupted basaltic and andesitic lavas of Lopevi Volcano, one of the most active in Vanuatu, were analysed for whole rock major and trace element abundances, Sr and Nd isotopic ratios and U, Th and Ra isotopic compositions; forming the first detailed U-series study of an individual volcanic centre within the Vanuatu (New Hebrides) arc. The data are used to constrain the processes and timescales of magma genesis and evolution beneath the volcano, leading towards a better understanding of the relationship between magma supply and eruption, which is invaluable for volcanic hazard assessment.

MgO contents of lavas erupted throughout 2000-2003 cluster at around 4-5 wt%, whereas those from earlier eruptions (during the 1930’s and 1960’s) exhibit a wider range, extending to more primitive MgO contents (up to 8.5 wt%). Fractional crystalisation is an important mechanism of differentiation at Lopevi, exerting strong control on major and trace element variations. Increases in SiO2, Na2O, Al2O3, TiO2 (and to a lesser extent K2O and P2O5) and decreases of CaO cannot be an important fractionating mineral during magmatic differentiation at mid-lower crustal depths beneath the volcano.

Enrichment of LREE relative to HFSE and HREE, high Ba/La ratios relative to MORB, uniform HFSE/HFSE ratios (e.g. Ta/Nb) along with 238U excesses (1.250-1.400) in Lopevi lavas identify the contribution of a fluid component to a relatively homogeneous, slightly depleted mantle source. Furthermore, the sub horizontal array displayed by the data on a U-Th equiline diagram indicates this addition occurred significantly recently. 228Ra excesses in the lavas suggest that crustal residence times of magmas at Lopevi are <8000 years. 87Sr/86Sr ratios lie between 0.703992 and 0.704078 and are characteristic of volcanoes similarly located in the central Vanuatu arc, above where the D’Entrecasteaux Ridge is being subducted and accreted (cf. northern and southern sections of the Vanuatu arc).
Functionally diverse chemosynthetic bacteria in hydrothermal sediment, Santorini, Greece: Geochemical implications

K.M. HANDLEY1, C. BOOTHMAN1, R.A. MILLS2 and J.R. LLOYD3

1School of Earth, Atmospheric and Environmental Sciences, The University of Manchester, Manchester M13 9PL, UK (kim.handley@postgrad.manchester.ac.uk; christopher.boothman@manchester.ac.uk; jon.lloyd@manchester.ac.uk)

2School of Ocean and Earth Science, National Oceanography Centre, University of Southampton, Southampton SO14 3ZH, UK (ram1@noc.soton.ac.uk)

A chemosynthetic microbial community displaying diverse respiratory processes was identified within iron- and arsenic-rich shallow marine sediment (20-40°C, pH 6.0-6.3) from an area of active hydrothermalism in Santorini, Greece. Marine hydrothermal sediments are host to abundant microbial life that exploits the steep geochemical gradients generated by the confluence of reduced metal-rich fluids and oxidised seawater. However, there is relatively little information on the functional range of prokaryotes in these settings, and their impact on geochemical cycling. Microbial functional diversity in the Santorini sediment was determined by enrichment culturing (from the suboxic to anoxic transition zone, Eh 0 to -138 mV), coupled with phylogenetic molecular techniques. Enrichment cultures were successfully obtained for: (1) Fe(III), NO3-, SO42-, and As(V) reducers (with acetate and lactate); (2) anaerobic and microaerophilic Fe(II) oxidisers; and (3) Na2S and As(III) oxidisers. Most-probable number (MPN) counts for these functional groups ranged from 7.50 x 107 to 2.30 x 105 cells ml-1, with relative abundances decreasing as follows: NO3-, As(V) and Fe(III) reducers; Na2S and FeS oxidisers; SO42- reducers; and As(III) and anaerobic Fe(II) oxidisers. 16S rRNA and specific functional gene analyses, utilising the clone library method, revealed a phylogenetically diverse range of enriched bacteria, including a number of novel organisms, and also sequences with close affinity for bacteria known to occur in deep-sea hydrothermal vent sediments (e.g. Shewanella sp., Thiomicrospira sp., Desulfovibrio spp., and Marinobacter spp.). Phylogenetic bacterial and archaeal sediment communities were dominated by δ-Proteobacteria, Chloroflexi, Bacteroidetes, Chlorobi, and Crenarchaeota. Dominant bacteria displayed closest affinities to known iron and sulphur respirers. In particular, community analyses of the oxidised orange surface sediment (Eh 0) were found to be dominated by an enriched anaerobic, nitrate-dependent Fe(II) oxidiser. Overall, results demonstrate the potential for bacteria to respire inorganic substrates important within the Santorini sediment, namely forms of iron, arsenic, sulphur and nitrogen. Moreover, solid-phase and pore water geochemical data allow correlation between the microbial community structure and the sequence of down-core biogeochemical (redox) zonation.

Behaviour of PGEs in sills from the Jurassic Ferrar Large Igneous Province, Antarctica

R. HANEMANN AND L. VIERECK-GOETTE

Institut fuer Geowissenschaften, Universitaet Jena, Germany (ricarda.hanemann@uni-jena.de)

The Jurassic Ferrar Large Igneous Province, exposed in a > 3000 km long belt along the margin of the East Antarctic craton, comprises numerous sills, dikes and lava flows as well as the layered mafic Dufek intrusion. Uniform crust-like trace element and isotope data indicate a single magma source within the subcontinental lithospheric mantle characterised by crustal enrichment due to Palaeozoic subduction along the Panthalassa margin of Gondwana. However, the thermal source for the voluminous melt generation is still under debate as the crust-like isotope signatures obscure the detection of a possible mantle plume involvement.

In addition to mineral and bulk-rock chemical data for basaltic andesites and andesites from sills in northern Victoria Land, a subset of 23 samples has so far been analysed for platinum-group elements (PGE) to further describe the genesis of the Ferrar magmatic rocks. The abundances of Ir, Ru, Rh, Pt and Pd were determined by ICP-MS using isotope dilution (except Rh) after sample preparation by NiS-fire assay at the University of Karlsruhe, Germany.

The studied rocks exhibit the common phase assemblage of tholeiitic differentiation sequences composed of varying amounts of pyroxenes, plagioclase, oxides and mesostasis. Most of the wide compositional variations (2-13 wt% MgO) are attributed to low-pressure differentiation after magma intrusion at upper-crustal levels. Compositional differences between rocks that are not affected by in-situ differentiation are ascribed to distinct conditions during pre-emplacement differentiation assuming an identical primary magma.

The PGE totals range from ~ 4 to 40 ppb. The single element abundances exhibit good correlations with the MgO contents of the distinctly evolved samples and are thus interpreted to result mainly from in-situ differentiation as well. While the IPGE (Ir, Ru) are highly compatible during differentiation of the Ferrar magmas, the PPGE (Rh, Pt, Pd) show bimodal variations. They decrease in cumulates, but either increase or decrease in differentiates. The distinct PGE fractionation behaviour results in strongly fractionated primitive mantle-normalised patterns for all analysed samples with considerable enrichment of the PPGE over the IPGE.

Compared to tholeiitic rocks from other magmatic provinces, only the Ferrar rocks exhibit coupled enrichment of Pd, Pt and Cu even in most evolved samples. The decrease of Pt and Pd in some of the more evolved samples does not necessarily signify sulphide fractionation, but may indicate the formation of other PGE-compounds. The inferred sulphur-undersaturated conditions during pre- and post-emplacement differentiation processes are in agreement with the elevated melting degrees as well as the refractory nature of the proposed subcontinental lithospheric mantle source.
Synthetic melt inclusion and quartz-trap methods for determining Pt solubility in a mafic mineral – Halide melt system at 750°C, 400 bar

JACOB J. HANLEY AND CHRISTOPH A. HEINRICH
IGMR, ETH Zürich, Zürich, Switzerland, CH-8092
(hanley@erdw.ethz.ch; heinrich@erdw.ethz.ch)

The solubility of platinum in a hydrous salt melt (S-free; ~75 wt% CaCl_2+MgCl_2, 25 wt% H_2O) was investigated at conditions consistent with the post-cumulus metamorphism of layered intrusions that host platinum-group element deposits. The salt melts were reacted with metallic Pt or Pt-PtAs_2 (sperrylite) in Pt capsules using conventional Rene 41 cold seal vessels which buffer jO_2 at FMQ-1. The activities of relevant metal-complexing species (e.g., HCl) were buffered by the assemblage tremolite-diopside-enstatite-quartz. Salt melts were trapped (simultaneously) in the matrix of a quartz trap (granulated natural quartz partially isolated in a smaller gold capsule) and in synthetic melt inclusions trapped in pre-fractured quartz. After quenching, the melt inclusions and quartz trap material were analyzed by laser ablation ICP-MS.

Platinum solubility is in the low ppm range. Analysis of different portions of the quartz trap using a 90 μm pit size yielded relatively consistent platinum concentrations of 14.4 ± 6.7 ppm (2σ, n=6; Pt metal source), and 4.6 ppm ± 1.9 ppm (2σ, n=6; Pt-PtAs_2). Based on the consistency of the metal concentrations from different parts of the trap, it is considered that these concentrations are most representative of metal solubility at run conditions and that the laser sampling size sufficiently overcomes local heterogeneity in the distribution of Pt quench products. By contrast, Pt concentrations in hydrosaline melt inclusions from different areas of a 3 mm x 10 mm quartz cylinder range from below detection limits (~0.1 ppm) to 14.4 ppm (n=28; Pt) and to 6.6 ppm (n=31; Pt-PtAs_2). The range in observed metal concentrations in this trapping medium increases with the number of inclusions analyzed, and varies between different areas in the quartz cylinder. This confirms observations that saline inclusions trapped in pre-fractured quartz heal quickly (as early as several hours) at elevated temperatures, and may trap disequilibrium metal concentrations in mineral- or melt-buffered systems (Hanley et al., 2005); thus, they are suitable only for qualitative evaluation of trace metal solubility.

The data demonstrates that Pt is highly soluble at conditions consistent with post-cumulus metamorphic activity in layered intrusions, and that salt melts may significantly modify primary metal concentrations in layered intrusions and redistribute these metals. Additionally, Pt solubility in the hydrosaline melt was reduced by a factor of ~3 in the presence of a platinum arsenide phase.

~560 Ma and ~300 Ma Re-Os ages constrain Neoproterozoic Varanger glaciation and record Variscan hydrocarbon migration on extension of Oslo rift

J.L. HANNAH1,2, G. YANG1, B. BINGEN2, H.J. STEIN1,2, AND A. ZIMMERMAN1

1AIRE Program, Geosciences Dept., Colorado State Univ., Fort Collins, CO 80523-1482 (jahannah@cnr.colostate.edu)
2Geological Survey of Norway, 7491 Trondheim, Norway

The Moelv tillite, exposed in the Lower Allochthon of the Scandinavian Caledonides represents the Neoproterozoic Varanger glaciation, which is generally correlated with the ~580 Ma Gaskiers glaciation in Laurentia. To refine a 620 ± 14 Ma maximum age for the Moelv tillite based on detrital zircons [1], Re-Os data were collected from a C-rich shale horizon in the Biri Formation underlying the tillite.

East of the town of Biri, the weakly deformed Biri shale contains a significant silt component, minor but ubiquitous fine-grained pyrite, and an average TOC of 0.7%. Exposures in a steep bedrock stream channel (Djupdalsbekken) show little bleaching or oxidation. Here, where the Biri shale is separated from the Moelv tillite by the Ring conglomerate, two localities were sampled. Seven analyses of four samples taken about 50 m below the Biri-Ring contact yield a statistically tight Re-Os age of ~560 Ma, with an initial 187Os/188Os (Os_i) near 1. Four additional samples, taken ~48 m below the contact, scatter slightly, but all samples regressed together still yield an age within uncertainty of 560 Ma. Re-Os data from samples taken ~3 m below the Biri-Ring contact scatter about a reference line of 600 Ma with Os_i = 1.0. Scatter may result from minor Re and lesser Os loss during recent oxidative weathering. Thus, there is some true geologic variation in the data, but the results clearly support an age close to that of the ~580 Ma Gaskiers glaciation.

A second Biri locality near Øvre Rendal lies on the northern extension of the ~300 Ma Oslo rift. Here, the shale shows strong cleavage, has an average TOC of 2.7%, contains lenses of pyritic sandstone, is unusually thick, and directly underlies the Moelv tillite. Road-cut exposures are locally rusty, but fresh, black samples were obtainable. Ten analyses from six samples taken in a 1-m stratigraphic interval scatter about a reference line of 300 Ma with Os_i = 1.1. Greenschist-facies, dynamic metamorphism does not disturb the Re-Os system in shales [2,3]. We therefore propose that heat from the ~300 Ma rifing event induced hydrocarbon maturation and migration, and that the organic material analyzed was isotopically homogenized (or introduced) during this event.

Li as a barometer for biminarlic eclogites

MARGARET HANRAHAN AND GERHARD BREY

Institut für Geowissenschaften, Universität Frankfurt Germany
(m.hanrahan@em.uni-frankfurt.de)

Seitz et al. (2003) suggested that the partitioning of Li between garnet and clinopyroxene is pressure dependent and may serve as a barometer for eclogites. This suggestion was based on the analysis of natural rocks, the fact that Li is a faithful follower of Mg into octahedral site positions and that only garnets with a majoritic component have MgVI. We can assume a coupled substitution with P and carried out high pressure experiments in CMAS + Li₃PO₄. The experiments were carried out from 6 - 12 GPa, 1200 -1500° using starting materials with varying Li contents to check for compliance with Henry’s law. The run products were analyzed by EPMA and SIMS. The results are shown in Figure 1.

Conclusion

Henry’s Law is fulfilled for Li partitioning between garnet and cpx in the concentration range of 1 - 0.01 wt% Li. The partitioning of Li is dependant mostly on pressure and less so on T (see above figure). Further experiments are needed to reach a better constraint on the pressure, T dependance of the Li-partitioning and achieve a functioning barometer.

Removal of uranium, arsenic and phosphorus from aqueous solutions using steel slag

E.J. HANSKI¹, K. MÄKELÄ¹, M. MANNINEN¹, K. KUJALA² AND P. PERÄMÄKI³

¹Department of Geosciences, P.O. Box 3000, FIN-90014 University of Oulu, Finland (eero.hanski@oulu.fi)
²Department of Process and Environmental Engineering, University of Oulu
³Department of Chemistry, University of Oulu, Finland

The European iron and steel industry produces annually ca. 45 million tons of metallurgical slag, of which 37% and 41% are utilized in cement production and road construction, respectively. Over the past ten years, much research has been devoted to potential environmental applications of slags due to their favorable adsorptive properties. We have investigated the uptake of U, As and P by steel slag from aqueous solutions using samples obtained from the Rautaruukki Co., Raabe, Finland. Mineralogically, the solid material is mainly made up of compounds of CaO, FeO and SiO₂. The behavior of the above-mentioned elements was investigated in 24-hour laboratory batch experiments with the initial concentrations of 2–250 mg/L for U, 0.5–60 mg/L for As and 20–500 mg/L for P. Long-term column experiments are also currently in progress in order to study the maximum phosphorus sorption capacity of steel slag. Phosphorus in equilibrated solutions was determined spectrophotometrically and U and As were analysed using ICP-MS.

Uranium showed practically a complete partitioning into the solid phase; for example, with a maximum starting U concentration of 250 mg/L and a liquid/solid (L/S) ratio of 100, only 0.05–0.06 mg/L was left in solution, corresponding to a solid/liquid distribution coefficient in the range of 4–5 x 10⁵. In the batch experiments with initial phosphorus contents of 60–100 mg/L and L/S ratios of 450–500, the sorption capacity of steel slag was mostly in the range of 25–33 g/kg and the sorption percentage 70–96%. In the column experiments on relatively coarse-grained slag (1–4 mm), the sorption efficiency declined to 80% when the slag had achieved a P concentration of 5.1–7.3 g/kg, while in the experimental columns containing fine-grained slag (<1 mm), which are still running, the phosphorus sorption has remained perfect (>99%) after retention of up to 12.4 g/kg of P. In common with U and P, arsenic had a pronounced sorption affinity to steel slag. In all batch experiments conducted so far with a L/S ratio of 1000 or less, the sorption percentage was higher than 92%.

Due to leaching of Ca from steel slag, the mechanism of P and As removal is mainly by precipitation of hydrous calcium phosphates and calcium arsenates, respectively, as confirmed with SEM. The mechanism of U sorption is not yet established but it seems that calcium also plays an important role in this case. In summary, our experimental study shows that steel slag can serve as an excellent sorbent for U, As and P from aqueous solutions.
Colloidal green rust behaviour: Adhesion, transformation and mobility

E. B. HANSSON AND S. L. S. STIPP
NanoGeoScience, Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen Ø, Denmark (ehansson@geol.ku.dk; stipp@geol.ku.dk)

One of the more poorly understood processes in nature is the transport mechanisms of solutes and particles. In order to predict the behavior of unwanted compounds in nature, we need to establish these processes. Colloidal transport is believed to be one of the major pathways for distributing contaminants. These contaminants might come from general pollution or from leaking radioactive waste repositories. One very interesting compound that forms colloids and which is believed to exist in such environments is green rust.

Green rust is a layered double hydroxide (LDH) of high reactivity. It consists of ordered layers of Fe(II) and Fe(III), alternating with hydroxide layers and intercalating anions, cations (see poster by Christansen et al.) and water. It can form from partial oxidation of ferrous iron in the groundwater or directly from corrosion of metallic iron, which we use in reactive barriers and for reinforcement of underground radioactive waste repositories. Green rust reacts readily with redox sensitive contaminants due to the Fe in the layered structure and allows for a high degree of adsorption due to a large external and internal surface area.

Im mobilisation of contaminants in or on a solid is desirable, but if the solid is transported as a colloid, the contaminant is mobilised anyway. Therefore, we investigated the attachment ability of green rust using atomic force microscopy (AFM). To survey general colloid behaviour, we examined adhesion on 11 substrates chosen to represent common natural solids. Green rust colloids adhered well to all these substrates regardless of their surface charge.

The mobility of the particles formed from aerial oxidation of green rust was also examined. Upon oxidation, the green rust crystals showed dissolution along the edges. On hydrophilic substrates, elongated goethite crystals typically formed on and near original green rust particles. The stickiness of green rust suggests that it also serves as a substrate for other colloids which might have contaminants adsorbed.

From our experiments we interpret that the presence of green rust will generally limit contaminant transport in the groundwater system.

Mantle magma chambers beneath Gran Canaria

T.H. HANSTEEN
IFM-GEOMAR, Kiel, Germany (thansteen@ifm-geomar.de)

A suite of basanite-hosted mantle xenoliths from the Quaternary Bandama volcanic center, Gran Canaria, comprises spinel harzburgites, spinel dunites and wehrlites, where Mg# of olivine range from 81 to 91, and clinopyroxenes encompass both igneous (Ti-augite to aegirine-augite) and upper mantle (Cr-diopside) types. They contain abundant silicate melt and CO2-dominated fluid inclusions. Clinopyroxene rim-melt thermobarometry of the host basanites indicates significant crystallization at pressures between 0.9 and 1.2 GPa. Barometry of primary magmatic CO2-inclusions in basanite olivines similarly yields minimum formation pressures between 0.7 and 1.0 GPa indicating cotectic olivine-clinopyroxene-Ti-magnetite crystallization at such pressures.

In the xenoliths, texturally late fluid inclusions coexist with melt inclusions thus indicating higher formation temperatures than the early fluid inclusions, which do not coexist with melt inclusions. The observed density differences of fluid inclusions is interpreted as in situ isobaric heating of the xenoliths in the upper mantle at 0.75 ±0.1 GPa (26 ±3 km depth), from about 750°C to near host-magma temperatures. This depth coincides with a change in the upper mantle P-wave velocity structure from anomalously low velocities of 7.5 -7.8 kms⁻¹ between the Moho and 26 km depth, to normal values of 8.3 kms⁻¹ below [1]. This low-velocity zone is interpreted as a clinopyroxene-enriched underplating zone in upper mantle, i.e. a region containing a complex mixture of harzburgite, wehrlite, and partly crystallized melt pockets. The xenoliths represent fragments of wall-rocks from a magma chamber within this region. A genetic link between magma chamber formation in the uppermost mantle, metasomatic overprinting and magmatic underplating is proposed for Gran Canaria, where a localized underplating zone has developed possibly from the late Pliocene to the Holocene through repeated metasomatic interaction between mantle rocks and ascending magmas.

Metasomatically induced alteration and re-equilibration of orthophosphate and silicate minerals: Textures, fluids, and mass transfer

DANIEL E. HARLOV
GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany (dharlov@gfz-potsdam.de)

In nature, total re-equilibration of minerals and mineral assemblages under prevailing P-T-X conditions is greatly enhanced when suitably reactive fluids are involved. Often, however, re-equilibration is only partial and limited to those areas of the grain in immediate contact with the fluid. This can be due to a variety of factors including limited amounts of fluid, a limited reactivity between the fluid and the mineral and/or sufficiently low P-T conditions thus guaranteeing very low reaction rates. In general re-equilibration, whether localized or total, occurs as a result of dissolution-reprecipitation processes, which can also allow for the nucleation and growth of mineral inclusions of one phase within minerals of another phase.

Here a series of different orthophosphate and silicate mineral textures with or without mineral inclusions will be described and interpreted. Each of these textures is the direct result of fluid-induced dissolution-reprecipitation processes and represents the re-equilibration of the orthophosphate mineral on a localized scale. Such re-equilibration textures can have profound implications with regard to dating metasomatic events as well as allowing for P-T-X conditions to be estimated.

From a broader perspective, these fluids have not only interacted with the orthophosphate and silicate minerals but also potentially with the rock as a whole. As a consequence, the documentation and interpretation of metasomatically induced alteration in orthophosphate and silicate minerals has broader implications with respect to obtaining deeper insights into the nature and role of fluids in the crust and upper mantle.

LIBS: A new paradigm for real-time and in-field geochemical analysis

R.S. HARMON1, F.C. DELUCIA2, N.J. MCMILLAN3, A.W. MIZIOLEK2 AND A. WHITEHOUSE4

1Army Research Office, Research Triangle Park, NC
2Army Research Laboratory, Aberdeen Proving Ground, MD
3New Mexico State Univ., Las Cruces, NM
4Applied Photonics Ltd, Skipton, UK

Laser Induced Breakdown Spectroscopy (LIBS) is a simple atomic emission spectroscopy technique capable of essentially non-destructive determination of the elemental composition of any substance in real time. In LIBS, a focused and pulsed laser beam is directed at a sample surface, where laser energy absorption and resulting material ablation produces a high-temperature microplasma at the sample surface. Small amounts (nanograms) of material are dissociated and ionized, with both continuum and atomic/ionic emission generated by the plasma during cooling. A broadband spectrometer equipped with a CCD array detector can be used to spectrally and temporally resolve the light from the plasma to record emission lines of the full suite of elements present in the sample.

Important attributes of a LIBS sensor system for geochemical analysis include (i) real-time response, (ii) in-situ analysis with no sample preparation required, (iii) a high sensitivity to low atomic weight elements which are often difficult to determine by other techniques, and (iv) standoff detection. LIBS technology is now sufficiently mature, inherently rugged, and affordable to offer a capability for both laboratory and field-deployable analysis. Successful laboratory benchtop and 30-m standoff feasibility studies have been conducted that highlight the potential of LIBS for variety of geochemical, mineralogical, and environmental applications that require either real-time or in-field chemical analysis.
Magmatic processes recorded by garnets from the AD 79 eruption of Vesuvius

D. Harries, A. Heumann, K. Simon and A. Kronz

Geowissenschaftliche Zentrum Göttingen, Abt. Geochemie, Georg-August-Universität Göttingen, Germany (dennis.harries@stud.uni-goettingen.de)

Introduction

Evolved K-phonolitic tephra of Mt. Somma-Vesuvius volcano (Campania, Italy) contains Ti-rich garnets of the andradite-grossular solid solution series (‘melanite’) which are interpreted to be of magmatic origin in the Mercato (~8.1 ka) and Avellino (~3.7 ka) eruptive products (Scheibner et al., 2007).

Here we present data on REE distribution patterns obtained by laser ablation ICP-MS profiles in garnets of similar composition from tephra of the AD 79 eruption of Vesuvius in order to potentially distinguish metasomatic and magmatic garnets. The studied garnets have melanitic compositions and show core/rim structures with higher Fe$$^{2+}$$/Al ratios in the rims and resorption features at the interfaces.

Samples and Analytical Methods

Garnet phenocrysts (~0.3-0.8 mm) were separated from crushed pumice samples taken from the basis of the chemicaly most evolved white tephra and from basis and top of the less evolved grey tephra at Pompeii (‘Necropolis’, Cioni et al., 1995).

Continuous profiles through sectioned garnet crystals were obtained by ICP-MS coupled to a 193 nm ArF excimer laser. Profile width/spot size was 30 µm and resulting profile depth was ~60 µm. Detection limits ranged between 1 to 7 ppm for REE. Major element quantification was accomplished by wavelength dispersive EPMA.

Results and Discussion

LREE concentrations peak at Nd and show almost no variations through cores and rims, in contrast HREE are strongly depleted in the cores by a factor of up to 30 (2 to 10 for individual crystals) relative to the rims. Very high partition coefficients for HREE in melanitic garnets (Scheibner et al., 2007) suggest crystallisation of the cores from a highly fractionated magma unlike any of the eruption products of AD 79. These findings imply a significant contribution of a fractionated magma unlike any of the eruption products of AD 2007).

We have analyzed Pb isotopic ratios of natural fluid and melt inclusions by LA-MC-ICPMS and demonstrate the ability to use Pb ratios normalized to both 204Pb and 206Pb in tracing ore mineralization. The case study follows extensive feasibility tests (Pettke et al., in prep) using synthetic Pb fluid inclusions, in which we attained within run precisions (± 2SE) of as good as 200 ppm (normalized to 206Pb) and 400 ppm (normalized to 204Pb) and shot to shot reproducibilities (± 2SD) of 800 ppm and 7000 ppm, respectively.

Fluid inclusions in this study are from quartz veins in two different Cu-Au porphyry systems in the Apuseni Mountains, Romania. The Apuseni Mountains represent the richest concentration of metal deposits in Europe, and have been mined since pre-Roman times. Mineralization is hosted by sub-volcanic Miocene magmas intruded in a transtensional geodynamic environment. The magmatic rocks are mostly andesitic in composition, several of which contain high Sr and Pb concentrations, LILE enrichment and MORB-like Sr and Nd isotopic compositions characteristic of adakite-like magmas. Stocks hosting the porphyry deposits have adakite-like chemical signatures. Whole rock major, trace, and Pb-Sr-Nd isotopic analyses on the magmatic rocks represent the maximum range in age and composition, including endmembers of hybrid magmas recognized in the field from mingling textures. Pb isotopic ratios of whole rock solutions were measured with MC-ICPMS using TI normalization. Fluid inclusions were measured by LA-MC-ICPMS while admixing desolvated 997-TI standard solution. In high temperature stockwork veins, fluid inclusion ratios are indistinguishable from high temperature sulfides but less radiogenic than galena from the same deposit. Pb ratios of fluids and sulfides overlap ratios from the magmatic host rocks. Feldspar cores and several melt inclusions hosted in the feldspar cores, however, exhibit Pb isotopes more radiogenic than the magmatic rocks and fluids, consistent with observed inverse feldspar zoning. Results will be explored in consideration of the idea that ore deposition is linked to a pulse of more primitive magma into the system (e.g., Kamenov et al., 2005).

Evidence for water on Hadean Earth

T.M. HARRISON

Dept. of Earth and Space Sciences & IGPP, UCLA, Los Angeles, CA 90095 U.S.A. (tmh@oro.ess.ucla.edu)

The criteria thought necessary for life are: an energy source, organic molecules, and liquid water. Since the necessary energy sources and molecular building blocks for life were surely available during the formative stages of planetary evolution, the question of when life could first have emerged on Earth reduces to: When did liquid water first appear at the Earth’s surface? While exposure of >3.83 Ga marine sediments indicates the presence of oceans by that time, strategies to assess an earlier hydrosphere are limited by the fact that there is no known Hadean (4.5-4.0 Ga) rock record. However, detrital zircons as old as nearly 4.4 Ga from the Jack Hills, Western Australia, present four kinds of evidence that suggest the presence of liquid water at or near the Earth’s surface during the Hadean. Oxygen isotopes analyses of zircon provides a means to assess the isotopic composition of the protolith. High δ^{18}O values of some Hadean zircons, indicative of a clay-rich protolith, are interpreted as indicating crust-hydrosphere interactions prior to 4 Ga. Inclusion assemblages in Hadean zircons characteristic of hydrated, peraluminous parent magmas are suggestive of the melt protolith having originated at the Earth’s surface and further suggest early development of sedimentary cycling in the presence of a hydrosphere. While specific circumstances could be convolved to create a high δ^{18}O signal along with peraluminous inclusions outside a surficial environment, they represent exceptional occurrences. Crystallization temperatures of >4 Ga granitoid zircons cluster strongly at 680±25°C from which we infer a regulated mechanism producing wet, minimum-melting conditions throughout the Hadean. This distribution is indisputably different from that produced by cooling of mafic and intermediate magmas and we conclude that the vast majority of Hadean zircons could not plausibly be derived from such sources. Instead, the simplest explanation for the dominant low temperature Hadean peak is that it reflects prograde melting under shallow conditions at or near water saturation. In effect, as soon as the source reached anatectic conditions, the majority of melt fertility was lost in the presence of excess water. Comparisons of U-Pb and U-Xe ages in Hadean zircons show varying degrees of Xe loss, but in some cases are concordant within uncertainty. Variable plutonium/uranium ratios in these zircons suggest that Pu and U could be mobile with respect to each other during the Hadean. As Pu and U can be strongly fractionated in aqueous systems, this may indicate, at least locally, the presence oxidized aqueous fluids in the Hadean crust. Although circumstantial, the four lines of evidence discussed above provide a cogent case for the presence of liquid water at or near the Earth’s surface during much of the Hadean.

Rutile 207Pb-206Pb ages in the Jack Hills quartzite, Western Australia

T.M. HARRISON1, D. TRAIL2, A.K. SCHMITT1 AND E.B. WATSON2

1Dept. of Earth & Space Sci. & IGPP, UCLA, Los Angeles, CA 90095 USA
2Dept. of Earth & Environmental Sci., Rensselaer Polytechnic Institute, Troy, NY 12180, USA

The Narryer Gneiss Complex of Western Australia is comprised of 3.73–3.30 Ga orthogneisses and ~3 Ga supracrustal rocks that experienced regional metamorphism and local granite emplacement at ~2.5 Ga. In the western Jack Hills, upper greenschist grade quartzites contain detrital zircons approaching 4.4 Ga and thus efforts have been made to date other detrital phases (e.g., monazite, chromite) but as yet the age distribution of rutile has not been assessed. The significance of discovering >4 Ga rutile grains is heightened by possible application of the recently calibrated Zr-in-rutile thermometer which permits a test the Hadean minimum-melting hypothesis of Watson & Harrison (2005). However, the lower bound of estimates of Tc for Pb in rutile, which range from 400-600°C, overlaps with the estimated peak metamorphic temperature in which case the potential for rutile to retain its primary crystallization age would be greatly reduced.

388 207Pb/206Pb SIMS multi-collector analyses of 369 rutile grains from Jack Hills quartzite sample JH0113 yield an distinct age peak at ca. 2.5 Ga and an average age of 2.3±0.2 Ga. Age uncertainty for a 1 min analysis is typically ±2%. A traverse across one large grain revealed significant 207Pb/206Pb age variability. 33 of the dated grains were also analyzed for Zr by EMPA, counting with four spectrometers simultaneously. [Zr] was converted into crystallization temperature using the Watson et al. (2006) thermometer yielding a broadly normal distribution at 665±18°C. The highest recorded temperature (718°C) was obtained near the rim of a ~200 µm rutile grain with the core of the grain closer to the average value.

Given that crystallization temperatures are substantially higher than that attained during greenschist metamorphism, one interpretation is that the Zr-in-rutile thermometer has not been reset but that essentially complete Pb isotope exchange occurred at ca. 2.5 Ga. Alternatively, the very high Ti contents in cracks in detrital zircons from the Jack Hills suggests high Ti mobility during regional metamorphism due to dissolution/reprecipitation of Ti-bearing detrital grains. Evidence supporting this view comes from 2.5 Ga EMPA chemical Pb ages of monazites included in rutile which further suggest fluid-mediated dissolution/reprecipitation reactions at that time. This would explain the substantial disturbance to the 142/144Nd systems in Hadean zircons (Caro et al., 2006) if monazite inclusions are the principal host of LREE’s. This interpretation, however, does not explain the level and uniformity of the Zr-in-rutile temperatures and could suggest non-equilibrium Zr abundances in rutile.
Intra-test variation in the trace element composition of planktonic foraminifera: Implications for biomineralization processes

ED C. HATHORNE1*, RACHAEL H. JAMES2 AND RICHARD LAMPITT3

1DFG-Research Center Ocean Margins (RCOM), University of Bremen, Bremen, Germany (ehathorne@marum.de)
*previously at2
2Department of Earth Sciences, The Open University, Milton Keynes, U.K. (R.H.James@open.ac.uk)
3National Oceanography Centre, Southampton, U.K. (R.Lampitt@noc.soton.ac.uk)

The trace element chemistry of the calcite shells (tests) of planktonic foraminifera is a prime source of palaeoenvironmental information. Trace element partition coefficients are usually determined empirically, yet it is clear that calcification is biologically controlled. Better interpretation of the chemistry of foraminiferal calcite thus requires an understanding of the fundamental processes of mineralization and their influence on the resulting mineral chemistry.

To this end we have analysed the intra-test variation of a number of trace elements in the planktonic foraminifera species Gr. inflata, Gr. scitula and O. universa. Samples were recovered from a deep sediment trap (3km water depth) in the N. Atlantic (48.6N, 16.3W). The chemical and physical characteristics of the water column at this site are monitored, so the conditions under which calcification took place can be assessed. Measurements were made by laser ablation (LA) inductively-coupled plasma mass spectrometry (ICP-MS). A 193nm ArF Excimer laser was used to ablate through the test walls and time resolved signals from the quadrapole ICP-MS provide depth profiles of trace elements. Internal standardisation was performed using Ca and signals were calibrated using a calcite powder pellet and NIST 612 glass.

All three species display a 100-200% increase in Mg/Ca through the test wall which is far greater than expected as a result of vertical migration of the foraminifera and associated changes in water temperature. Other light trace elements (Li/Ca and B/Ca) show similar behaviour, but Sr/Ca ratios show no variation greater than the analytical uncertainty (~10% RSD). The change in Mg/Ca, Li/Ca and B/Ca through the test wall is most likely due to biomineralization processes. The implications of these data for foraminifera calcification models will be discussed.

Hydrogeochemical Properties of Ladik Hot Water Spring (Samsun, Turkey)

E. HATİPOĞLU, F. GÜLTEKİN AND A. FIRAT ERSOY
Karadeniz Technical University, Department of Geological Engineering, 61080, Trabzon Turkey (esrahatipoglu@ktu.edu.tr)

In this investigation Ladik (Samsun) hot water spring has been studied from the point of geology, hydrogeochemistry and discharge. The study area is located around middle-north of Turkey. The geology of the study area and its vicinity consist of Permian aged recristallized limestone, Jurassic-Cretaceous limestone, Eocene-Neogene aged sandstone and claystone and Quaternary aged alluvium. The North Anatolian Fault (NAF) is situated near the hot water spring. Ladik hot water is come out to the surface where cross cut the NS and NW-SE directed fault, which is parallel to the NAF. Spring has 18 l/s discharge rate and 36.7 °C temperature. Hot water is analysed by Hacettepe University, Hydrogeochemistry Laboratory. According to the analyse results total dissolved ion matter for Ladik spring 339 mg/l, Hamamayağı River 192 mg/l and Kocapınar cold water spring 378 mg/l are obtained. The hot spring are classified according to the following criterias:

-according to the structural properties “fault spring”
-according to the temperature “medium hot water”
-according to the geothermal energy “low entalphy geothermal system”
-according to the hot water analyse result cation and anion trend of the springs are;
  -for Ladik hot water spring, Kocapınar cold water spring and Hamamayağı River
    rCa2+>rMg2+>rNa+>rK+ and rHCO3->rSO42->rCl-
  -Saturation indexes of the hot and cold water springs have been calculated in PHREEQC program. Springs are not saturated with respect to the calcte, dolomite and aragonite. According to the Schoeller and Pipper Diagrame, springs and river waters have similar chemical properties but Ladik hot spring has high Mg2+, Na+ and K+ ion values. The reason of these high concentrations have been assumed that the hot water add the ions of the recristallized limestone and limestone.

Abstract
Laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) is frequently used for spatially resolved chemical characterization of a wide variety of minerals, soils and many other samples. Despite its successful use, accurate quantification of elemental concentrations can still be problematic, due to effects commonly summarized under the term “elemental fractionation”. This is most pronounced when matrix matched calibration standards are not available, which may result in variations of the relative sensitivities of the elements. This has been mainly attributed to non-representative laser sampling due to variations in the ablation process, causing preferential vaporization of elements. Recent reports, however, indicate that vaporization, ionization of the aerosol inside the ICP as well as the transfer of ions through the vacuum interface of the ICPMS are affecting the relative responses of individual elements significantly [1, 2, 3]. To describe these effects in detail the dependence of relative elemental sensitivities on the operating parameters of the ICPMS was studied for different samples using different laser ablation units (266 nm and 193 nm lasers). It can be shown that the relative sensitivities can vary significantly with the particle size distribution of the laser generated aerosol and the total mass load presented to the ICP. These variations are least pronounced when helium is used as carrier gas with 193 nm laser ablation which produces the generated aerosol and the total mass load presented to the ICP. What comes around goes around: Mantle convection and the meaning of mantle isochrons

E. H. HAURI1, J.P. BRANDENBURG2 AND P.E. VAN KEKEN2

1Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015, USA
2Dept. of Geological Sciences, University of Michigan, Ann Arbor, MI 02543, USA

The perceived significance of isotopic data arrays for oceanic basalts has long occupied a middle ground between the endmember interpretations of mixing and age. Brooks et al. [1] were the first to attach age significance to the correlations between parent-daughter ratios (e.g. 87Rb/86Sr) and daughter isotope ratios (e.g. 87Sr/86Sr) that are a regular feature of the geochemistry of OIB and MORB [e.g. 2,3]. Pseudo-isochrons derived from mixed mantle can still have age significance if the various packets of source material have been physically juxtaposed for long periods of time, yet the current paradigm has generally been to focus on daughter ratios alone, and to interpret their variations in terms of multi-component mixing.

Numerous high-quality geochemical data sets now exist, and continue to be generated, for specific regions of OIB and MORB volcanism. In order to take the next step in a more accurate interpretation of this data, a forward model is needed that delimits the bounds of chemical variability and isotopic correlations expected to arise from the major processes operative during terrestrial mantle convection. In this talk, we will present the results of cylindrical 2D convection models with force-balanced plates [4] and examine specifically the role of subduction and convective mixing of oceanic crust.

In these models, melting occurs at divergent plate boundaries and geochemical evolution is recorded by millions of passive (harzburgite) and active (basalt) tracers that record the times, extents of melting, and extents of degassing at every melting event, allowing the geochemical evolution of any isotope system to be easily calculated (and recalculated) in a post-processing algorithm that operates on the tracer data independently from the dynamic calculations. We will explore the range of isotopic variability in these models as functions of partition coefficients, chemical density of basalt tracers, and convective vigor. In particular, these models reveal relationships between mantle isochron “ages” and true tracer ages that is not obtainable from statistical box-model calculations incorporating idealized mixing scenarios [e.g. 3-5].

Giant impacts, late veneers and the gradual hydration of the earth’s mantle by subduction

E. H. HAURI1, A.M. SHAW2 AND A.E. SAAL.3

1Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015, USA
2Dept. of Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA
3Dept. of Geological Sciences, Brown University, Providence RI 02912, USA

The likelihood of one or more giant impact events occurring during the accretion of the Earth is very high [1,2], and most of these late-stage impact events impart enough energy to completely melt the silicate portion of the proto-Earth [3,4]. Despite the uncertain nature and composition of the terrestrial atmosphere immediately after such impacts, it seems inescapable that the Earth’s mantle suffered a catastrophic loss of volatiles (including H2O, CO2 and noble gases) within the first 100 Ma of the planet’s history.

For these volatile species, the subsequent evolution of the Earth’s mantle has thus involved a gradual re-hydration from without, via the subduction of lithosphere altered by water from an exosphere whose existence has been dated to 4.4 Ga [5,6]. The estimated composition of this exosphere shows many similarities to a mass-fractionated proto-atmosphere mixed with volatiles released during impact degassing of a chondritic late veneer.

We will present the results of forward-modelling the evolution of volatiles in the Earth’s interior via subduction hydration of an initially dry mantle, with an emphasis on H2O. The model estimates the extent of (de)hydration of subducted hydrated lithosphere, and any associated isotopic (D/H) fractionations, based on studies of altered oceanic crust and Mariana arc magmas [7,8]. A defining characteristic of these models is the prediction of an initially high mantle viscosity, with gradual growth of a low-viscosity upper mantle due to the introduction of water at subduction zones. The fraction of the mantle that exchanges water with the exosphere thus grows with time, but the details of this growth depend on the extent of mixing between a hot, dry primordial mantle and a cooler and wet subduction-modified mantle. Nevertheless, virtually all conditions are expected to result in temporal shifts of the D/H ratios of the mantle and atmosphere that never reach steady-state, even over the age of the Earth.

Determination of trace metal-nanoparticle associations in contaminated riverine systems using analytical TEM

K.L. HAUS 1, J.R. JENSCH 1,2,3, J.N. MOORE4 AND M. HOCHELLE, JR 1,2

1Department of Geosciences, 4044 Derrin Hall, Virginia Tech, Blacksburg, VA 24061 USA
2Institute for Critical Technology and Applied Science (ICTAS), Virginia Tech, Blacksburg, VA 24061 USA
3Department of Materials Science and Engineering, Virginia Tech, Blacksburg, VA 24061 USA
4Department of Geology, University of Montana, Missoula, MT 59812 USA

Analytical electron microscopy (AEM) is being used to study the associations between trace metals and nanoparticulate material in riverine systems. Seven samples have been taken from the Clark Fork River system in western Montana, USA, over a distance of 200 river kilometers, and during normal summertime flow. This river is being used as a model system because it is contaminated with toxic trace metals (principally Pb, As, Zn, and Cu) from over 150 years of copper and silver mining activities, and it has been studied in great detail. All samples were digested and analyzed using Inductively Coupled Plasma Mass Spectroscopy (ICPMS) to determine total metal concentrations and it was found that every sample contained significant amounts of at least two of the toxic metals of greatest interest. To date, extensive AEM analysis using an FEI Titan high resolution scanning/transmission electron microscope (S/TEM) (equipped with EDS and EELS detectors) on one water sample has been performed. Grains of aragonite, titanium oxide and hematite, bearing Zn, Pb and As, respectively, have been identified. These particles range in size from 8 to 200 nm in diameter, show various stages of crystallinity, and are often heterogeneous even on a nanometer scale. The nanometer size range is important not only because grains this small represent a disproportionately large amount of surface area available in the biogeochemical system, but also because the properties of these materials are expected to be dramatically altered from larger grains of the same material. These property changes, along with a potential for increased activity, may have a large impact on the bioavailability and toxicity of trace metals in natural systems. Further sampling and AEM analysis of existing samples will lead to a better understanding of trace metals in riverine systems and how nanoparticles are likely influencing their fate and availability.
Basalt weathering rates on Earth and the duration of water on Mars

E.M. Hauşrath¹, A.K. Navarre-Sitchler¹, P.B. Sak², C. Steefel³ and S.L. Brantley¹

¹Department of Geosciences, Penn State University, University Park, PA 16802 (emh191@psu.edu)
²Department of Geology, Dickinson College, Carlisle, PA 17013
³Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720

Understanding the duration of time that Martian rocks were exposed to liquid water is of great interest because it influences the interpretation of the climate history and the potential for life on that planet. The presence or absence of primary minerals may provide constraints for the presence, duration and characteristics of liquid surface water on Mars.

Weathering rates are very sensitive to the pH of the reacting fluid. If pH values of terrestrial and Martian weathering solutions were similar, then mineral persistence ages on Mars are likely to be ≥ those on Earth. We present a compilation of field terrestrial persistence ages for 8 common rock-forming phases (plagioclase, volcanic glass, quartz, feldspar, micas, pyroxene, amphibole, and olivine) collected from dated chronosequences representing a wide climatic spectrum ranging from -10°C to 30°C mean annual temperature and 400 mm to 4500 mm mean annual precipitation. The extent to which these minerals persist may help constrain the rates at which primary phases weather under field conditions on Earth, and likely represent minimum mineral persistence times on Mars if pH values were similar.

However, Mars weathering solutions may have been more acidic than on Earth. Relative mineral dissolution rates at different pH values can be predicted from laboratory dissolution experiments. Here we compare relative mineral weathering rates observed in the field with laboratory predicted trends. Relative mineral weathering rates observed for basalt in Svalbard (Norway), Pennsylvania, and Costa Rica are explainable by pH. These results suggest that the pH-dependence of laboratory rates can be used to interpret relative mineral persistence on Mars to yield information about the pH of the reacting fluid.

We also interpret both terrestrial and Martian weathering profiles using reactive transport modeling, which can yield insights into the duration of weathering. The interpretation of weathering profiles on Mars is a promising approach to study that planet’s aqueous history, and highlights the need for additional depth profiles.

The generation and evolution of the continental crust

Chris Hawkesworth¹ and Tony Kemp²

¹Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ UK (c.j.hawkesworth@bristol.ac.uk)
²School of Earth Sciences, James Cook University, Townsville QLD, 4811 Australia (tony.kemp@jcu.edu.au)

Detrital and inherited zircons encapsulate a more representative record of igneous events than the rock record, and their hafnium isotope ratios reflect the time since the source of the parental magmas separated from the mantle. O and Hf isotope ratios on well-dated zircons are used (i) to distinguish crust formation ages that reflect involvement in the sedimentary cycle, and those that do not, and (ii) to reconcile the crust formation ages of material whose isotope ratios reflect evolution in the igneous and sedimentary reservoirs.

Global peaks in juvenile igneous activity have been identified at 2.7, 1.9 and 1.2 Ga from the geological record. An initial study on samples from the Lachlan Fold belt revealed sharp peaks in Hf model ages in zircons with δ¹⁸O of < 6.5 per mil at 1.9 Ga and 3.3 Ga. It is rare to find zircons with similar crystallization and Hf model ages. At issue are the links between such peaks in the geological and zircon records, and the time periods between initial crust formation and the generation of high silica magmas that might crystallize zircon in different tectonic settings.

The sedimentary record shows no evidence for major pulses of crust generation, and one interpretation is that it can take up to one billion years for new crust to dominate the sedimentary record. The residence times of material in the lower crust appears to be much lower than in the upper crust. Finally, the development of granulite facies rocks, and their effects on the deformation history of the continental crust, will be briefly explored.
Paleoproterozoic post-orogenic evolution of the North China Craton: Geochemical and isotopic constraints from the Xiyanghe Group along the southern margin of the North China Craton

YANHONG HE, GUOCHUN ZHAO AND MIN SUN
Department of Earth Sciences, the University of Hong Kong, Hong Kong (h0492037@hkusua.hku.hk)

There is now a coherent outline of the timing and tectonic processes involved in the Palaeoproterozoic amalgamation and much intensive knowledge concerning the pre-collisional history of the North China Craton. However, much of the post-collisional history of the craton remains unknown. The Xiyanghe volcanics, together with the Xiong’er volcanics, constitute a large Paleo-Mesoproterozoic volcanic belt along the southern margin of the North China Craton. In this study, we provide geochemical and Sr-Nd isotopic data for the Xiyanghe volcanics, which provide important constraints on their petrogenesis and tectonic environment.

The Xiyanghe volcanics could be subdivided into three units: BA1 (basaltic andesites-1), BA2 (basaltic andesites-2) and andesites, all of which show consistent εNd(t), La/Nb and Th/Nb values irrespectively of SiO₂, precluding significant crustal contamination during ascent. Based on the covariation between La and La/SmN, the basaltic andesites show the trend of partial melting processes with the BA1 unit representing the major products of a magma chamber, whereas the andesites may fractionally crystallize from the BA1. The BA1 rocks and andesites show HSFE enrichments (especially Nb>6 ppm) and high Fe-Ti contents, comparable with Nb-enriched basalts, suggesting that the Xiyanghe volcanics were derived from a met-metasomatized mantle source. The BA2 unit is characterized with variable Ti/Eu, Zr/Sm and Nb/La ratios, suggesting that amphiboles have been involved in a partial melting process, which implies that the Xiyanghe volcanics were derived from hydrous magma. A large range in initial Sr (0.7039 to 0.7111) and a relatively narrow range in 143Nd/144Nd (εNd≈-6.8~--10) suggest inheritance of the enriched Nd-isotopic composition from the mantle wedge metasomatized by slab derived fluid. On the primitive mantle normalized trace-element diagrams, the Xiyanghe volcanic rocks show enrichments in the LILE and LREE and negative anomalies on the Nb-Ta-Ti, similar to arc-related volcanics produced by the hydrous melting of the metasomatized mantle wedge. The arc-related characteristics of the Xiyanghe volcanic rocks suggest that the southern margin of the North China Craton may have recorded the outbuilding history of the Columbia Supercontinent during Paleo-Mesoproterozoic time.

This research was financially supported by Hong Kong RGC grants (HKU7055/05P, 7048/04P and 7063/06P), China NSFC grant (40429001) and a HKU Seed Funding for Basic Research (200411159122), all to G.C. Zhao.

Np(V) coprecipitation with calcite

FRANK HEBERLING, MELISSA A. DENECKE AND DIRK BOSBACH
1Institute for Nuclear Waste Disposal, Forschungszentrum Karlsruhe, PO Box 3640, 76021 Karlsruhe, Germany

The actinide elements U, Np and Pu form oxo-cations (’actinyl-cations’) in oxidizing aqueous environments. The environmental behaviour of the actinyl ions U(VI), Np(V) and Pu(V,VI) is to a large extent controlled by sorption reactions (adsorption, coprecipitation / structural incorporation) with minerals. We study the structural incorporation of Np(V) into the host mineral calcite by coprecipitation in mixed flow reactors under steady-state conditions at room temperature. In this way reaction rates and partitioning coefficients can be determined under varying conditions. We found that homogeneous partition coefficients for Np in calcite (0.5 - 11) are significantly higher than those reported for U(VI) (0.01 - 0.2 [1]). The local structural environment of incorporated Np(V) is characterized from the Np L3 EXAFS. Measurements are performed at the INE-Beamline at ANKA (Forschungszentrum Karlsruhe). Our data suggest that the Np(V)-ions occupy calcium lattice sites, but with two missing carbonate groups in the first coordination sphere. The two axial oxygen atoms of the linear neptunyl-ions are likely oriented towards these vacant sites. Consequently, only four carbonates are observed to coordinate the Np(V)-ion. Np-O and Np-C interatomic distances (2,41Å, 3,34Å, respectively) indicate slight structural relaxation of the carbonate groups from their ideal sites. A similar structural model was reported for U(VI) incorporated into natural calcite [2].

Geochemistry and mechanic emplacement of Late proterozoic dyke swarms, Eastern Desert, Egypt

Hussein A. Hegazy
Geology Department, Faculty of Science, Assiut University, Assiut, Egypt (hegazy512000@yahoo.com)

Geologic and geochemical data of intraplate Late Pan-African (493±7Ma) dykes assemblage in the Eastern Desert of Egypt are presented. The dyke swarms consist of a bimodal mafic-felsic suite of transitional alkaline to subalkaline chemistry and exhibit a broad compositional range. Geochemical studies show that they can be subdivided into three distinct chemical groups with two distinct compositional gaps and correlate fairly well with other occurrences of late Pan-African dykes in Egypt. This bimodal suite bears a genetic relation to corresponding rock types in the study area. These dykes trend predominantly in NW and NNW directions and less frequently in NW and N orientations; parallel to the major fracture pattern and lineament trends. Despite of the small geographic area and limited time interval in which the dykes were extruded, their complex geochemistry requires multiple sources together with varying amounts of open system fractionation assimilation. It is believed that the crystallization of the studied dykes follow the one-step emplacement either in open or closed system under both brittle and ductile crustal conditions. The time (ts) required to solidify these types of dykes is generally longer in the acidic than the basic variety.

Nb-depleted calc-alkaline dacites from Iceland: Implications for Archean crust formation

E. Hegner1, M. Willbold2, A. Stracke3 and A. Rocholl1

1Universität München, Department für Geowissenschaften, Luisenstrasse 36, 80333 München, Germany
2University of Bristol, Department of Earth Sciences, Bristol, BS8 1RJ, United Kingdom
3ETH Zürich, Institut für Isotopengeologie, Clausiusstr. 25, 8092 Zürich, Switzerland

Samples from the dacitic Kroksfjordur volcanic center, NW Iceland, have calc-alkaline compositions contrasting the alkaline to tholeiitic composition commonly observed for felsic rocks from ocean islands or plateaus (Jónasson, 2006). New major, trace element, and isotope data show that these samples display a distinct depletion of Nb (La/NbPM = 2.7 ± 0.4; 1σ) and enrichment of Pb (Ce/Pb PM = 0.7 ± 0.1) in primitive mantle normalized trace element plots, and high Na/K ratios (3.6 ± 0.3).

The Sr-Nd-Hf-Pb isotopic compositions preclude the involvement of old continental lithosphere in the petrogenesis of the dacitic melts. The limited variation in major element data and the small though systematic variation of La/Nb and Ce/Pb ratios with TiO2 and Ce concentrations, respectively, suggest that the dacites were derived by partial melting of a mafic protolith comprising plagioclase + clinopyroxene + amphibole + Fe-Ti oxides. Inverse modelling shows that the calculated trace element composition of the source is similar to that of mafic crustal xenoliths hosted by one of the dacitic bodies. This observation suggests that partial melting of Icelandic mafic lower crust, most likely during magmatic underplating, has produced the calc-alkaline dacites at Kroksfjordur.

The major and trace element composition of the dacites closely resembles that of Archean tonalite - trondjemite - granodiorite (TTG) associations. Depletion of Nb and enrichment of Pb in TTG associations have hitherto been interpreted as evidence for their exclusive formation in Archean subduction zones (e.g. Drummond and Defant, 1990; Martin, 1999). The new findings from the Kroksfjordur volcano demonstrate that partial melting of mafic protoliths in an oceanic intra-plate setting can also lead to chemical signatures similar to that of magmatic rocks generated in subduction zone environments. This provides evidence that the Archean continental crust could have been formed in a variety of geodynamic settings including intra-plate as well as plate margin settings.

Mineralized microbial mats with extreme lanthanum enrichments in the tunnel of Äspö, Sweden

C. HEIM, K. SIMON, N.-V. QUÉRIC AND V. THIEL
Geoscience Centre, University of Göttingen, Germany (cheim@gwdg.de)

Microbial mats precipitating iron oxides and thereby accumulating trace and rare earth elements (REE) are widely recognized [1, 2, 3]. A key role in that biomineralization process is assigned to negatively charged organic surfaces (cell surfaces and extracellular polymeric substances, EPS) binding cations and forming complexes [2,3,4]. Depending on the nature of these surfaces, a fractionation of specific cations may occur, thus giving the resulting minerals an inorganic “biosignature”. Bacteriogenic iron oxides covering granitic surfaces in the 450m deep Äspö Hard Rock Laboratory (Sweden) were analysed for inorganic biosignatures using LA-ICPMS. The study revealed an extreme enrichment (about 1000fold) in lanthanum (La) compared the other REE (Fig. 1). According to the similar chemical behaviour of the light REE (La - Nd), this phenomenon cannot be explained by an inorganic precipitation of REE. Likewise, the REE concentration of the water supplying the microbial mat did not show a positive La anomaly. This points to a biologically driven, selective fractionation of La by the bacterial community involved. The resulting biosignature may help to build a better understanding of modern and fossil microbially induced minerals and rocks, even in the absence of fossil remains and organic molecular indicators.

Figure 1: REE plot of mineral precipitates (line 2a-2e on the mineralized microbial mat), and the supplying water (H2O).

Fe isotopes in siliceous igneous rocks: Evidence for fluid-rock interaction in plutons

A. HEIMANN, B. BEARD AND C. JOHNSON
Univ. Wisconsin – Madison (heimann@geology.wisc.edu; beardb@geology.wisc.edu; clarkj@geology.wisc.edu)

The average δ²⁶Fe value of bulk plutonic rocks (PR) with >70wt% SiO₂ is 0.18±0.08‰ (1-SD; n=19; data from Poitrasson and Freydier 2005 CG; Poitrasson 2006 EPSL; this study). In contrast, the average δ²⁶Fe value of bulk volcanic rocks (VR) with >70wt% SiO₂ is 0.02±0.07‰ (1-SD; n=6; data from Beard et al., 2003 CG; Beard and Johnson, 2004 GCA; this study). We have conducted a detailed study of minerals and bulk PR and VR samples using high-precision Fe isotope analysis (±0.06‰, 2SD) to evaluate the origin of these differences.

Magnetite in PR has consistently higher δ²⁶Fe values (δ²⁶Fe= +0.13 to +0.51‰) than its host rock, whereas VR magnetite has lower δ²⁶Fe values (-0.05 to +0.27‰). Silicates in both PR and VR have δ²⁶Fe values that fall within the range for mafic VR (δ²⁶Fe= -0.14 to +0.10‰). Fractionation factors between magnetite and silicates are larger for magnetite-biotite pairs in PR (Δ²⁶Femag-bt= +0.15 to +0.58‰) than for magnetite-silicate pairs in VR (Δ²⁶Femag-sil= -0.02 to +0.19‰, one at +0.34‰). Both are positively correlated with the δ²⁶Fe values of magnetite and show a weak negative correlation with those of silicates, but in PR they are also correlated with δ²⁶Fe of the host rock. The positive correlation between Δ²⁶Femag-sil and bulk δ²⁶Fe in PR indicates that magnetite and bulk PR underwent open-system Fe exchange; the near-zero δ²⁶Fe values in VR indicate that high δ²⁶Fe values in silicic igneous rocks do not reflect crystal fractionation.

Open-system Fe isotope exchange in PR is influenced by cooling rates, Fe content, crystallization temperatures, fO₂ conditions, Fe diffusion rates in minerals, and interaction with late-stage exsolved fluids and/or saline hydrothermal fluids. There is no correlation between δ²⁶Fe and δ¹⁸O values for PR, indicating that Fe was not mobilized by dilute meteoric fluids; the largest range in δ²⁶Fe values of minerals and bulk samples occurs in PR that have been mineralized. Fe isotope shifts likely occurred during exsolution of Fe-rich brines during solidification and deuteric alteration. The relatively high δ²⁶Fe values of magnetite from PR probably reflect sub-solidus isotopic equilibration upon cooling and the high Fe diffusion rates in this mineral relative to silicates. Exsolved Fe-chloride solutions will have low δ²⁶Fe values as compared to silicates or magnetite based on theory (Polyakov and Mineev, 2000 GCA; Schauble et al., 2001 GCA), suggesting that the remaining pluten will increase in its δ²⁶Fe value; this effect will be most significant in low-Fe, high-SiO₂ rocks, matching the observation that δ²⁶Fe values for bulk samples and magnetite in PR are higher at higher SiO₂ contents.
Synthetic forsterite grain boundaries: Tilt [100] and 9.9° to 21.5°

S.HEINEMANN1,2, R.WIRTH1 and G.DRESEN3

1GeoForschungsZentrum Potsdam, Germany
2Present address: AMD, Center for Complex Analysis, Dresden, Germany (stefan.heinemann@amd.com)
3Laboratory for Isotope Geology, Swedish Museum of Natural History, Stockholm, Sweden (Martin.Whitehouse@nrm.se)

Forsterite is a main constituent of rocks in the Earth’s mantle. The refractory nature of forsterite makes it suitable for ceramics used in thermal insulations. The properties of rocks and ceramics are largely determined by their grain boundaries. Structure and transport properties of grain boundaries in rocks are still poorly understood. In general grain boundary structure, grain boundary energy and grain boundary properties depend on orientation. Low angle grain boundaries show dislocations, have low grain boundary energy and their transport properties (e.g. grain boundary chemical and thermal diffusion, grain boundary migration and sliding) are slow. High angle grain boundaries do not reveal dislocations, have high grain boundary energy and their transport properties are fast. In oxides, the transition from low to high angle grain boundaries is not studied in detail, but the transition to a high angle grain boundary is commonly defined at an angular lattice misorientation of ~ 10°-15°.

We synthesized a series of symmetric tilt grain boundaries in forsterite bicrystals with tilt axis a and increasing tilt angle from 9°-21° by direct bonding (Heinemann et al. 2001, 2005). For each bicrystal two oriented and polished synthetic forsterite single crystal plates were joined at room temperature and annealed at 400°C in vacuum for one week. All bicrystals were cut in two parts and one part was annealed further at 1650°C for 48h. Specimens were prepared for investigations in the TEM with focused ion beam (FIB).

HRTEM investigations of the grain boundaries parallel to tilt axis a show symmetric tilt grain boundaries with arrays of regular spaced edge dislocations between undisturbed crystal regions for all annealing temperatures and all tilt angles. The grain boundary structure developed below 400°C and did not change till 1650°C. All grain boundaries with tilt angles from 9°-21° are low angle grain boundaries. The Burgers vector of the edge dislocations is a. The regular dislocation spacings decrease with increasing tilt angles and dislocation cores do not overlap up to a tilt angle of 21°.

The dislocation model of low angle grain boundaries can be applied and the observed dislocation spacings d are related to tilt angle θ and Burgers vector length b by Frank’s formula:

\[ d = b(2\sin(\theta/2))/b = \theta \]

with tilt angles increasing from 9° to 21° the dislocation spacing decreased.

Using Frank’s equation and a rough estimation of the dislocation core radius of \( r_0 \approx 0.4nm \approx 2/3b \) we propose that in forsterite the transition between low and high angle grain boundary occurs at a misorientation of ~ 42°.

Evaluating the role of superoxide (O$_2^-$) and hydrogen peroxide (H$_2$O$_2$) in the dissolution of Saharan dust in the Tropical Atlantic

M. HELLER AND P. CROOT

IFM-Geomar, Kiel, Germany
(mheller@ifm-geomar.de; pcroot@ifm-geomar.de)

Method and Theory

The major source of iron to the Tropical Atlantic is through aeolian deposition of Saharan dust. Presently within SOPRAN (German SOLAS) we are investigating, at the TENATSO site in Cape Verde, water column processes that control the dissolution of Saharan dust deposited at the seawater surface. The thermodynamic solubility of Fe(III) in surface seawater is thought to be controlled by the presence of iron complexing organic ligands. However in tropical waters, where high fluxes of superoxide (O$_2^-$) may exist, due to photochemical reactions of dissolved organic material, there exists the possibility of a kinetic controlled reduction of Fe in colloids and particles to the more soluble Fe(II) [Kustka et al., 2005; Rose and Waite, 2006].

\[ \text{Fe}^{III} + \text{O}_2^- + 2\text{H}^+ \rightarrow \text{Fe}^{II} + \text{H}_2\text{O}_2 \]

Photochemistry may not be the only source of O$_2^-$ in seawater as recent work suggests a significant biological source also [Kim et al., 2004]. Overall these processes may lead to longer residence times for dissolved Fe in surface waters [Croo et al., 2004].

Discussion

Current work focuses on laboratory work evaluating analytical methodologies and focuses on three key aspects:

(i) The influence of temperature on the dismutation rate of O$_2^-$ in seawater.

(ii) How O$_2^-$ can alter the Fe organic speciation in seawater.

(iii) Assessment of the enhancement of Fe dissolution from Saharan dust via increased O$_2^-$

Conclusion

Using this approach we hope to be able to critically examine the role in which photochemistry and biology play in solubilizing Fe from Saharan dust in Tropical seawater. Overall this information will help in better assessing the key processes controlling iron bioavailability in natural seawater.

The reactivity of ferric (oxy)hydroxides toward dissolved sulphide between pH 3 to 9

K. HELLIGE AND S. PEIFFER

Dept. of Hydrology, University of Bayreuth, Germany
(katrin.hellige@uni-bayreuth.de;
s.peiffer@uni-bayreuth.de)

The reaction between H$_2$S and ferric (oxy)hydroxides exerts a major role for the sulphur and iron cycle as for the electron and carbon flow in many aquatic systems (e.g. Canfield, 1992). The reaction mechanism is reasonably well understood (Dos Santos Afonso et al., 1992; Peiffer et al., 1992). The reaction rate depends on pH which can be explained by a surface speciation model according to which the electron transfer is preceded by an adsorption step of a sulphide species to the neutral ferric oxide surface $>$FeOH.

In a recent study, steady-state experiments have been performed at low pH ($<5$) using a fluidized-bed reactor that is supplied with a constant flow of electrochemically generated hydrogen sulphide (Peiffer & Gade, 2007). The surface area normalized experimental reaction rates depended on bulk properties of the used minerals and decreased in a sequence Gt $>$ 2lfh $>$ 6lfh. These observations are in contrast to results from batch experiments obtained at pH 7.5 where mineral reactivity seemed to be related to the free energy of their formation (Poulton et al, 2004). Under these conditions Fe$^2+$ strongly adsorbs to the mineral surface and thereby interacts with dissolved sulfide.

In this study we attempt to resolve these contradictions. Using the same experimental approach as described in Peiffer & Gade (2007), we have extended the experimental pH range to study the steady-state reactivity of various iron (hydr)oxides to values between 3 and 9. In this poster we will present the first results from these experiments.

Investigating the dependence of feldspar dissolution rates on Gibbs free energy in the presence of high pCO₂

R. HELLMANN¹, D. DAVAL² AND D. TISSERAND³

¹LGIT, CNRS UMR C5559-Univ. Grenoble, France (hellmann@obs.ujf-grenoble.fr)
²IPGP, Paris and Laboratoire de Géologie, ENS, UMR 8538 Paris, France (daval@ipgp.jussieu.fr)
³LGIT, CNRS UMR C5559-Univ. Grenoble, France (tisserand@obs.ujf-grenoble.fr)

Here we report on results from an ongoing experimental investigation of the dissolution kinetics of albite feldspar at 100 °C in aqueous solutions significantly enriched in dissolved carbon dioxide (pCO₂ = 9 MPa). The purpose of this study is to measure CO₂-water-rock interactions as a function of solution saturation (ΔG), thereby providing data needed to model physico-chemical interactions associated with mobile CO₂-plumes in subsurface environments. Over the fluid saturation range of –70 to –40 kJ mol⁻¹ the dissolution rates can be characterized by a dissolution rate plateau, where the rates are roughly equal and independent of dissolved Na, Al, and Si. At higher solution saturation states, the rates begin to decrease sharply. In addition, the stoichiometry of dissolution changes from stoichiometric to non-stoichiometric, and is most probably due to the precipitation of an Al phase. Current experiments are being run to measure the kinetics at ΔG > -30 kJ mol⁻¹. The present data set, even though incomplete, is in general accord with many other studies that show a sigmoidal dissolution rate-free energy relation (e.g. Hellmann and Tisserand, 2006; and refs therein). Most importantly, the data also deviate dramatically from the behavior predicted by transition state theory (TST).

Lower mantle phase-boundary variability

DON V. HELMBERGER AND DAOYUAN SUN
Seismological Laboratory 252-21, California Institute of Technology

A lower mantle S-wave triplication with a Scd branch occurring between S and ScS appears to be explained by a recently discovered Perovskite (PV) to Post-Perovskite (PPV) phase-change. It is predicted to have a positive Clapeyron slope (γ) between 5 to 13 MPa/K with a small S-velocity jump (1.5 to 4%) and an even smaller 1 to 2% jump in P-velocity. Seismic observations indicate that Scd arrives earlier and stronger beneath fast regions indicating a positive γ (circum-Pacific) than slow regions (super plumes). However, it proves difficult to separate effects produced by down-welling (slab debris) from up-welling (plumes) in refining the actual physical properties. Here we model dense record sections collected from USAArray and existing PASSCAL data to isolate effects produced by lower mantle structure as evidenced by P and S-waves, to better define the seismic phase-change properties beneath Central America. We find that the PV-PPV velocity jump is twice as strong beneath slow regions than fast regions requiring distinct reference heights indicative of changing chemistry. Moreover, the edges of the supposed buckled slabs delimited by both P and S-waves display very rapid changes in phase-boundary heights producing Scd multipathing. These features can explain the unstable nature of this phase with easy detection to no detection commonly observed. The fine structure at the base of the mantle beneath these edges contains particularly strong reflections indicative of local ultralow velocity zones, which is predicted in some dynamic models.

Different origin for mafic and intermediate/felsic lavas from Moorea island (Society, French Polynesia)

C. HÉMOND¹, C. CHAUVEL², R.C. MAURY³ AND E. LEWIN²

¹Domaines océaniques, IUEM, Brest University 29200 Plouzané, France (chhemond@univ-brest.fr)
²LGCA, Grenoble University, 38041 Grenoble cedex, France.

Moorea, a Quaternary volcanic island in the linear Society chain (French Polynesia) is made up of shield (alkali basalt to trachybasalt) capped by intermediate lavas (basaltic trachyandesites, trachyandesites, tephri-phonolites) and alkali trachytes. These intermediate to evolved lavas were emplaced between 1.55 and 1.35 Ma, just after the end of the shield stage which started at 1.72 Ma. The Moorea alkali basaltic suite cannot, however, be easily explained by closed-system fractionation processes because (i) the suite is bimodal in terms of rock abundances (60% mafic lavas and 40% intermediate/felsic ones), and (ii) fractional crystallisation tests fail to account for the transition between these two types.

In order to understand the relationship between basalts and felsic lavas, we determined trace element concentrations, as well as high precision Pb isotope ratios, and Hf, Sr and Nd isotopic compositions of a selection of 18 samples representing the various lava types. Basalts have relatively uniform ²⁰⁶Pb/²⁰⁴Pb (~ 19.2) but variable Nd, Hf and Sr ratios (i.e., ⁸⁷Sr/⁸⁶Sr between 0.7044 and 0.7052). In contrast, the felsic lavas have uniform Nd and Hf isotopic ratios but variable Sr and Pb ratios. The high precision Pb isotopic data define a straight line for the felsic lavas while the basalts form a cluster. Interestingly, the felsic lava straight line does not intersect the basalt cluster.

The composition of the basalts can be explained by conventional models involving partial melting of a garnet peridotite within a plume with EMII characteristics. The composition of the felsic material requires a completely different origin. We suggest that the felsic lavas originate from melting of a basaltic component and not from fractional crystallization of the plume derived basalts. This basaltic component is isotopically heterogeneous but its location is uncertain: it could be located at the base of the oceanic crust below the island or it could be an integral part of the plume.

Schwertmannite transformation to hematite by heating: Implications for pedogenesis, water quality and CO₂/SO₂ export in acid sulfate soil landscapes

S.P. HENDERSON*, L.A. SULLIVAN, R.T. BUSH AND E.D. BURTON

Southern Cross University, PO Box 157, Lismore, NSW 2480, Australia (scott.henderson@scu.edu.au)

Naturally occurring schwertmannite (Fe₈O₇(OH)₅.₅(SO₄)₁.₂₅), a product of acid sulfate soil oxidation and severe acidification, has been identified as a labile source of iron, sulfate and acidity. Schwertmannite forms surface accumulations on coastal flood plains of eastern Australia that are subject to wild fire events. We report experimental evidence that fire in acid sulfate soil landscapes will convert schwertmannite to hematite (α-Fe₂O₃), consequently reducing the potential acidity store whilst liberating Greenhouse gases. At ≥ 800°C, naturally occurring schwertmannite was transformed completely to hematite. Thermal gravimetric analysis of this transformation process showed that CO₂ and SO₂ evolved simultaneously at relatively low temperatures (200-250°C and 300-340°C respectively). Aqueous dissolution experiments with samples of the initial schwertmannite and the resultant hematite showed that there was a significant decrease in the acidity potential associated with the heating-induced conversion to hematite. The data clearly shows natural fires may convert schwertmannitic surface accumulations to hematite. Hematite surficial layers have been observed previously in these landscapes and this study provides an explanation for their pedogenesis. Theoretical acid loads, based on this research, indicate fire can greatly reduced potential acidity. Relatively low temperature fires in these landscapes can combust schwertmannitic accumulations resulting in the discharge of CO₂ and SO₂. These results have implications for the assessment of acidity and the sustainable management of acid sulfate soil landscapes.
Evidence for natural, non-thermal annealing of fission tracks in apatite

B.W.H. Hendriks¹, R.A. Donelick², P.B. O’Sullivan² and T.F. Redfield¹

¹Geological Survey of Norway, Trondheim, Norway
(bart.hendriks@ngu.no, tim.redfield@ngu.no)
²Apatite to Zircon, Inc., Viola, Idaho, USA
(donelick@apatite.com, osullivan@apatite.com)

Apatite fission-track (AFT) analyses using a LA-ICP-MS based approach on samples from Finland and Canada provide evidence for a non-thermal AFT annealing process that is dependent on the present-day concentration of alpha-emitter actinides (U, Th, Sm) within grains. In one example, 118 grains were dated from a sample from central Finland (see below).

Because all of the dated grains are from a single hand sample, the inverse correlation between the concentrations of alpha-emitter actinides and AFT age cannot be explained simply by intra-grain variations in temperature history. Electron microprobe analysis of the dated grains indicates that chemical elements that are known to control the annealing rates in apatite (Cl, Mn, Fe, REE, etc.) do not show a similar correlation.

Electron beam induced annealing of fission tracks in apatite (Paul and Fitzgerald 1992) and studies of phosphates as nuclear waste forms (e.g. Ewing and Wang 2002) indicate that processes other than thermal annealing can cause fading of fission tracks under laboratory conditions. The above example from Finland represents a natural example of non-thermal, radiation-induced annealing.

Modelling of AFT data from cratonic settings with annealing models that do not incorporate non-thermal annealing processes will lead to overestimation of palaeotemperatures.

Trace element distributions and coral skeleton micromorphology following a bleaching event

E.J. Hendy¹, A. Lanzirotti², T. Rasbury³ and J. Lough⁴

¹Department of Earth Sciences, University of Bristol, UK
(e.hendy@bristol.ac.uk)
²The University of Chicago – CARS, Brookhaven National Laboratory, Upton, NY, USA (lanzirotti@bnl.gov)
³Department of Geosciences, SUNY Stony Brook, NY, USA (erasbury@notes.cc.sunysb.edu)
⁴Australian Institute of Marine Science, Townsville, Australia (j.lough@aims.gov.au)

The massive tropical corals commonly used as palaeoclimate archives, such as Porites sp., contain zooxanthellae (symbiotic photosynthesizing algae). Coral bleaching occurs when these pigmented zooxanthellae are expelled from the coral tissue. In this study we investigate how the biomineralization process and trace element distribution within the coral skeleton are impacted by zooxanthellae population dynamics following a bleaching event. The non-destructive, high resolution in-situ mapping capabilities of synchrotron µ-XRF is an ideal tool to investigate differences in trace element partitioning that correspond to the fine-scale architecture of coral skeleton.

A healthy ~30 year old Porites australensis colony was collected 2 ½ years after the February 1998 mass coral bleaching event from the inshore central Great Barrier Reef, Australia (18.48°S, 146.26°E). During the 1998 coral reef bleaching event ~80% of coral to a depth of 10m bleached at this reef, and bleaching mortality subsequently reduced coral cover by ~20%. At the time of collection (August 2000) there were no signs that the specimen had bleached, however, x-ray images show a marked and sustained skeletal growth response with lower extension and calcification rates and higher skeletal density.

Synchrotron µ-XRF mapping was carried out at Beamline X26A (NSLS, BNL) with the beam set at 16.5 keV to target elements up to Sr and a 10µm spot size. Sr, Ca, Br, Zn, Ni, Cu, Fe Pb and Ba were mapped in 20µm steps (equivalent to daily growth rate) down the width of a single corallite for a 4-year period of skeleton growth including the 1998 bleaching event. Skeletal structures are compositionally zoned, with a strong response 6 months after the start of the bleaching event. An adjacent CT-X-ray microtomography scan recorded the contemporary morphological changes in skeleton micro-architecture. Bulk analyses of Sr/Ca, Mg/Ca, δ¹³C, δ¹⁸O were measured on a parallel milled transect. To isolate the role of tissue smoothing on the seasonal signal µ-XRF elemental maps were also collected across the most recent skeleton deposited within the tissue zone of specimens collected in both summer and winter seasons.
Tourmaline in evaporites and meta-evaporites: Perspectives from Namibian metasediments

DARRELL J. HENRY1, HAITING SUN1, BARBARA L. DUTROW1 AND JOHN F. SLACK2

1Dept. of Geology and Geophysics, Louisiana State Univ., Baton Rouge, LA 70803, USA (dhenry@geol.lsu.edu)
2U.S. Geological Survey, National Center, MS 954, Reston, VA 20192

Tourmalines associated with evaporitic or meta-evaporitic rocks commonly exhibit a compositional trend where there is low Al in the structural formula that is compensated by the introduction of Fe i.e., Al = Fe3+ exchange. This compositional trend has been found in the few occurrences of known evaporitic tourmalines: the caprock of a salt dome in the Gulf of Mexico, a brecciated and metamorphosed cap rock from Alto Chapare (Bolivia), an amphibolite-facies metaborate deposit from eastern Liaoning (China), and some tourmaline in tourmalinites from the meta-evaporitic sequence of the Duruchaus Formation (Damara Belt, Namibia – this study). These tourmalines follow a trend that defines a complete solid solution between dravite (NaMg3Al6(Si6O18)(BO3)3(OH)3(OH)) or “oxy-dravite” (Na(MgAl2)(MgAl5)(Si6O18)(BO3)3(OH)3O) and povondraite (NaFe3+(3Fe3+2Mg2)(Si6O18)(BO3)3(OH)32). These trends are interpreted to represent tourmalines developed in an Al-poor, Fe3+-rich environment, consistent with evaporitic settings.

Although some of the tourmalines from the Duruchaus Formation follow this Al for Fe3+ trend, a number of clearly meta-evaporitic tourmalines do not. The tourmalinites in two of the three localities studied are interlayered with biotite- and muscovite- semipelite and with calcite-dolomite marble. Despite their derivation from evaporitic sediments (tourmalinites preserve pseudomorphs after a variety of primary evaporitic minerals), the tourmalines in these tourmalinites exhibit an Al- and Mg-rich composition that appears to reflect a local compositional influence from the semipelitic interlayers. In fact, these Al-Mg-rich compositions are similar to those found by Prof. Werner Schreyer and his colleagues in tourmalines from the ultrahigh-pressure rocks of the Dora Maira massif (Italy) that they interpreted as meta-evaporites.

Geochemistry of cold vent fluids at the Central American Convergent Margin

C. HENSEN1, K. WALLMANN1, M. SCHMIDT2, V. LIEBETRAU1, U. FEHN3, D. GARBE-SCHÖNBERG2 AND W. BRÜCKMANN1

1IFM-Geomar, Kiel, Germany (chensen@ifm-geomar.de; kwallmann@ifm-geomar.de; vliebetrau@ifm-geomar.de; wbrueckmann@ifm-geomar.de)
2Geosciences, CAU, Kiel, Germany (mas@gpi.uni-kiel.de; dgs@gpi.uni-kiel.de)
3Univ. of Rochester, NY, USA (fehn@earth.rochester.edu)

The active continental margin offshore Central America is characterised by a high number of cold vent sites associated with typical sea floor features such as mud volcanoes and diapirs (mounds) or submarine slides. Over the past couple of years a solid geochemical database of fluid samples has been collected from various locations along the Costa Rica - Nicaragua forearc. Similar to pore fluids from other, mostly accretionary convergent margins, these fluids are typically less saline than normal seawater. There is clear evidence (using oxygen and hydrogen isotope ratios) that chloride-depleted fluids originate from clay-mineral dehydration processes at elevated temperature and pressure conditions. This interpretation is supported by a number of additional observations such as the occurrence of thermal methane and highly elevated boron concentrations. Due to the lack of suitable conditions for the presumed processes within the sedimentary sequence of the overriding plate, it has been hypothesized that the fluids may originate from mineral dehydration in subducted sediments at about 10 km depth (Hensen et al. 2004). This is supported by mass balance estimates between input of mineral-bound water by subducting sediments and output through known vent sites. At many sites, however, the geochemical signature does not reveal clear evidence for a “deep” origin, such as the abundant occurrence of shallow biogenic gas. Conspicuous differences in the geochemical composition of fluids from various locations allow a general subdivision into regional, potentially structurally-controlled, types. We will present a comprehensive description of the available data set – covering the main element composition and various isotope systems (δ18O, δD, δ13C, 87Sr/86Sr, δ44Ca, 129I/I) – and discuss fluid sources and potential ages as well as processes of formation and alteration. In addition, we will present an outline of current efforts to drill key sites of the most prominent dewatering structures within IODP (633 full2, Costa Rica Mounds).

The application of granular activated carbon on remediation in trichloroethylene contaminated groundwater

JOONG-HYEOK HEO¹, DAL-HEUI LEE² AND HO-WAN CHANG¹

¹School of Earth and Environmental Sciences, Seoul National University, Korea
²Research Institute of Groundwater and Soil Environment, Yonsei University, Korea

The objective of this study is to evaluate the effect of ionic strength and hardness of trichloroethylene (TCE) contaminated groundwater on remediation using granular activated carbon (GAC). The sorption rate of TCE by GAC was observed by batch experiments. The sorption kinetic of GAC was analyzed by kinetic models. As the ionic strength and hardness of the synthetic groundwater increased, the TCE sorption rates of GAC in the synthetic groundwater decreased. The TCE sorption rates of GAC in synthetic groundwater were 100%, 93.0%, 90.2%, and 86.2%, respectively. These results showed that the TCE sorption rates were affected by the relationship between the ionic strength and the hardness of the synthetic groundwater. The Elovich model ($r^2=0.99$) is more precise than Pseudo first order model ($r^2=0.96$). This indicates that the Elovich model is well represented in the contaminated groundwaters which have various factors like ionic strength and hardness. The surface area of the GAC was 958.98 m²/g and the calculated sorption areas of TCE & ions were 318.38 m²/g, which were 32.2% of the GAC surface area. Therefore, the ionic strength and hardness of groundwaters must be considered in the remediation of TCE-contaminated groundwater using GAC.

Accessory phase control on the trace element signature of subduction zone fluids

J. HERMANN AND D. RUBATTO

Research School of Earth Sciences, ANU, Canberra 0200
(joerg.hermann@anu.edu.au; daniela.rubatto@anu.edu.au)

In order to understand the general trace element signature of arc lavas, phase and melting relations in metapelites at sub-arc depth are of first order importance. Here we present results from experimental studies on a trace element doped, hydrous (2-7 wt.% H₂O), synthetic pelite and granite in the range 20-45 kbar and 600-1050°C, i.e. conditions relevant for the slab at sub-arc depth. In the metapelite, a hydrous melt that quenches to a glass is present at conditions above 700°C, 25 kbar; 750°C, 35 kbar and 800°C, 45 kbar. At lower temperatures, a solute-rich aqueous fluid is present that is not quenchable. This fluid has been captured in diamond traps in the experiments and the quench material as well as the glass have been analysed with LA-ICP-MS.

One surprising feature in the run products is the presence of accessory phases at subsolidus as well as at suprasolidus conditions, even at large melt proportions of 50%. Rutile, apatite and zircon have been found over the entire investigated P-T range. Allanite is present at 2.5 GPa up to 800°C, and at 3.5 and 4.5 up to 750°C. At higher temperatures, monazite is stable up to 1000°C. This has profound bearings on the trace element characteristics of the fluid phase. In a residue consisting of garnet, clinopyroxene, phengite and coesite all trace elements in the fluid phase are governed by partitioning behaviour. In contrast, in the presence of accessory phases, several trace elements are buffered (Ti by rutile, P by apatite, Zr by zircon, LREE by monazite/allanite). Additionally, other HFSE and REE are preferentially retained in the residue with respect to a system without these accessory minerals. This is documented in the measured composition of the fluid phases. For example LREE display only incompatible behaviour at the highest temperature investigated (950-1000°C) whereas at 800°C, LREE are compatible in the residue due to the presence of monazite or allanite. In the aqueous fluid LREE are about an order of magnitude lower than in the hydrous melt at 750°C. Zircon is able to fractionate geochemical twins such as Zr and Hf. Hf decrease in the melt is less pronounced than Zr decrease with decreasing temperature and thus hydrous melts at 750-800°C leaving the slab have a Zr/Hf significantly lower than the primitive mantle value. Aqueous fluids are very dilute in all trace elements and even LILE are higher in the residue than in the fluid. For example Ba is more than 10 times lower in the aqueous fluid than in the residue. This provides evidence that hydrous melts and not aqueous fluids are needed to significantly recycle incompatible elements from the slab to the mantle wedge. This observation provides evidence that top slab temperatures ≥ 750°C are required below arcs that show significant LILE and LREE enrichment or a Hf contribution from sediments.
Validation of normalisation concepts for in situ µ-EDXRF data

Y. HERMANNS1,2, A. WITTENBERG2, D. RAMMLMAIR2 AND A. SCHWALB1

1Institut für Umweltgeologie, TU Braunschweig, Germany (y.hermanns@gmx.net)
2BGR, Hannover, Germany (a.wittenberg@bgr.de, rammlmair@bgr.de)

Column experiments were performed to study hard pan formation processes in mining dumps. The special focus of this study was to develop a better understanding concerning the time-dependent transport behaviour of element towards the capillary fringe. Therefore, three 50 cm long vertical columns were filled with homogenized tailings material from Freiberg/Germany (35cm) and purified silica sand (top part of column). At the bottom of the columns water is injected and because of capillary transport a continuously fluid transport occurs. The resulting changes in the local chemical conditions (e.g. Eh, pH) create the environment for dissolution, transport and precipitation. Hence, an enrichment of mobile behaving elements like Cu, Zn and Fe are expected to occur in the upper levels and accordingly a decrease within the bottom parts of the column.

The measurements were performed by using the µ-EDXRF method, which has been described in detail by Rammlmair et al (2006). The experiment was set up for a period of six month. Within this time frame 20 runs were achieved to record the changes in the elemental concentrations. The results were calculated by using the Q-Spec 6.5 software (COX Analytical Systems).

There is no way to compare scans of different dates directly, since we havened found a proper way to calibrate the method yet. In the frame of a student research project the collected µ-EDXRF data are studied for comparison using various normalizing methods. Hence, effects due to e.g. matrix or water content changes can be shown.

7Pyrenean Institute of Ecology - CSIC, Apdo. 202, 50080 Zaragoza, Spain

Lake Chungará (18°15' S, 69°09' W, 4520 m a.s.l. 22.5 Km2 and 40 m of water depth) is a hydrologically closed lake located on the Andean Altiplano. The lake is polyemic, meso to eutrophic and currently primary productivity is mainly governed by diatoms and chlorophyceans.

Three laminated intervals were selected for detailed petrographical studies as well as a high resolution diatom oxygen isotope analysis. These laminated sediments are made up of bands of white and dark mm-thick laminae and thin layers of diatomaceous ooze with variable carbonates and amorphous organic matter.

Assuming no significant changes in the isotopic compositions of the water sources and according to the diatom microstratigraphy of the laminae, two alternating environmental scenarios can be described. Lower-level water conditions are interpreted during the intervals of white laminae deposition (high values of δ18O), since those conditions are more favourable for the massive short-term deposition of monospecific large centric diatom blooms and δ18O enrichment. These white laminae are probably the result of exceptional periods of mixing of the shallow water column during lowstands, which recycle nutrients from the hypolimnion. Lower δ18O values, and therefore deeper water conditions, are more favourable for the development of dark laminae (normal annual cycle of the lake with alternating phases of stratification and mixing).

These conditions would lead to the development of a complex diatom community, among other algal groups.
The energy balance at the core-mantle boundary

J. W. HERNLUND\textsuperscript{1}, S. LABROSSE\textsuperscript{2} AND N. COLTICE\textsuperscript{3}

\textsuperscript{1}Department of Earth and Ocean Sciences, University of British Columbia, Canada (hernlund@gmail.com)
\textsuperscript{2}Laboratoire des Sciences de la Terre, Ecole Normale Supérieure de Lyon, CNRS, Université Lyon 1, France (stephane.labrosse@ens-lyon.fr)
\textsuperscript{3}Laboratoire des Sciences de la Terre, Ecole Normale Supérieure de Lyon, CNRS, Université Lyon 1, France (coltice@univ-lyon1.fr)

Cooling of Earth’s core occurs because relatively cool rocks sink to the core-mantle boundary (CMB) and absorb heat by conduction in a continuous cycle of sluggish mantle convection. A thermal boundary layer (TBL) is formed where heat is conducted from the core into the mantle and is characterized by an increased geothermal gradient in the D′′ region. The recent discovery of post-perovskite (pPv) and increasing seismic evidence for a double-crossing of the pPv phase boundary by the TBL geotherm provides auspicious new constraints on the heat flow in D′′, yielding lower bounds in the range 5-15 TW. However, if a several km thick layer of partially molten material just above the CMB was much thicker in the past when Earth’s deep interior was hotter, then it is possible that the layer fractionally crystallized over time to achieve its present state and could therefore retain a significant budget of incompatible radioactive species. The power released by radioactivity (on the order of several TW) in this ultralow-velocity zone (ULVZ) layer would contribute to overall D′′ heat flow and have potentially important consequences for the structure and dynamics of the mantle and core. Numerical models of mantle convection including a thin dense radioactive layer show that significant lateral variations in the thickness of the ULVZ arise which enhance variations in heat flux at the top of the core, with the thickest and hence most internally heated patches swept up beneath upwelling plumes. On the other hand, inclusion of larger modestly dense chemical piles (or “crypto-continents”) moderates the excess heat that would otherwise be transferred into upwelling plumes.

An integrated NMR and FTCIR mass spectroscopic study to characterize a new and major refractory component of (marine) natural organic matter (NOM) at the molecular level, CRAM: Carboxyl-rich alicyclic molecules

N. HERTKORN\textsuperscript{1}, R. BENNER\textsuperscript{2}, M. WITT\textsuperscript{3}, M. FROMMBERGER\textsuperscript{1}, PH. SCHMITT-KOPPLIN\textsuperscript{1}, K. KAISER\textsuperscript{2}, A. KETTRUP\textsuperscript{1} AND I. J. HEDGES\textsuperscript{4}

\textsuperscript{4}School of Oceanography, Box 355351, University of Washington, Seattle, WA 98195-5351, USA (deceased).

Advances in organic structural spectroscopy have enabled a direct molecular level analysis of very complex natural mixtures such as the very abundant natural organic matter (NOM), a key contributor to the global carbon cycle and other element cycles (N, P, S,…). NOM often defines the chemical environment and the bioavailability of toxic and nutrient metal ions in the biosphere. Little is known about the chemical composition of NOM and the reason for its refractory nature. Recently we have identified a new and major constituent of NOM, namely carboxyl-rich alicyclic molecules (CRAM), using nuclear magnetic resonance spectroscopy and ultrahigh resolution mass spectrometry [Fourier transform ion cyclotron mass spectrometry (FTICR-MS)]. CRAM are compositionally and structurally more heterogeneous than other NOM constituents (like peptides and carbohydrates), and are comprised of a complex mixture of carboxylated and fused alicyclic aliphatics with a carboxyl:C:aliphatic-C ratio of 1:2 to 1:7. The structural diversity found within CRAM and their substantial content of alicyclic rings and branching contribute to their resistance to biodegradation and refractory nature.

CRAM are expected to constitute a strong ligand for metal binding, and multiple coordination across cations could promote aggregation and marine gel formation thereby affecting CRAM reactivity and the bioavailability of nutrients and trace metals. It appears CRAM are ultimately derived from biomolecules with structural similarities to sterols and hopanoids. The occurrence of CRAM in freshwater and terrestrial environments seems likely, considering the global distribution of biomolecules and the similarities of biogeochemical processes among environments.
Modelling the geochemical variation of granitic mushes

J. HERTOGEN AND J. MAREELS
Geo-Instituut, K.U.Leuven, Celestijnenlaan 200E, B-3001 Leuven, Belgium (jan.hertogen@geo.kuleuven.be)

Straightforward Rayleigh-type fractional crystallisation models have merits to outline the main factors that caused geochemical evolutionary trends of granites, but the implied complete separation of mineral phases from residual liquid is at best a poor approximation of reality. A more elaborate crystallisation model of granitic ‘mushes’ tracks the trace element variation in two subsystems - a ‘congealed mush’ and a ‘residual mush’ - that develop as crystallisation proceeds. It takes into account any separation of less-viscous, water-rich melts and fluid phases from the residual mush during the final stages of solidification. Special attention is paid to the role of accessory minerals on the evolution of the Rare Earth Element (REE) patterns. Petrography learns that accessories are often present as clusters of minerals that crystallised from pockets of trapped interstitial melts. These accessory minerals crystallised too late to significantly affect fractionation trends. Moreover, these clusters frustrate efforts to estimate effective crystallisation rates from modal abundances. Parameters of the model are the fraction of crystals trapped in the congealed mush, and the crystal-to-trapped liquid ratio in the congealed mush. Calculations are based on a ‘finite step’ numerical simulation of crystallisation and melt expulsion processes.

The model calculations will be illustrated with results for two closely related leuco-granitic series from the Variscan Northern Vosges (France): the Natzwiller granite and the highly evolved Kagenfels granite. The variation trends of the Natzwiller granite demonstrate the crucial role of the accessory minerals apatite, sphene, allanite and zircon. The pronounced decrease of the concentrations of the middle REE (relative to Light and Heavy REE) of the Kagenfels granite cannot be explained by models based on reasonable values of modal abundances of accessory minerals and of partition coefficients. It is argued that the Kagenfels granite matches the composition of expelled liquids from the residual mush at 50 to 60% solidification of the Natzwiller body. The expulsion of interstitial liquids is presumably promoted by tectonic activity.

The first Lu-Hf garnet ages of North Penninic alpine eclogites

D. HERWARTZ1, C. MÜNKER1,2, E. E. SCHERER2, T. NAGEL1, J. PLEUGER1 AND N. FROITZHEIM1
1Universität Bonn, Germany (danielherwartz@gmx.de) 2Universität Münster, Germany

Despite a large geochronological database there are still various models for the tectonic evolution of the Alps. Current rapid progress in dating metamorphic minerals such as garnet has given this technique a key role in the ongoing discussion. Recently, [1] recognized the so called Balma Unit in the upper Sesia valley, previously interpreted as part of the Zermatt-Saas Zone (South Penninic Ocean), as a fragment of the North Penninic Ocean. Most previous studies dating peak metamorphism of Alpine ophiolites have focussed on the Zermatt-Saas zone. Here, we present the first Lu-Hf garnet data for eclogites from the North Penninic Ocean.

Electron microprobe analyses show typical prograde zoning profiles in garnet. A selective digestion procedure for garnet was applied, where zircon and rutile inclusions are not dissolved. The garnet-whole rock Lu-Hf ages obtained for three samples are 42.19 ± 0.47 Ma (MSWD: 1.8), 43.19 ± 0.36 Ma (MSWD: 1.2) and 45.4 ± 1.1 Ma (MSWD: 2.3), which is significantly younger than all Lu-Hf ages established so far for South Penninic Units. Notably, existing SHRIMP U-Pb zircon ages [2] of 93.4 ± 1.7 Ma (synmagmatic core) and 40.4 ± 0.7 Ma (synmetamorphic rim) for the sample in which the Lu-Hf age of 42.19 Ma was obtained, indicate that growth of metamorphic zircon postdates garnet growth.

Despite the fact that all three samples originate from the same tectonic unit, their Lu-Hf ages differ outside of error. The cause of this is not yet known, but if the garnets grew over a long time interval (several million years) it is possible that varying core-to-rim distributions of Lu in garnet could result in the observed age range. Such Lu zoning can occur by Rayleigh fractionation during garnet growth [3] or by diffusion-limited garnet growth [4]. Our new Lu-Hf data indicate that garnet growth, and possibly peak pressure conditions in the North Penninic ophiolites postdates those in the South Penninic ophiolites.

Convective Dissolution of CO₂ in Saline Aquifers

M.A. HESSE, A. RIAZ AND H.A. TCHELEPI

Department of Energy Resources Engineering, Stanford University (mhesse@stanford.edu; ariaz@stanford.edu; tchelepi@stanford.edu)

Dissolution of CO₂ into the brine is one of the major trapping mechanisms that increases storage security. The increase in density of the brine that occurs when CO₂ dissolves drives convective motion that enhances the dissolution rate of CO₂. We present the results of a hydrodynamic stability analysis that describes the onset of convective motion. We have obtained expressions for the critical time necessary for the onset and the initial wavelength of the fastest growing disturbance. In high permeability aquifers onset of convection will be rapid (<1 yr), but wavelength are very small (~1 m). Resolution of these small length scales is a challenge standard reservoir simulators.

We present numerical results of the long term evolution of the convection in the brine and the dissolution rate of the CO₂. The numerical simulations show three mass transport regimes, an early diffusive regime, followed by an infinite-acting convective regime, and finally a finite-acting convective regime. The infinite acting convection regime is characterised by a constant dissolution rate. The depth of the aquifer determines the duration of this highly efficient convective mass transfer regime. As the plumes of CO₂-rich brine reach the bottom of the aquifer mass transfer decays rapidly, despite continued convective motion (finite acting convection).

We conclude that dissolution trapping will be an important mechanism in high permeability aquifers, because the onset time is short, the dissolution rate is high. In large aquifers the high infinite-acting dissolution rate can be maintained longer and therefore dissolution trapping will be more important in large aquifers.

Microbial life in a hydrothermal spring rich in arsenic compounds

A. HETZER¹, H. MORGAN¹, I. MCDONALD¹ AND C. DAUGHNEY²

¹University of Waikato, Hamilton, New Zealand (hetzer.adrian@web.de)
²Institute of Geological and Nuclear Sciences, Lower Hutt, New Zealand (C.Daughney@gns.cri.nz)

The geothermal spring Champagne Pool in Waiotapu, New Zealand has an estimated volume of 50,000 m³ and discharges fluid at 75° C, which is oversaturated with arsenic and antimony compounds such as orpiment (As₂S₃) and stibnite (Sb₂S₃) that precipitate and form orange deposits. Although Champagne Pool is geochemically well characterized only few studies addressed its role as a potential habitat for microbial life. In the current investigation, a combined approach of first culture-independent studies followed by culturing experiments was applied to describe microbial density and diversity within Champagne Pool. ATP measurements and epifluorescence microscopy showed relatively low biomass in Champagne Pool compare to other terrestrial hot springs within New Zealand and relatively low cell numbers of 5.6 ± 0.5 x10⁶ cells per ml. Denaturing Gradient Gel Electrophoresis and 16S rRNA gene clone libraries analyses indicated low microbial diversity and the abundance of hydrogen-oxidizing and sulfur-dependent populations, which were dominated by members belonging to the order Aquificales. On account of the results culture media were designed and two novel bacteria and a novel archaeon were successfully isolated. Experiments suggested that the observed relatively low biomass and biodiversity might be due to the presence of volatile components (H₂S, methyl and hydride derivatives of arsenic and antimony) within the spring which are inhibiting microbial growth.
Carbon is isotopic compositions of acetate as proxies for biogeochemical processes in gas hydrate bearing sediments

VERENA HEUER1, JOHN POHLMAN2, MARCUS ELVERT1, AND KAI-UWE HINRICH1

1Dept. of Geosciences, University of Bremen, 28359 Bremen, Germany (vheuer@uni-bremen.de, melvert@uni-bremen.de, khinrichs@uni-bremen.de)
2U.S. Geological Survey, Woods Hole, USA (jpohlman@usgs.gov)

A large fraction of methane in marine gas hydrates results from biogenic sources, but the processes that generate methane in the deeply buried sediments remain to be elucidated. IODP Expedition 311 drilled a transect across the Cascadia Margin, NE Pacific, to study the distribution and evolution of gas hydrates in an active continental margin. In our post-cruise research, we seek to identify processes and reactants involved in methane formation by compound-specific isotopic analysis (CSIA) of dissolved carbon-bearing compounds such as acetate. So far, deep pore-water profiles of acetate concentration are rare and δ13C values of acetate are largely lacking due to analytical obstacles.

Our recent survey of a wide range of natural sediments and sediment incubations has revealed a large variability in the carbon isotopic compositions of acetate and incubation experiments suggest a systematic link between the carbon isotopic composition of acetate and the dominant carbon transforming processes of the sediments, i.e., fermentation, methanogenesis and homoacetogenesis (Heuer et al., 2006).

At the Cascadia Margin, both concentrations and δ13C of acetate vary considerably. Acetate concentrations increase from <5 µM at the sediment-water interface to 670 µM at 250 meters below seafloor. δ13C values of acetate range from -50 to -8‰ vs VPDB. Given uniform δ13C values of dissolved organic carbon (DOC) close to -23‰, the low values of acetate require either partial production of acetate from a 13C-depleted pool of precursors such as biomass from methanotrophs or partial production of acetate by CO2 reduction (homoacetogenesis). On the other hand, the high values of δ13C of acetate in some hydrate-bearing sediment intervals likely point to aceticlastic methanogenesis as an important sink of acetate. CSIA of dissolved organic compounds provides novel information on the molecular-scale processes in deeply buried sediments that lead to formation of methane and ultimately methane hydrate.

Biological fractionation of Ca isotopes (δ44/40 Ca): A study in Göttingen minipigs

A. HEUSER1, A. EISENHAUER1, K.E. SCHOLZ-AHRENS2 AND J. SCHREZENMEIR2

1IFM-GEOMAR, Kiel, Germany (aheuser@ifm-geomar.de)
2Institute of Physiology and Biochemistry of Nutrition, Federal Research Centre for Nutrition and Food, Kiel, Germany

Calcium is an essential element in human physiology and plays an important role in many processes. Due to its important role Ca concentrations are kept within small limits in the extracellular space. This Ca homeostasis is maintained by three organs, the gastrointestinal tract (input of Ca), the skeleton (store of Ca) and the kidney (output of Ca). Physiological ageing processes and many chronic diseases are associated with disturbances of the calcium metabolism.

In a study at the Federal Research Centre for Nutrition and Food several animal trials with the Göttingen miniature pig for generation of osteopathies have been carried out. The Göttingen miniature pig was chosen for these trials as their physiology is comparable to human physiology (e.g. Scholz-Ahrens et al., 2007). We analyzed food, feces, blood, bone and urine samples of six animals from these trials in order to study the calcium metabolism with respect to stable Ca isotopes and their fractionation.

Feces had δ44/40Ca values similar to the δ44/40Ca of the semi-synthetic diet (0.42‰) or exhibit a fractionation which tends to result in lower δ44/40Ca values in feces. Blood δ44/40Ca values vary from 0.06‰ to 0.68‰ and are on average 0.68‰ heavier than the bone δ44/40Ca values (-0.60‰ to -0.03‰). This difference between the δ44/40Ca values of blood and bone is only half of the difference between soft and mineralized tissue reported by Skulan and DePaolo (1999).

δ44/40Ca values of urine samples range from 2.05‰ up to 2.68‰ and are approximately 2‰ higher than the corresponding blood δ44/40Ca values of the same animal. Presumably, the observed fractionation between blood and urine mainly occurs in the kidney. This enrichment of heavy Ca in urine may be due to preferential transport of 40Ca by Ca transporters in the renal tubules, by which more than 98% of the calcium of the primary urine is reabsorbed (Hoenderop et al. 2005) in a repetitve process.

Continental crust as a source component for NW Central American Arc lavas?

K. HEYDOLPH1, K. HOERNLE1,2, F. HAUFF2 AND P.V.D. BOGAARD1,2

1SFB 574 University of Kiel and Leibniz Institute for Marine Science (IFM-GEOMAR), Wischhof Straße 1-3, 24148 Kiel, GER (kheydolph@ifm-geomar.de)
2Leibniz Institute for Marine Sciences (IFM-GEOMAR), Wischhof Straße 1-3, 24148 Kiel, GER

Our group evaluates along and across arc geochemical variations from various volcanoes and volcanic centres in the NW Central American Volcanic Arc from NW Nicaragua to Guatemala. Additional data from several Guatemalan continental crust samples as well as Cocos Plate sediments help to clarify the potential endmember compositions for the observed trends.

Subduction input from the subducting Cocos Plate consists of carbonate to hemipelagic sediments, seawater altered and unaltered igneous crust and serpentinites. Slab dip decreases while the thickness of the continental crust increases beneath the volcanic front (VF) from a maximum in central Nicaragua to NW Guatemala. Continental crustal thickness also increases behind the VF.

Our comprehensive geochemical data set consists of major elements, a wide variety of trace elements and Sr-Nd-Pb-HF-O isotope data. As shown previously by the Carr group, ratios of fluid mobile to less fluid mobile elements (e.g., Ba/La, Ba/Th and U/Th) decrease and Pb isotope ratios increase systematically from Nicaragua to Guatemala. The 143Nd/144Nd and 176Hf/177Hf isotope ratios decrease systematically from Nicaragua to Guatemala. These geochemical variations suggest a decreasing role for a hydrous fluid component and an increasing role for a sediment or continental crustal melt component in volcanic rocks towards Guatemala (NW) along the VF and behind the volcanic front (BVF). Samples from the back arc in Honduras have the most mid-ocean-ridge basalt (MORB) like compositions and are believed to represent the composition of the mantle wedge. Samples from the Nicaraguan VF have similar Nd but higher Sr isotope compositions most likely reflecting enrichment with slab derived fluids containing a subducted sediment or seawater Sr component.

A positive correlation in 206Pb/204Pb vs. 207Pb/204Pb isotope ratios for VF and BVF volcanic rock samples from El Salvador and Guatemala trends towards the granitic basement in Guatemala. Combined εNd vs εHf isotope data for VF and BVF samples from Nicaragua to Guatemala tend from high εNd and εHf MORB like compositions towards continental crust like compositions with increasingly lower εNd and εHf values. Supplementary εNd vs εHf isotope data from Guatemalan continental crust and Cocos Plate sediment samples provide further support for a continental crustal component in the generation of the NW CAVA magmas.

Melt/wallrock interaction shown by silicate melt inclusions in peridotite xenoliths from Pannonian Basin

1Lithosphere Fluid Research Lab, Eötvös University Budapest, H-1117 Pázmány P. stn. I/C, Budapest, Hungary (cszabo@elte.hu)
2Bayerisches Geoinstitut, University of Bayreuth, D-95447 Universitatsstrasse 30, Bayreuth, Germany (eniko.bali@uni-bayreuth.de)
3Department of Earth Sciences, Institute of Isotope Geochemistry and Mineral Resources, ETH Zürich, 8092 Zürich, Switzerland (zajacz@erdw.ethz.ch)
4Research School of Earth Sciences, The Australian National University, ACT0200 Building 61 Mills Road, Canberra, Australia (istvan.kovacs@anu.edu.au)

Samples
Primary silicate melt inclusions (SMI) in clinopyroxene (cpx) rims and secondary ones in orthopyroxenes (opx) along healed fractures from two equigranular amphibole-bearing spinel lherzolite xenoliths representing the subcontinental lithospheric mantle (Szliglet, Pannonian Basin, Hungary) have been studied. Microthermometry of dense CO2-bearing fluid inclusions, associated with SMI, was also carried out.

Discussion
Electron microprobe analysis reveals in both xenoliths that cpx and opx are zoned, especially in terms of basaltic major elements. Cores of both cpxs show trace element distribution close to the primitive mantle. Rims display an overall enrichment with high positive anomalies in Th, U and moderate LREE content, as an indication for metasomatism. The pargasitic amphiboles, formed after rims of the cpx, exhibit elevated Rb, Ba, Nb, Ta and moderate LREE content. The SMI are composed mostly of silicate glass and dense CO2 bubble. The primary SMI show evidence for significant crystallization on the wall of the host cpx. The major element composition of glass in SMI, regardless of xenoliths and host minerals, covers a wide range, mostly with trachyandesitic composition. The SMI, either primary or secondary ones, are extremely enriched in incompatible elements (particularly in U, Th, La, Zr) with a slight negative Hf anomaly.

Conclusion
The development of zoned pyroxenes, and the trapping of primary SMI in the cpx rims happened after the partial melting and subsequent crystallization of cpxs, most probably due to an interaction between a hot volatile-rich mafic melt and mantle wallrock. This interaction resulted in evolved silicate melts, which filled microfractures in opxs, leading to the formation of secondary SMI and, via metasomatism, the development of zoned pyroxenes. Most probably the formation of amphiboles is not related to this evolution.
Acessing the surface area of natural nanoparticles

TJISSE HIEMSTRA¹, JUAN ANTELO, RASOUL RAHNEMAIE, AND WILLEM H. VAN RIESMDIJK

¹(tjisse.hiemstra@wur.nl)

Information on the reactive surface area of natural samples is essential for the application of surface complexation models (SCM). The PO₄-CO₃ interaction on oxide surfaces is used to quantify the reactive surface area of soil particles. In the approach, phosphate is used as probe ion in natural samples brought at well-chosen solution conditions enforced by a 0.5 M NaHCO₃ extract solution. This matrix suppresses the influence of Ca²⁺ ions, desorbs organic matter (further high values for the specific surface area (~200-900 m²/g). Scaling of SA on the experimental soil oxide contents shows that the natural oxide particles are embedded in an OM matrix, the correlation of OM with the Fe oxide fraction, suggesting organic matter (OM) content of the samples, which is due to extracted oxide, pointing to the presence of nanometer-sized particles (~1-5 nm).

The CO₃-P-O₄ interaction is calibrated by studying it for goethite, using the CD model [1] with an Extended Stern (ES) double layer option. The CD values are independently obtained from MO/DFT optimized geometries of iron-carbonate and phosphate complexes and are additionally corrected for dipole orientation effects [2]. The surface speciation derived from the data analysis of the CO₃-P-O₄ interaction on goethite agrees with ATR-FTIR spectroscopy. Application to data of natural samples shows SA values from ~1000-10,000 m²/kg soil. The SA correlates to the organic matter (OM) content of the samples, which is due to the correlation of OM with the Fe oxide fraction, suggesting that the natural oxide particles are embedded in an OM matrix. Scaling of SA on the experimental soil oxide contents shows high values for the specific surface area (~200-900 m²/g extracted oxide), pointing to the presence of nanometer-sized particles (~1-5 nm).

In situ Hf and O isotopic data from Archean zircons of SW Greenland

J. HIESS¹, V. BENNETT¹, A. NUTMAN² AND I.S. WILLIAMS¹

¹Research School of Earth Sciences, The Australian National University, Canberra, Australia (joe.hiess@anu.edu.au; vickie.bennett@anu.edu.au; ian.williams@anu.edu.au)
²Chinese Academy of Geological Sciences, Beijing, China (nutman@bjshrimp.cn)

We have obtained new, coupled U-Pb, O and Hf isotopic data from Archean TTG suites in Southwest Greenland in order to explore mechanisms for Archean tonalite genesis and crust formation. The dataset comprises analyses of >250 zircon spots from 11 rocks ranging in age from 3.85 Ga to 2.55 Ga, including the most ancient tonalites of the Itsaq Gneiss Complex through to late Archean granitoids of the Qørqut Granite Complex. All grains were characterized by CL, reflected and transmitted light imaging prior to analysis. U-Pb ages were determined using either SHRIMP RG or SHRIMP II; ¹⁸O/¹⁶O ratios were measured on the same zircon spots using SHRIMP II in multi-collector configuration; ¹⁸⁷⁶⁶⁸⁵Hf/¹⁷⁷Hf data was subsequently acquired by LA-MC-ICPMS (ANU Neptune).

Zircons from the oldest, ca. 3.85 Ga, tonalites record δ¹⁸O compositions within 1‰ of mantle values (δ¹⁸O mantle = 5.3 ± 0.3 [e.g. 1]) and initial εHf values largely within ±1 epsilon unit of chondritic composition (calculated using χ¹⁷⁶⁶⁸⁵Lu = 1.867x10⁻¹¹yr⁻¹). These narrow, mantle-like, O–Hf fields contrast markedly with results from studies of Phanerozoic suites [2, 3], which show diverse Hf–O isotopic arrays, displaced from mantle compositions.

Hf isotopic compositions of zircons from the youngest sample analysed, the 2.55 Ga Qørqut Granite Complex (initial εHf ≈ -25), are in agreement with earlier Pb isotopic studies [4] suggesting the origin of the Complex by the remelting of >3.7 Ga crust. The O isotope data from this suite however lie 1-2‰ below mantle compositions, again in contrast with results for Phanerozoic suites.

A striking feature of the overall dataset is the absence of high (>7‰) δ¹⁸O values highlighting the lack of recycled supracrustal material in the genesis of the TTG. Of particular note is the prevalence of low δ¹⁸O values, with 4 out of 11 samples, with ages from 3.7 to 2.55 Ga, having compositions 1-3‰ below mantle values. Low δ¹⁸O values are a relatively rare feature in granitic suites (e.g. [1]) and typically result from hydrothermal alteration by surface waters, in some cases enhanced by glaciation. The presence of low δ¹⁸O in these mid-crustal level Archean granitoids is unexpected and may reflect different surface conditions and hence fluid compositions in the Archean.

Confocal micro-Raman spectroscopy: A tool for the allocation of organic and inorganic components in calcified biominerals

S. HILD1, U. SCHMIDT2 AND A. ZIEGLER3

1Central Facility for Electron Microscopy; University of Ulm, Albert-Einstein-Allee 11, D89081 Ulm
2WTec Wissenschaftliche Instrumente und Technologie GmbH, Hoervelsinger Weg 6, D89081 Ulm

Mineralized biological composites have attracted increasing interest because of their outstanding mechanical properties that are well adapted to their function. Microcharacterization of these materials allows a better understanding of the structure-properties relation ship of these materials. Since the mineralized exoskeleton (cuticle) of crustaceans is composed of various types of calcified biominerals e.g. calcium phosphate, calcite, and amorphous calcium carbonate (ACC) embedded in a chitin matrix this material is an excellent model for a biocomposite. High resolution scanning electron microscopy has been extensively used to investigate the morphology of the crustacean cuticle. However, to allocate the spatial resolution of the various organic and inorganic components an additional chemical characterization is required. Scanning confocal µ-Raman spectroscopy (SCµ-RS) provides complementary important information about the spatial distribution of both the organic and the inorganic components because the Raman spectrum can be unequivocally attributed to a certain compound even when its concentration is very low. Additionally, SCµ-RS enables one to allocate the different calciumcarbonate polymorphs.

For these studies the cuticle of the terrestrial isopod *Porcellio scaber* is be used as a model system. The spatial distribution of minerals, elements, and organic compounds was studied on the sub-micrometer scale using cross sections of the cuticle. Calcite and amorphous calcium carbonate (ACC) were found to be the main biominerals within the cuticle. For the first time, it was shown that the minerals are arranged in distinct layers. Calcite is restricted to the outer area of the cuticle, whereas ACC is localized in the middle having only little overlap with the calcite layer. The proximal region of the cuticle mainly consists of chitin. Since the cuticle is subjected to periodic molting it is periodically decalcified and shed. A new larger cuticle, synthesized before shedding, is mineralized after every molt. These processes cause spatial and temporal variations of the mineral distribution. The change in mineral during the molting cycle was monitored with respect to the organic matrix. It was shown that the protective outer calcite layer is shed away during each molt, while ACC is recycled to quickly re-establish the protective calcite layer in the new cuticle. Thus, ACC is used as a transient reservoir for calcium and carbonate ions.

Demonstrating equilibrium Fe-isotope fractionation in Fe-Cl solutions

P.S. HILL, E.A. SCHAUBLE, E.D. YOUNG AND A. SHAHAR

Dept Earth and Space Sciences, UCLA (phil@ess.ucla.edu)

A major problem when conducting isotopic fractionation experiments in aqueous solutions is determining if isotopic equilibrium has been reached. We have successfully demonstrated the attainment of equilibrium isotopic fractionation in a two-phase aqueous/ether system containing a mixture of Fe-Cl complexes, using the Fe three-isotope equilibrium method of Shahar et al. (2006; Matsuhisha et al., 1978). The immiscible liquid/spiked reversal procedure should also be applicable to other aqueous systems. These reversal experiments are part of our continuing integrated theoretical and experimental studies of the effects of changing bond environments on Fe fractionation. We use aqueous Fe-Cl complexes as a example of possible Fe-ligands because of the structural similarity of chloride to other potential iron-ligands, such as sulfides (e.g., pyrite, FeS2) and small organic ligands (e.g., rubredoxin, FeS2R2 similar in structure to tetrahedral FeCl4–), and the tractability of chloride in aqueous experiments.

Our experiments consist of a series of low pH solutions of ferric chloride, with total chlorinity varying from 0.5 to 5.0 M, to which an equal amount of immiscible diethyl ether has been added. As the aqueous-ether mixture equilibrates, FeCl4–, the only Fe-Cl complex soluble in the ether, moves from the aqueous into the ether phase. We use measurements of δ56Fe(aq) – δ54Fe(ether), in conjunction with a speciation model, to determine the relative fractionations among the complexes. At [Cl–]=1M the aq-ether fractionation is ~0.8‰.

To establish the attainment of equilibrium between the ether and aqueous phases, we paired an aq/ether mixture of unspiked 56Fe/54Fe with an equivalent mixture prepared with 54Fe spike. Once both mixtures had equilibrated, half the ether from the spiked experiment was added to the ether of the normal Fe experiment, so that spiked FeCl4– from the ether phase would have to pass into the aqueous phase of the unspiked experiment to reach equilibrium. We removed small aliquots from both the ether and aqueous phases after 20, 30, and 40 minutes, without disturbing the equilibrium of the mixture, and measured the aqueous-ether fractionation.

At 20 minutes, the ether and aqueous solutions were ~80% equilibrated, and they were totally equilibrated by 30 minutes. Equilibrium was demonstrated by the reversal in two ways: 1) both the aqueous and ether phases arrived at the same mass fractionation line; and 2) the final aqueous-ether fractionation of the reversal experiment was ~0.8‰, in agreement with the unspiked forward experiments.

Potassium as a heat source in the core? Metal-Silicate partitioning of K and other alkali metals

VALERE J. HILLGREN, BEATE SCHWAGER AND REINHARD BOEHLER
Max Planck Institut für Chemie, Postfach 3030, 55020 Mainz, Germany [hillgren@mpch-mainz.mpg.de]

The alkali metals (Li, Na, K, Rb, and Cs) are depleted to varying degrees in the Earth’s upper mantle. This is generally assumed to be due to volatility of these elements during accretion of the Earth. However, it is also often argued that some amount of K may have partitioned into the core and act as an additional heat source for the core dynamo. If K could partition into the core, it is not unreasonable to assume that the other alkali metals might also do so. Therefore, we have begun an experimental study of the partitioning of K and the other alkali metals between metals and silicates at lower mantle conditions using the laser-heated diamond anvil cell.

Our samples consisted of either pure Fe-metal or an Fe-S mix containing 10 wt. % S surrounded by either a K-silicate glass, a (Li, Na, K, Rb, Cs)-silicate glass, or a mixture of a (Na, K, Rb, Cs)-silicate glass and San Carlos olivine and overlain by an Al2O3 disk (to act as an optical window and to insulate the sample from the diamond). Pressures for the runs ranged from 23 to 110 GPa, and the temperatures for each sample were above the melting point of Fe for that pressure. Samples were recovered, polished and analyzed with the electron microprobe.

Experiments with pure Fe-metal and K-silicate glass in the pressure range 38-77 GPa showed no pressure dependence for the partitioning of K into metal. They also implied a maximum of 5 ppm K in the core.

Results from the experiments with the alkali-silicate glass or alkali–silicate glass mixed with olivine and Fe or Fe-S mix suggest that all the alkalis partition more readily into a sulfide than pure metal, and we found the general trend that DMET/SIL for Na > K ≥ Cs > Rb. However, under all conditions all the alkalis remained distinctly lithophile, and even at 110 GPa and 3200 K with 5 wt. % S and 1.5 wt. % O in the metal, the results suggest no more than 10 ppm K in the Earth’ core. Thus, K could only be responsible for less than 1% of the core’s heat budget.

Helium isotope studies in seismically-active regions of Turkey and California

D.R. HILTON1, G. DE LEEUW1, E. FUERI1, N. GULEC2, H. MUTLU3, M.D. TRYON1 AND K.M. BROWN1

1Scripps Inst. Oceanography, La Jolla, CA, USA (drhilton@ucsd.edu; gdeleeuw@ucsd.edu; efueri@ucsd.edu; mtryon@ucsd.edu; kmbrown@ucsd.edu)
2METU, Ankara, Turkey (nilgun@metu.edu.tr)
3Osmangazi University, Eskisehir, Turkey (hmutlu@ogu.edu.tr)

He isotopes in groundwaters and geothermal fluids are sensitive indicators of crustal-mantle interaction. Here, we present new He isotope (and associated carbon) data from two of the world’s great fault systems - the North Anatolian Fault Zone, Turkey (NAFZ) and the San Andreas Fault, California (SAF) - to further utilize He isotopes in regions of crustal unrest.

Following the catastrophic earthquakes in 1999, we initiated a periodic monitoring program (4 times/yr for 3 yrs) targeting geothermal fluids at 9 localities along an 800-km stretch of the NAFZ. 3He/4He ratios vary between 0.29 R A (Yalova, Gozlek) and 2.2 R A (Mudurnu) (R A – air 3He/4He) indicating a magmatic He contribution throughout. There were no large earthquakes over the monitoring period and little variation in 3He/4He values at individual localities. However, there are significant changes in the CO2/3He ratio and especially δ13C. We discuss these changes with respect to the regional stress pattern in Turkey.

Mantle-derived He is also pervasive in the vicinity of the SAF: 3He/4He reaches 0.11 R A (Mojave River Basin); 0.26R A (East Morongo Basin) and 3.4 R A (Monterey Bay). The whole region adjacent to the SAF is therefore leaking mantle-derived He to the surface albeit heavily diluted with crustal He. At Monterey Bay, cold seep fluids collected in long Cu-coils preserve temporal variability in He isotopes. This technique has enormous potential in future monitoring studies of earthquake-prone regions as it produces a continuous record of He isotope and gas chemistry variations.
Accessory mineral dating by ims-1270 ion microprobe

R.W. HINTON

Edinburgh Ion Microprobe Facility (EIMF), Grant Institute of Earth Science, University of Edinburgh, West Mains Road, Edinburgh, EH9 3JW, UK;
(Richard.Hinton@ed.ac.uk)

A number of accessory minerals concentrate small amounts of U and Th and if they (initially) contain very little Pb they will be amenable to ion microprobe analysis. Each mineral presents different analytical problems not the least of which is the identification of well characterised standards. Changes between analyses in the ionisation and detection of Pb⁺ relative to U⁺ ions (i.e. in the Pb⁺/U⁺ ratio) do occur but can be shown to correlate with measured UO⁺/U⁺ ratios and corrections applied. At the EIMF we believe that measurement of a second molecular species e.g. UO₂⁺ or ThO₂⁺ can improve the correction procedures or, at least, be simply used to give confidence in the correlating ratios. Routinely, Pb, U, UO, ThO and UO₂ are all measured.

In monazite the high Th/U ratios make it possible to utilise both U and Th decay systems. Corrections are applied using a combination of Pb, Th, ThO and ThO₂ peaks. In the work to date monazite has given good reproducibility in the Pb/Th system but some open system behaviour has been observed in the Pb/U system.

Rutile, like zircon, gives good correlations for Pb/U vs UO/U or UO₂/UO ratios. However, this phase discriminates so strongly against Th that in some cases no Th signal can be detected and any ²⁰⁸Pb⁺ signal can be assumed to be common Pb. The total background common Pb, either that originally incorporated in the mineral or that added to the surface during sample preparation, can be shown to be less than 1 ppb (and ²⁰⁶Pb less than 0.03 ppb). This increases the confidence that dating rutile with relatively low U content (<5 ppm) should be possible.

Baddeleyite is the only mineral analysed so far where variations in the Pb/U ratio have been shown to be dependent on crystal orientation (Wingate and Compston, 2000). Similar effects have been observed in baddeleyite analyses made on the Edinburgh ion probe. Future EBSD work will be used to study the effects of crystallographic orientation and whether corrections can be systematically applied.

The origin of compositional variation of mafic magma and genesis of associated silicic magma in the Shirataka volcano, NE Japan: Constraints from Sr isotopic compositions of mafic inclusions and their hosts, with detailed petrologic features of the mafic inclusions

SHIHO HIROTANI¹, MASAO BAN² AND MITSUHIRO NAKAGAWA³

¹Graduate School of Science and Engineering, Yamagata University, Japan (ss073@kdw.kj.yamagata-u.ac.jp)
²Department of Earth and Environmental Science, Faculty of Science, Yamagata University, Japan (ban@sci.kj.yamagata-u.ac.jp)
³Graduate School of Science, Hokkaido University, Japan (nakagawa@mail.sci.hokudai.ac.jp)

Eruptive products of Shirataka volcano (0.9-0.7 Ma) in NE Japan are calc-alkaline andesite-dacite (57-66% SiO₂), and are divided into six petrologic groups (G1-6). Mafic inclusions, basalt-andesite (48-58% SiO₂), are always observed in G1, G2, G5 and G6. All rocks are mixing rocks formed by mixing/mingling between mafic and silicic end-members judging from many petrologic aspects, such as linear trends defined by hosts and inclusions in variation diagrams and coexistence of mafic and silicic magmas origin phenocrysts in each group. The mixing trends defined by hosts and inclusions are divided into high- and low-Cr Ni types, and both types coexist in G1, G2 and G5. Cr and Ni contents of the high type show some variation. Estimated mafic end-members are high-Cr-Ni (1120-1150°C, 47-52% SiO₂, Fo-rich olv±Mg-rich cpx±An-rich plg) and low-Cr-Ni type magmas (ca.1100°C, 48-52% SiO₂, Mg-rich cpx±An-rich plg), while the silicic end-members of both types have similar petrologic features in the same petrologic group (790-840°C, 63-68% SiO₂, hbl±qtz±Mg-poor px±An-poor plg). The high-Cr-Ni type mafic end-member magma is richer in compatible elements and poorer in incompatible elements than the low type one. Besides, ⁸⁷Sr/⁸⁶Sr data of all rocks show broad ranges (0.70377-0.70537), but the compositional range of each group is restricted. In each petrologic group, the high-Cr-Ni type mafic and associated silicic end-members have lower values in ⁸⁷Sr/⁸⁶Sr ratio than the low type ones, indicating that mafic and silicic end-members in the same type have co-genetic relationships. The MELTS and trace element model calculations suggest that the low-Cr-Ni type mafic end-member magma can be produced through <25% fractional crystallization (olv±cpx±plg) from the high-Cr-Ni type mafic end-member magma accompanied with the assimilation of basement plutonic rocks (r=0.03-0.07). In terms of associated silicic magmas, the trace element model calculations indicate that the silicic magmas can be produced through <30% partial melting of corresponding solidified mafic magmas leaving a gabbroic residue.

Carbonatite-mantle interaction in the formation of highly alkalic oceanic island basalts

MARC M. HIRSCHMANN1 AND RAJ DASGUPTA2

1Dept. of Geology and Geophysics, University of Minnesota, Minneapolis, MN 55455 USA
(Marc.M.Hirschmann-1@umn.edu)
2Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY 10964, USA (rajdeep@ldeo.columbia.edu)

In heterogeneous basalt source regions, variations in mantle composition correspond to variations in melt production, leading more enriched compositions to produce partial melts at depths where more refractory lithologies do not. Migrating melts from easily melted heterogeneities can enrich refractory surroundings, which may subsequently partially melt. Thus, there is a direct link between heterogeneity and metasomatism in basalt source regions. In the source regions of oceanic islands, carbonated lithologies partially melt to form small amounts of carbonatite at >300 km. These highly mobile melts react with mantle rocks at shallower depths to form carbonated silicate liquids. Experiments show that these silicate partial melts are stabilized in peridotite and eclogite ~130 °C and ~250 °C cooler, respectively, than the volatile-absent peridotite solidus (Dasgupta et al., 2006; 2007). Thus, migrating carbonatite produces carbonated silicate liquids when it encounters eclogite bodies at depths of >150 km. Such melts may metasomatize surrounding peridotite, which can produce highly alkalic carbonated magmas when it encounters eclogite bodies at depths of >150 km. Such melts may metasomatize surrounding peridotite, which can produce highly alkalic carbonated magmas at depths of 90-150 km that are compositionally similar to basanites, nephelinites, and melilitites common in many OIB localities. Such magmas are expected where potential temperatures are not much greater than those in the MORB-source mantle (weak plumes, the margins of hotter plumes, or petit spots). Implantation of small-degree partial melts produces peridotite that is enriched in highly incompatible elements and that has isotopic signatures of crustal recycling, characteristics typical of sources of highly alkalic OIB.

How nanoscience has changed our understanding of environmental geochemistry

M.F. HOCHELLA, JR.
NanoBioEarth, Department of Geosciences, Virginia Tech, Blacksburg, Virginia, USA (hochella@vt.edu)

Naturally occurring nanoscale materials, many containing trace elements, appear to be ubiquitous in the environment, and it can be hypothesized that due to their behaviour which is unlike both molecules and bulk materials, they play roles that have not yet been appreciated, or even realized. More specifically, nanoscale particles, films, and/or confined fluids are present throughout the Critical Zone, and in the atmosphere and oceans. And it has been well established that the structural and electronic properties of these materials change, often dramatically, as a function of their size in the nanorange. As a result, chemical and physical properties of nanomaterials change as a function of size (in the case of particles) or thickness (in the case of films). Yet we do not understand these nanomaterials very well, even from a fundamental physical chemistry point-of-view. Nevertheless, it is straightforward to hypothesize about their importance because it is becoming more common to observe their deviant behavior (relative to the same material at a larger scale) in laboratory and field studies in both biologically and abiotically dominated systems. In addition, because of the minute sizes involved, the interface to bulk ratios are extremely large in these nanoscale components of bulk systems, and therefore interfaces become even more important than usual. Critical insights into local, regional, and even global phenomena await our understanding of processes that are relevant at the smallest scales of Earth science studies. More and more investigators are beginning to uncover a fascinating story of how the immense surface area, unusual properties, and widespread distribution of natural nanomaterials affect Earth phenomena in ways that are surprising.
Chromite-rich cumulates in mafic xenoliths, São Vicente, Cape Verde Islands
B. HOEJSTEEN¹ AND P.M. HOLM²

¹(b.hoejsteen@webspeed.dk)
²Institute of Geophraphy and Geology, University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen, Denmark

Mafic xenoliths from two basanitic lavas at São Vicente have mineral compositions and textures indicating that they could be early cumulates, fractionated from magmas similar to the host of the xenoliths. In one of these lavas some xenoliths accumulated up to 25% anhedral chromite in poikilitic olivine (mg# 83-86) and ferri-titan-chromdiopside. The shape of the chromite grains as well as their high concentration has not been reported from other xenoliths from the Cape Verde Islands. We have puzzled our brains over their origin.

The chromites have cr# and fe2+/~ 40-60 and are relatively rich in Ti and Fe3+. Such composition is known from chromite in Kimberlites and is thought to be a result of fluid release from the magma during decompression. The anhedral shape could form either

1. By early precipitation and later partly dissolution of chromite in the magma. Complete dissolution of chromite was avoided by the high concentration of chromite buffering the melt, or 2. Matveev and Balhaus report an experiment on an olivine and chromite saturated basaltic melt which holds sufficient H₂O (> 4 % H₂O) to release fluid when decompressed. Chromite then precipitated as pearls inside the fluid bubbles. They rose towards the top of the magma chamber until the bubbles got overloaded with chromite and sunk. This could be the explanation for the shape and concentration of the São Vicente xenoliths although the chromite concentration maybe never passed the critical mass limit but kept flowing. Based on the primitive nature of olivine and clinopyroxene and because the necessary water may have been present we prefer the second solution.

Comparison of laser ablation and micromill sampling techniques for MC-ICPMS ²³⁰Th-²³⁴U-²³⁸U measurements on speleothems
DIRK L. HOFFMANN¹, CHRISTOPH SPOETL² AND AUGUSTO MANGINI³

¹Bristol Isotope Group, University of Bristol, Bristol, UK (dirk.hoffmann@bristol.ac.uk)
²Institut für Geologie und Paläontologie, Universität Innsbruck, Innsbruck, Austria (christoph.spoetl@uibk.ac.at)
³Heidelberger Akademie der Wissenschaften, Heidelberg, Germany (augusto.mangini@iup.uni-heidelberg.de)

In situ laser ablation (LA) MC-ICPMS can be used to achieve U-series isotope measurements at very high spatial resolution without prior chemical separation procedures. However, matrix effects especially for mass and elemental fractionation pose significant problems for accurate determinations of ²³⁰Th/²³⁴U,²³⁸U ratios.

Procedures for accurate determinations of U-series isotope ratios using in situ laser ablation (LA) and MicroMill techniques for carbonates such as speleothems are presented. For LA analyses we are using a New Wave UP193HE laser and a new multiple ion counting detector system available for the ThermoFinnigan Neptune MC-ICPMS. Multiple ion counting increases the efficiency of low level ion beam collection by allowing simultaneous collection of all ion beams and also circumvents problems associated with unstable, transient beams. We present details of our measurement setup for LA measurements and the correction procedures for instrumental fractionation effects using a matrix matching carbonate standard.

We compare results of LA U-series measurements on a U rich (40 - 90 µg/g) speleothem from Spannagel Cave (Austrian Alps) to results on samples from the same speleothem section prepared using a New Wave MicroMill and processed through separation and purification solution chemistry. For laser ablation results, we currently obtain precisions of ²³⁰Th/²³⁸U in the range of 3 % (2σ), the solution analyses yield more precise ²³⁰Th/²³⁸U isotope ratios in the range of 1 %. Accuracy is assessed by comparison to conventional MC-ICPMS and TIMS measurements.

Key advantages of our LA technique are, for example, a matrix matching calibration standard, high spatial resolution analyses and the possibility of rapid determination of numerous coeval subsamples. We also demonstrate that LA measurements yield accurate but less precise results on speleothem samples with less than 1 µg/g U. The results on MicroMill samples are more precise but this sample preparation technique is time consuming and for a single measurement a bigger sample size is needed. For solution U-series MC-ICPMS measurements a minimum total load of about 5 ng for ²³⁰U and about 10 fg for ²³⁰Th should be used.
Evidence for Hadean mantle depletion in the sources of ~3.75 Ga subduction-related rocks, Isua, SW Greenland

J.E. Hoffmann 1,2, C. Münker 1,2, A. Polat 3 and K. Mezger 2

1Universität Bonn, Germany (joerg.elis.hoffmann@gmx.de; muenker@uni-bonn.de)
2Universität Münster, Germany (klaush@uni-muenster.de)
3University of Windsor, Canada (polat@uwindsor.ca)

The Hf isotope compositions of Earth’s oldest zircons provide growing evidence that crust-mantle differentiation started as early as 4.4 Ga. Yet, the size of these differentiated Hadean reservoirs and their persistence over Earth’s history are still under debate. Lu-Hf studies on zircons younger than ~3.8 Ga do not reveal any evidence for the long term presence of ancient depleted mantle reservoirs [e.g. 1].

Rocks from the ~3.71-3.81 Ga Isua supracrustal belt (ISB) comprise the oldest preserved record of mafic crustal material, thus potentially providing evidence for any large scale mantle depletion in the early Archean. Here, we report Hf and Nd isotope data for the least altered samples from a suite of ~3.75 Ga old, submarine boninite-like metabasalts from the central tectonic domain of the eastern ISB [2]. These metabasalts are among Earth’s oldest preserved subduction related rocks [2]. They were metamorphosed under amphibolite to greenschist facies conditions.

Initial εHf values of the boninite-like metabasalts range from -1.3 to +7.9. The samples have 176Lu/177Hf values as high as 0.9, indicating a previous depletion of the mantle source(s) in the garnet stability field. These εHf values are clearly of primary origin, as the initial εHf, εNd and γOs [3] correlate with major and trace elements [2], exhibiting a magmatic differentiation trend. All samples follow AFC curves, suggesting assimilation of up to 30 % enriched crustal material, possibly marine sediments or igneous rocks with TTG-like composition. Two different parental mantle sources can be identified: one has an initial εHf value of ca. +7.9 and the other of ca. +1.3. In order to have an initial εHf of +7.9, a source must have an old and strong depletion in incompatible elements. Hence the presence of a complementary enriched component is required, which may be the earliest continental crust. These results provide the first evidence from mafic Archean rocks for the persistence of Hadean mantle depletion into the early Archean. As other ISB rocks do not display such strongly depleted initial εHf values, the volume of these depleted mantle domains was probably small.

Is D" a low-mu reservoir?

A.W. Hofmann 1,2, S.L. Goldstein 2 and C. Class 3

1Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (hofmann@mpch-mainz.mpg.de)
2Lamont-Doherty Earth Observatory, Palisades, NY, 10964 USA (steveg@ldeo.columbia.edu)
3Lamont-Doherty Earth Observatory, Palisades, NY, 10964 USA (class@ldeo.columbia.edu)

Preservation of a “hidden” reservoir in the lowermost mantle, the D" layer, since the early Earth has recently been proposed to explain unbalanced geochemical signatures of accessible terrestrial reservoirs relative to a chondritic Earth, on the basis of xenon (Tolstikhin and Hofmann, 2005) and 142Nd isotopes (Boyet and Carlson, 2005). How could such a reservoir have formed and subsequently survive for more than 4 Ga? Here we explore the possibility that following large-scale early mantle melting, the partially molten lowermost mantle solidified by downward migration of a dense melt fraction. This is the inferred consequence of the measured crossover of melting temperatures of silicate perovskite and magnesio-wüsitê at about 1200 km depth, and the predicted Fe-rich eutectic and low melting temperatures in the lowermost mantle (Boehler, 2000). This suggests that D" formed during early solidification of the lower mantle and that it survives because of its Fe-rich composition.

The high melting temperatures of Mg and Ca perovskites in the lowermost mantle suggest that both phases remain in the residual solid. Corgne et al. (2005) have measured remarkably high partition coefficients for U and Th in Ca-perovskites. They suggested that this might provide an explanation for the “HIMU” (high mu = high U/Pb) ocean island source reservoir. In contrast, we suggest that the downward solidifying scenario should create a low-mu lowermost mantle region, because Pb is incompatible in the perovskites and is therefore enriched in the liquid, whereas U and Th are enriched in the Ca perovskite of the residual solid. Using the partition coefficients of Corgne et al. (2005) with simple fractional crystallization models yields a low-mu D" layer and a higher-mu overlying mantle. If the time scale of this lower-mantle solidification was on the order of 100 to 500 Ma, this offers a simple solution to the classic “Pb paradox” (estimated bulk silicate lead lying “to the right” of the Pb-Pb geochron) and the well-known two-stage evolution of terrestrial lead. We also explore possible solutions of other geochemical puzzles, such as the high, time-integrated Th/U ratios calculated from early Archean galenas and feldspars, the subchondritic Nb/Ta ratios of accessible terrestrial reservoirs, and the decoupled ε(Hf) and ε(Nd) values of early Archean rocks in terms of this model.

Sub-micron-scale variations in Ti abundance in zircon

A.E. Hofmann1, A.J. Cavosie2, Y. Guan1, J.W. Valley3 and J.M. Eiler1

1Division of Geological & Planetary Sciences, California Institute of Technology, Pasadena, CA 91125, USA. (hofmann@gps.caltech.edu)

The Ti-in-zircon geothermometer [1,2] can constrain growth and/or re-equilibration temperatures of zircons and is particularly useful for constraining Archean and Hadean events where detrital zircon is the only surviving mineral. Zircons are often small (ca. <100 μm in the long dimension) and preserve evidence of fine-scale (sub-micron) compositional zonation. Methods for determining Ti abundances in natural zircons typically analyze domains 10s of microns across, which must average fine-scale compositional variations. Although Ti can correlate with coarse cathodoluminescence (CL) zones (e.g., [3]), it is unknown whether Ti exhibits fine-scale variations and thus may be compromised by coarse-scale measurements.

We report Ti abundances in natural and synthetic zircons down to length scales of ca. 250 nm based on measurements made with the Caltech Microanalysis Center Cameca NanoSIMS 50L. All data reported here were calibrated by comparison with primary and secondary standards previously studied in other laboratories. The external precision of our measurements for 2-μm raster images are typically 2%, relative, at 10 ppm Ti, and degrade with decreasing spot size as expected by counting statistics.

We analyzed detrital zircons from Archean metasediment in the Jack Hills (Australia) and from Proterozoic metapelite in the Adirondacks (New York). Ti concentrations commonly vary by factors of 2-3 over distances of ca. 3 μm, conformable to μm-scale CL zonation and corresponding to nominal temperatures of ~700 to ~750 °C. In some cases, banding extends down to sub-micron scales with gradients at least as sharp as a factor ~3 in concentration over 250 nm. The preservation of such gradients through granulate facies metamorphism attests to slow diffusion of Ti in zircon. Curiously, compositional variations include ca. 1-2 μm bands of very low Ti content (<2 ppm, corresponding to apparent temperatures of <600 °C). Hf concentrations commonly covary with Ti, but the sense of correlation can be either positive or negative; i.e., there is no general correlation among all data. All zircons studied to-date also contain 1-2 μm-wide bands or ca. 1 μm spots having Ti concentrations up to 80 times that of the background, corresponding to nominal temperatures up to 1200 °C. These presumably reflect sampling of micron or sub-micron inclusions of Ti-rich phases.

Ferrihydrite in porous media – An inner-sphere complexation and transport approach to describe multiple reactions and predict colloid mobilization

A. Hofmann1 and L. Liang2

1Université des Sciences et Technol. de Lille 1, UMR/CNRS 8110 PBDS, 59655 Villeneuve d’Ascq Cedex, France (annette.hofmann@univ-lille1.fr)
2Oak Ridge National Laboratory, MS-6250, P.O. Box2008, Oak Ridge, TN 37831-6250 USA (liangl@ornl.gov)

Prediction of colloid release and transport as affected by reactive species remains a significant challenge for field applications. We report experimental and modeling results of ferrihydrite colloid release under the influence of citrate species. Using CD-MUSIC, a 3-plane surface complexation model (1), equilibrium constants were obtained for the three proposed inner-sphere complexes by fitting citrate adsorption isotherm and pH adsorption envelopes. The constants are used in a reactive transport model (implemented in ORCHESTRA (2)) for simulating reaction fronts of dissolved species during injection of citrate in ferrihydrite-coated quartz columns. Simulation results show that sorption alone may not adequately describe the breakthrough curves. Inclusions of ferrihydrite dissolution and re-adsorption of Fe(III) improve the prediction of dissolved species transport. Additionally, matrix diffusion may be needed for a better prediction. The mechanisms of colloidal iron oxide release change over time. At complete breakthrough of citrate, oxide dissolution and interfacial repulsion control particle release from sediment. However, the peak release of colloids, corresponding to the breakthrough front of citrate, was mainly brought by electric double layer forces. These particles underwent detachment-deposition-detachment cycles along the flow path, and emerged in the effluent with the major reaction front. To quantitatively predict colloid release, a semi-empirical linear correlation is proposed, linking the calculated electric potential to experimental colloid release rates. The model works well for the prediction and scaling of field experiments concerned with organic ligand injection in subsurface environments.

Theoretical and experimental arguments for Earth’s heat flux being 31±2 TW

A.M. HOFMEISTER1, V.M. HAMZA2 AND R.E. CRISS1

1Dept. of Earth and Planetary Sci., Washington U., St. Louis MO 63130, USA (hofmeist@wustl.edu; criss@wustl.edu)
2Observatório Nacional, Rua General José Cristino, 77 Rio de Janeiro, Brazil (Hamza@on.br)

Global power (heat flux averaged over Earth’s surface) links to radiogenic content, geodynamic state and thermal evolution. Recent computations involve replacing measured flux over substantial parts of the ocean floors with calculations from 1-D cooling models. Cooling models must support through their alleged prediction of seafloor depths. But, a factor of 3 error exists in equations used to predict depth as a function of seafloor age. Specifically, 1-D models presume that temperature varies in the Z-direction only, so contraction is only in Z and is governed by linear thermal expansivity, not volumetric as mistakenly implemented. Values predicted for depth are 1/3 those measured if reasonable physical parameters are used. To reproduce depth data requires using ~3000 K as the basal temperature, which is incompatible with petrology, and provides global power of ~132 TW, not 44 TW. Other problems exist with cooling models and the database. Recent asessment of heat flow data, corrected for duplications and errors in location, limits global power to between 28.6 and 34.1 TW, with uncertainties largely stemming from the need to estimate flux in certain geographic regions. Hydrothermal circulation has been rationalized as causing the discrepancy of model with measurements, but practically speaking, measurements are made mostly in strongly sedimented areas where the confining lid prevents effects of hydrothermal circulation, local or extensive. In hydrothermal systems, temperature gradients in the rocks are reduced below ideal conductive values where the water enters the system in recharge regions far from the ridges and rocks heat from the rocks, not near the ridges where ascending hot water warms rocks and enhances conductive gradients. The rationalization thus implicitly assumes that measurement sites are preferentially located over recharge zones, which is unlikely. Harmonic expansions, up to degree 36, reveal that previous low-degree hybrid spherical harmonic analysis (wherein high fluxes near the ridges from 1-D cooling models are used in place of data) causes heat flux in the mathematical representation to be overestimated, even in continental regions, due to the importance of lowest order spherical harmonic coefficients. Enstatite chondrite models provide ~30 TW, suggesting that additional heat sources, such as K in the core or secular delay, are not necessary to explain Earth’s thermal state.

Timescale for metal-silicate separation by metal rainfall in a magma ocean

TOBIAS HÖINK1, JÖRG SCHMALZL2 AND ULRICH HANSEN2

1Department of Earth Science, MS-126, Rice University, 6100 Main St, Houston TX, 77005, USA (Tobias.Hoeink@rice.edu)
2Institut für Geophysik, WWU Münster, Corrensstr. 24, 48149 Münster, Germany (joergs@uni-muenster.de, hansen@earth.uni-muenster.de)

The largest sequestering event in Earth’s evolution, which ultimately lead to the differentiation of Earth’s mantle and core, was the separation of metal from silicate in a magma ocean. The only separation mechanism that can explain geochemical observations is metal rainfall. Essential to the metal rainfall mechanism is that metal disperses into small droplets which chemically equilibrate with the surrounding silicate while they sink by means of turbulent density currents. Höink et al. (2006) have studied the metal rainfall mechanism under the assumption of constant silicate viscosity and found that the time scale of metal silicate separation under these conditions are on the order of the Stokes’ settling time, which for centimeter-sized metal droplets in Earth’s magma ocean corresponds to a time scale of weeks.

However, it is well known that magma dynamics are fundamentally influenced by variations in viscosity. A non-constant viscosity, i.e. a temperature dependent viscosity, or even more realistically, a temperature- and pressure dependent viscosity may alter the mechanism of metal rainfall significantly. In the present work we analyse the influence of temperature dependent viscosity and temperature- and pressure dependent viscosity on the rainfall mechanism by employing a numerical convection model combined with a sedimentation method.

We find that the metal-silicate separation time depends on the thermal viscosity contrast and also on the viscosity contrast due to pressure. For values suitable to Earth’s magma ocean, the time scale of metal-silicate separation by metal rainfall increases to the order of tens to hundreds of years. Accordingly, metal rainfall is a very rapid mechanism for metal-silicate separation in a magma ocean. This short timescale has profound implications for the timing of Earth’s evolution.

Comparison of the development in melt compositions in the Faroe Islands and East Greenland during continental breakup in the Paleogene

P.M. HOLM AND N. SØAGER

Institute of Geography and Geology, University of Copenhagen, Øster Voldgade 10, DK-1350 Copenhagen, Denmark (paulmh@geol.ku.dk)

The upper part of the Faroe plateau lavas erupted during continental rifting and can be correlated with East Greenland counterparts of the Paleogene North Atlantic Igneous Province (Søager & Holm, this conf.). Low-Ti lavas with typically La/Sm = 0.3-0.4 have fractionated Dy/Yb up to 1.25 which require substantial melting with residual garnet and thus a relatively hot source. Compared to late low-Ti lavas, the early tend to have more radiogenic Pb and occur in the northeastern parts. There is also a 7/4 decrease from 0 to -3 with time, while positive 8/4 show a rough increase with time. The low-Ti basalts with the most radiogenic Pb show a marginal overlap with Icelandic rocks. Dy/Yb has a negative correlation with 208Pb/204Pb and on formation level there is an increase in 206Pb/204Pb with time.

While the low-Ti basalts seem to be similar on both sides of the rift, the high-Ti basalts in the Faroes indicate decreasing depth of melting throughout the development, whereas the contemporaneous RFF in East Greenland has melts derived at high pressure. However, as in East Greenland, there is a change with time from IE2 to IE1 (Thirlwall & al., 2004) end-member composition. The increasing fraction of high-Ti basalts to the south could be caused by lateral variation in the mantle plume. Relatively low Dy/Yb indicates lithospheric thinning to have continued at the Faroes in contrast to East Greenland. A MORB-type source dominates the early low-Ti thinning to have continued at the Faroes in contrast to East Greenland.

Bubble gas-exchange in an artificially aerated lake traced using noble gases

C. P. HOLZNER1,2, N. GRASER1 AND R. KIPFER1,3

1Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland (christian.holzner@eawag.ch)
2Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
3Institute of Isotope Geochemistry and Mineral Resources, ETH Zurich, Switzerland

The concentrations of dissolved atmospheric noble gases in open waters generally correspond to the equilibrium concentrations determined by temperature and salinity during atmospheric gas exchange. As noble gases are chemically inert, only physical processes may change the noble-gas abundance and hence are responsible for deviations from the initial equilibrium. Gas bubbles that are released at the bottom of a lake will affect the concentrations of dissolved gases in the water column, as the bubbles strip gases from the surrounding water and dissolve simultaneously during their ascent. The effect of these secondary gas exchange processes on the concentrations of dissolved gases varies depending on the solubility and diffusivity of the respective gas and on the initial gas concentrations in the bubbles.

We measured dissolved noble gas concentrations in Lake Hallwil (Switzerland), a small eutrophic lake, to trace the effects of gas release from an aeration system. This installation prevents anoxia in the deep water by the injection of oxygen-rich gas bubbles at the bottom of the lake. Noble gases in both the aeration gas and dissolved in the water of the lake were analyzed.

The measurements show that noble gases in the injected gas are strongly fractionated with respect to air. He, Ne and Ar are enriched, whereas Kr and Xe are virtually absent. Noble gases dissolved in the lake water show corresponding deviations from the atmospheric equilibrium concentrations. Deep-water samples taken at three different locations in the lake are supersaturated in He, Ne and Ar. The magnitude of the enrichment decreases with increasing distance from the bubble source. The observed noble gas supersaturations were also found to vary according to the operation mode of the aeration system, with higher gas flow leading to stronger noble gas enrichment. In contrast, only minor changes of the dissolved oxygen concentrations could be detected due to fast oxygen consumption.

In conclusion, the example of Lake Hallwil demonstrates that gas exchange with injected bubbles affects the noble gas abundance in the water body. Noble gas analyses allow quantifying the effectiveness of the aeration system, i.e. noble gas enrichments can be interpreted as a measure for the oxygen transfer to the lake water. Note that these findings may also help to understand natural systems like gas seeps in lakes and oceans.

TEM investigations of bacterial effects on biotite dissolution

J. HOPF, F. LANGENHORST AND D. MERTEN

Institute of Geosciences, University of Jena, Burgweg 11, D-07749 Jena, Germany (JulianeHopf@web.de)

Introduction

In natural environments minerals and rocks are not only weathered by chemical and physical processes but also by biological activity. In order to understand the role and interaction between alteration processes, the interface between minerals and bacteria must be investigated at the microscopic to nanometer scale.

Methods and results

In batch culture experiments three different bacteria strains (*Bacillus subtilis* spizizenii, *Shewanella putrefaciens* and *Streptomyces acidiscabies E13*) were grown for 35 days with ground biotite as main nutrient source. The release of major and minor elements (Al, Fe, K, Mg, Mn, Si, Ti) was measured using inductively coupled plasma-optical emission spectrometry (ICP-OES). In comparison with an abiotic control the sample with *Bacillus subtilis* spizizenii showed an increase in the dissolution of Al and Mg. Compared to the control, the dissolution rates of Al and Mg in experiments with *Shewanella putrefaciens* and *Streptomyces acidiscabies E13* are however slightly decreased. These first results demonstrate that bacteria have a diverse control on the dissolution behaviour of biotite.

To understand this diversity in dissolution behaviour of biotite, we have employed transmission electron microscopy (TEM) and energy dispersive X-ray microanalysis (EDX). These techniques were used to detect changes in structure, morphology, and element chemistry of the untreated and biologically treated biotite. Pure visual TEM observations of the bacteria treated specimens provide clear evidence for intense degradation. The small bacteria treated biotite flakes show frayed rims and etch pits on surfaces, whereas untreated biotite from the control experiment displays the normal shape of unaltered starting biotite with unaffected crystal edges and surfaces. Crystal-chemical changes have been detected in experiments with *Bacillus subtilis* spizizenii, which show an K-Na cation exchange in biotite interlayers. The Na is thereby provided by the liquid media. Additionally, we found small crystals of a secondary phase, which is currently under identification.

Conclusion

Bacteria are able to influence the dissolution processes of biotite in various ways. Especially the gram-positive soil bacteria *Bacillus subtilis* spizizenii increases the dissolution of certain elements and triggers the precipitation of a secondary phase.

An evaluation of He, Ne and Ar isotope and element systematics of oceanic mantle sources

JENS HOPP AND MARIO TRIELOFF

Mineralogisches Institut, Universität Heidelberg, Im Neuenheimer Feld 236, D-69120 Heidelberg (jhopp@min.uni-heidelberg.de)

The more radiogenic character of Mid Ocean Ridge Basalts (MORB), i.e. higher air corrected mantle ratios of \( ^{4}\text{He}/^{3}\text{He} \), \( ^{33}\text{Ne}/^{22}\text{Ne} \), \( ^{40}\text{Ar}/^{36}\text{Ar} \) compared to many Ocean Island Basalts (OIB), is commonly attributed to a higher degree of depletion of primordial noble gases within the MORB source. In addition, He/Ne and He/Ar elemental ratios found in MORB glasses are higher relative to OIBs. This had been considered as evidence for solubility controlled elemental fractionation during gas - melt partitioning. However, the generally lower He concentrations in OIBs compared to a presumed degassed MORB source appears in contradiction with this conclusion.

To resolve this issue in terms of a two-stage fractionation and binary mixing model we evaluated literature data from MORB and Loihi-Kilauea glasses and used their He, Ne and Ar isotope and element systematics and concentrations. We can describe mantle \( ^{33}\text{Ne}/^{22}\text{Ne} - ^{4}\text{He}/^{3}\text{He} \) isotope systematics by a simple binary mixing process between a MORB and a ‘plume’ endmember that differ in their \( ^{3}\text{He}/^{22}\text{Ne} \) ratios at time of admixing. The ‘plume’ endmember is a postulated component, basing on the premise that both endmembers shared a common radiogenic evolution history, i.e. the same initial \( ^{3}\text{He}/^{22}\text{Ne} \) ratio, but a different time integrated accumulation of radiogenic isotopes. Within this model a primary fractionation process must have occurred before admixing of both subcomponents. We performed a back calculation of this mixing process and extended this procedure to the Ar system assuming a linear relationship of mantle \( ^{22}\text{Ne}/^{38}\text{Ar} \) and \( ^{40}\text{Ar}/^{36}\text{Ar} \) ratios. With the implicit assumption that the composition of basalt glasses represents the melt phase and that the initial He/Ne, He/Ar compositions of the melt will only evolve towards higher values in course of solubility controlled secondary fractionation during magmatic degassing we derive upper limits for the \( ^{3}\text{He}/^{22}\text{Ne} \), \( ^{3}\text{He}/^{38}\text{Ar} \) and \( ^{4}\text{He}/^{40}\text{Ar} \) ratios of both mixing endmembers. The MORB component appears not or weakly fractionated, in opposite to the ‘plume’ component displaying a significant He deficit. A simple calculation of unfractionated initial ‘plume’ \( ^{3}\text{He}/^{22}\text{Ne} \), \( ^{3}\text{He}/^{38}\text{Ar} \) and \( ^{4}\text{He}/^{40}\text{Ar} \) concentrations and He concentrations are in broad agreement with observed MORB data. A more compatible behaviour of He relative to Ne and Ar during crystal - melt partitioning could explain the data: OIB melt could represent low degree melts from an isotopically different source region that admixes with higher degree MORB melts at shallow depths. Alternatively, a more complex magmatic fractionation scenario is addressed.
The H-, C-, N-, and O-isotopic compositions of cometary matter returned by STARDUST

PETER HOPPE
Max-Planck-Institute for Chemistry, 55020 Mainz, Germany (hoppe@mpch-mainz.mpg.de)

Introduction
The STARDUST spacecraft collected about 1 mg of dust during a flyby in January 2004 of comet 81P/Wild 2 in two collection media, low-density silica aerogel and Al foil (Brownlee et al., 2004). The dust collector was successfully returned to Earth in January 2006 and the cometary dust was analyzed by an international Preliminary Examination Team. These analyses showed that comet Wild 2 is an unequilibrated mixture of materials that have both solar and presolar origins (Brownlee et al., 2006). Here, I will briefly review the results obtained for H-, C-, N-, and O-isotopic compositions by the Isotope subteam (McKeegan et al., 2006; Stadermann et al., 2007).

Hydrogen
The H-isotopic composition was measured in five particle fragments. Moderate D enrichments were observed with D/H ratios of up to ~3x the terrestrial value. This is qualitatively consistent with the signature found in IDPs and insoluble organic matter (IOM) from chondrites, although the maximum D enrichments are smaller in the Wild 2 samples.

Carbon and Nitrogen
C- and N-isotopic compositions were measured in several microtome sections, particle fragments, and crater residues in Al foils. No circumstellar C- or N-rich grains were found. Two hotspots enriched in 13C and depleted in 14N were recognized, possibly the signature of labile organic material. 15N enrichments with 15N/14N ratios of up to ~2x the terrestrial value are found in bulk samples and as hotspots as similarly observed for IDPs and IOM from chondrites.

Oxygen
Most studied samples (crater residues, microtome sections) have O-isotopic compositions compatible with those of bulk chondrites. One circumstellar O-rich grain, about 250 nm in size, was found. The 17O/16O ratio of ~2.6x solar and 18O/16O ratio of ~0.9x solar suggest an origin from a RGB/AGB star. A CAI-like particle exhibits enrichments in 16O of ~4% as similarly observed for CAIs from chondrites. The presence of a CAI-like particle among cometary matter is suggestive of large-scale radial mixing in the solar nebula.

Mineral-melt trace element equilibria in plutonic rocks studied by Laser Ablation ICP-MS

K. HORCKMANS AND J. HERTOGEN
Geo-Instituut, K.U.Leuven, Celestijnenlaan 200E, B-3001 Leuven, Belgium (karolien.horckmans@geo.kuleuven.be)

Magmatic intrusive systems often yield very complex cumulate rocks, consisting of different solid phases and interstitial residual liquid phases. It is an intrinsic difficulty of cumulate rocks to properly interpret whole rock contents of incompatible trace element data, because the amount of trapped interstitial residual liquid might be the controlling factor. Moreover, as early formed cumulates might have been permeated by later-stage evolved liquids, there is no guarantee that whole rock data represent ‘equilibrium’ compositions. In the late stages of differentiation accessory minerals often start to crystallize and have an important impact on the behavior of trace elements during differentiation. This raises an important issue since models of fractionation are usually largely based on whole rock geochemical trends.

Equilibria at the micro-scale can be studied in situ in standard, thick polished mounts with LA-ICP-MS. The most promising minerals for the study of REE melt/mineral distributions are clinopyroxenes and plagioclase. However, accurate results require rather meticulous standardisation. Several standard materials have been tested in the present study: the commonly used NIST612 glass, USGS BCR-2 fused glasses, and a natural, very homogeneous obsidian glass from the Krafla volcanic area, Iceland. The equipment consisted of a Cetac200 266 nm UV-light of a NdYAG laser, coupled to a quadrupole based HP4500 ICP-MS. The Krafla obsidian yielded the best analytical results.

Ongoing studies include the analysis of core samples from the oceanic gabbro section of Hole735B drilled during Ocean Drilling Program Legs 118 and 176, and a section from the Tron pluton from the Caledonide Trondheim Nappe Complex, Norway. The accuracy of the LA-ICP-MS could be checked against analysis of separated pure mineral fractions analyzed by other methods. The micro-analytical data allow to calculate the liquid compositions with which clinopyroxene and plagioclase equilibrated, and to estimate the stage of solidification at which interstitial liquids were expelled. Mass balances further make it possible to estimate the amount of dispersed trapped late stage residual liquids.
Development of in situ U-Pb analysis of uranium oxides using an ion microprobe

K. HORIE¹ AND H. HIDAKA²

¹Institute of Geology and Geoinformation, Geological Survey of Japan (JSPS fellow) (kenji-horie@aist.go.jp)
²Department of Earth and Planetary Systems Science, Hiroshima University, Japan (hidaka@hiroshima-u.ac.jp)

The chronological study of uranium minerals provides practical information on the formation of uranium deposits as well as elemental transportation in association with the alteration of uranium minerals. Moreover, the timing of uranium mineralization from the Archean to the Paleoproterozoic period is a good indicator of atmospheric oxygen evolution, because uranium is only mobilized as a uranyl ion (UO₂⁺) under oxidizing conditions (e.g., Holland, 1984). However there are some issues to estimate the 2⁰⁶Pb/²³⁸U age from SIMS analysis such as large variation of the ionization efficiency of secondary ions and standard material. In this study, we established a method for the in situ U-Pb isotopic analysis of uranium minerals in a similar manner to the conventional zircon analysis.

The Faraday mine uraninite from Bancroft, Canada was used as a standard material for the U-Pb calibration of three uranium minerals from Chardon, Ecarpière (the Armorican Massif, France) and Mistamisk (Labrador, Canada). Quantitative analysis of major elements was carried out by EPMA. In situ U-Pb analyses of uranium minerals were performed by using a SHRIMP at Hiroshima Univ. The calibrated SHRIMP ²⁰⁶Pb/²³⁸U ratios of three uranium minerals from Chardon, Ecarpière and Mistamisk show a good correlation with Pb/U elemental ratios obtained from EPMA, which indicates the reliability of the SHRIMP calibration in this study. The SHRIMP ²⁰⁶Pb/²³⁸U data of Ecarpière (285 Ma) and Mistamisk (1729 and 421 Ma) uraninite are consistent with previous chronological data obtained by TIMS. As shown in Figure, the selected SHRIMP data of the Chardon mine provide a ²⁰⁶Pb/²³⁸U age of 313 Ma, which is older than the previously reported age of 264 Ma. Considering that the analytical spots were selected to avoid impure minerals and altered phases, which were probably formed by later processes, it is interpreted that the Chardon uraninite was crystallized by the remobilization of U during the cooling of the Mortagne granite (310-313 Ma).

Calcite-water oxygen isotope fractionation at elevated temperatures: Experimental and theoretical study on the effect of pressure and dissolved NaCl

J. HORITA¹, V.B. POLYAKOV² AND D.R. COLE³

¹Chemical Sciences Division, Oak Ridge National Laboratory, TN 37830-6110 (horitaj@ornl.gov)
²Institute of Experimental Mineralogy, RAS, Russia (polyakov@iem.ac.ru)
³Chemical Sciences Division, Oak Ridge National Laboratory, TN 37830-6110 (coledr@ornl.gov)

We have conducted an experimental and theoretical study for investigating the effect of pressure and dissolved NaCl on oxygen isotope fractionation in the system calcite – water at elevated temperatures. First, our novel corresponding state principles approach for calculating the effect of pressure (density) on the reduced partition function ratio (RPFR) of H₂¹⁸O (Polyakov et al., 2007) shows that the RPFR increases up to 1.0 % by increasing pressure to 1 kb at 273-523°C. The RPFR of CaCO₃ increases only slightly, thus the oxygen isotope fractionation of the system CaCO₃-water decreases up to 1.0 % at 1 kb.

Our calculations of oxygen isotope fractionation factor between CaCO₃ and pure water are significantly (up to 2 %) lower than experimental values between CaCO₃ and calcite-sturated water at 300-750°C at 1 kb (this study) and 15 kb (Hu and Clayton, 2003). The cause of this discrepancy is due most likely to either errors in the calculation of ideal-gas RPFR of H₂¹⁸O (Polyakov et al., 2007), is found to be small (≤0.5 ‰).

It is very likely that pressure and dissolved CaCO₃ decrease and increase the calcite-water oxygen isotope fractionation at low and high pressures, respectively. In contrast, dissolved NaCl appears to have a small effect. However, the available data are still sketchy, and we have just begun to quantify the effects of these important variables for mineral-water isotope fractionation at elevated temperatures.

The late Eocene Chesapeake Bay impact structure – Status of research, insights, and implications

J. W. HORTON, JR., G. S. GOHN, AND D. S. POWARS
U.S. Geological Survey, 926A National Center, Reston, VA 20192, USA (whorton@usgs.gov)

This is an overview of studies since 2000 by the USGS Chesapeake Bay Impact Crater Project and the ICDP-USGS Chesapeake Bay Impact Structure Deep Drilling Project. The ~35.5 Ma Chesapeake Bay impact structure (CBIS), on the Atlantic margin of Virginia, USA, may be Earth’s best preserved large impact structure formed in a siliciclastic, continental-shelf environment. The 85-km-wide structure formed in a layered target (seawater-sediments-rock), has an inverted-sombrero shape (deep central crater surrounded by a shallower annular trough), and is well preserved beneath postimpact sediments. Saline ground water in the CBIS affects water resources in an area of urban growth.

In 2000-2003, USGS drilled the Watkins School corehole just outside the structure, and the North, Langley, and Bayside coreholes in the annular trough, at 43, 39, 36, and 25 km from the center. These cores revealed (top to base) polymict sedimentary breccia interpreted as ocean-resurge deposits, target sediments modified by liquefaction, injection, and extensional structures, and unshocked Neoproterozoic basement. The sedimentary breccia contains shocked quartz and impact-damaged, mixed-age microfossils. In 2004, USGS drilled and partly cored the Cape Charles test hole on the central uplift, 1 km from the center. It revealed suevite, impact-melt clasts having a meteoritic component, a shock-induced TiO₂ polymorph, and hydrothermal alteration. Gravity, magnetic, seismic, and magnetotelluric surveys delineated the central uplift, moat, and outer margin. Numerical models simulated the inverted sombrero using strength contrasts of weak over strong layers.

In 2005-2006, the ICDP-USGS Eyreville coreholes were drilled to 1.77-km depth in the moat (deepest part) of the central crater, 9 km from the center. They cored (top to base) postimpact sediments, allochthonous sedimentary breccia and sediment megablocks, granite megablock(s), sediment with lithic blocks, suevite and lithic impact breccias, and brecciated schist and pegmatite with breccia veins [1]. Studies by seven science teams will allow unprecedented understanding of a shallow-marine impact and its consequences. Topics include impactor type and relation to other late Eocene impacts (Popigai?), tektite formation, shock-pressure variations with depth and lithology, layered-target influence on cratering, resurge dynamics, unknown target basement, environmental consequences and hazard implications, hydrothermal conditions, source of contained ground-water brines, subsurface microbial diversity, and habitats unique to impact structures.

Petrological investigations, quantitative phase diagram modelling and monazite dating were carried out on medium-grade metamorphic rocks from the Kutjevačka Rijeka transect in the Slavonian Mts., Tisia Unit (NE Croatia). Micaschists contain complex zoned garnets with Mn-rich cores and Ca-rich rims. Mn decreases steadily from core to rim, but there is an abrupt increase in Ca between core and rim. This complex zoning was not observed in garnets from intercalated paragneisses and amphibolites. Quantitative phase diagrams and garnet composition isochores using bulk rock compositions revealed that the garnet cores formed at 584-592°C and 6.4-7.8 kbar. For establishing the PT conditions responsible for garnet rim formation the composition of the garnet cores was removed from the bulk data and a new effective bulk composition was established. Using quantitative phase diagrams, mineral isochores and thermobarometric methods we calculated peak PT conditions of ~600-660 °C and 11-12 kbar for the garnet rim and the matrix assemblage of biotite, muscovite, plagioclase and quartz. Staurolite mentioned in the literature was not observed in this study and the application of quantitative phase diagrams contoured for H₂O mode isochors supports our opinion that during the retrograde PT path the rock did not pass staurolite-bearing fields. PT conditions for the intercalated paragneisses and amphibolites are the same as for the micaschists.

The Th, U and Pb contents of yttrium-rich accessory monazites indicate a pre-Variscan (428 ± 25 and 444 ± 19 Ma) age for the medium-grade metamorphism. These data are 70-100 Ma older than previously published mica Ar-Ar and K-Ar ages from the study area.

This study was financially supported by the Hungarian National Science Fund (OTKA, grant number F047322 to PH) and by the Croatian Ministry of Science, Education and Sports, Projects 119-1191155-1156 (DB) and 195-1951293-3155 (BT).
Environmentally hazardous trace elements of Eocene coal deposits in the north Anatolia, Turkey

FATMA HOŞ ÇEBİ AND SADETTIN KORKMAZ
Karadeniz Technical University, Department of Geological Engineering, Trabzon/Turkey (hos@ktu.edu.tr, korkmaz@ktu.edu.tr)

Amasya, Bolu and Kastamonu in Northern Anatolian Region in Turkey host high-calorie lignite coals of Eocene age with reserve more than 1 million tones. In this study, distribution of environmental elements in coals, enrichment factors of these elements and total organic material-element relations were investigated.

The lignite coals in Amasya are found in 4 different fields within the Eocene clastic deposits. In these fields, concentrations of Cu, Zn and Se are generally higher than that of the Turkish coals. Considering the enrichment factor calculations with respect to world coals, Mo, Pb, Cd and Sb are depleted while Cu, Ni, Co, Mn, V, Cr, Hg, Se, Th and As elements are enriched.

Mo, V, B, Se and S% values of the Bolu field coals are higher than the average value of Turkey. Enrichment factor calculations on these coals reveal that Pb, Cd, Sb and Th are depleted and Se, Cr, Co, Zn and Cu are enriched while Mo, Ni, Mn, As, V, B, Hg, U and S are considerably enriched.

Lignites in Kastamonu are found within the Eocene marl-limestone sequence. It was determined that Cu, Pb, Zn, Ni, Co and S concentrations of this field are higher than the average value of Turkish coals. Enrichment factor calculations on the Kastamonu coals reveal that Cd, Sb and Se are depleted and Mo, Cu, Pb, Zn, Co, Mn, As, V, B, U, Th and S are enriched while Ni, Cr, and Hg are considerably enriched.

Using the environmentally sensitive elements and total organic matter values of coals from all the fields, statistical evaluation was made.

In the Amasya-Kastamonu coals, Cr-V and As-S element pairs show positive correlations while B-TOC, Th-TOC, Cu-TOC and B-Cu element pairs display negative correlations.

Except for S-Cu element correlation resembling to the Amasya field, the Bolu field does not display any similarity to any of the fields.

Zeolite-calcite-silica formation in basalt during orogenic collapse, Washington Cascades

PAUL W.O. HOSKIN
Department of Geology & Geophysics, University of Calgary, Alberta, Canada (hoskin@ucalgary.ca)

Regional extension and collapse of the 96 to 45 Ma Cascade orogen during the Eocene is recorded by rapid basin subsidence, mafic to intermediate dike swarms, and exhumation of a partially migmatized gneiss complex (Miller et al., 2007). Shallow hydrothermal systems developed as a response to high regional geothermal gradients (35–40 °C km⁻¹) and local intrusions. The fossil hydrothermal system in the vicinity of the largest dike swarm (Teanaway dikes) is recorded by calcite-gold veins in sandstone-shale and by zeolite-calcite-silica ± Fe-oxo/hydroxide assemblages in distal and stratigraphically higher basalt lavas and pyroclastics. Silica in distal assemblages occurs as α-quartz, chaledony, and moganite forming agate. Zeolite phases are heulandite and stilbite.

Oxygen-isotope (δ¹⁸Oₛ=$((O_{SiO})/_{(SiO)}) values for silica phases range about 10–16 ‰ and 10–15 ‰ for calcite. Values of δ¹³C它可以 for calcite range –9 to –11 ‰. Calculated temperatures of formation based on calcite-quartz pairs, calcite-water, and quartz-water thermometry indicate precipitation at 50–60 °C in a meteoric water dominated system. Field-constrained 2D thermal models indicate that these temperatures are likely to have existed for about 10⁴ years at subsurface depths of 50–100 m.

Compositional modeling using PTAX and the Geochemists Workbench indicate that zeolite-calcite-silica formation occurred at log[aCa²⁺/a²H⁺] ≈ 12–13 and low log[aAl³⁺/a²H⁺] values that evolved up to 3–4 with time. Low Na activity in the fluid meant that mordenite or phillipsite were not stable zeolite phases in the CNKASH system. Based on phase relations in the albite-anorthite-quartz-H₂O system (Liou et al., 1991), heulandite + stilbite may coexist at 50–100 m depth at temperatures less than about 105 °C which is consistent with isotopic thermometry and inferences based on field observations.

Analytical and modeling results indicate that heated meteoric fluids reacted with basalt to produce an assemblage that at first was in equilibrium with basaltic glass, but later became more Al-rich indicating equilibrium with glass + plagioclase. It appears that as for the zeolite-calcite-silica occurrences of Iceland (Neuhoff et al., 1999), porosity is an important factor in determining which zeolite precipitates during low-grade alteration-metamorphism of basalt.

Chemical weathering, erosion, and CO\textsubscript{2} consumption in the southern Tibetan Plateau and Eastern Syntaxis of the Himalaya

MICHAEL T. HREN, C. PAGE CHAMBERLAIN, GEORGE E. HILLEY, PETER M. BLISNIUK AND BODO BOOKHAGEN

Stanford University, Dept. Geological and Env. Sciences, Stanford, CA 94305, USA (hren@stanford.edu, chamb@pangea.stanford.edu, hilley@stanford.edu, Blisniuk@stanford.edu, bodo@pangea.stanford.edu)

The Yarlung Tsangpo-Brahmaputra River drains a large portion of the Himalaya and southern Tibetan plateau, including the eastern Himalayan syntaxis, one of the most tectonically active regions on the globe. We measured the solute chemistry of 161 streams and major tributaries of the Tsangpo-Brahmaputra to examine the effect of tectonic, climatic, and geologic factors on chemical weathering rates. Specifically, we quantify chemical weathering fluxes and CO\textsubscript{2} consumption by silicate weathering in southern Tibet and the eastern syntaxis of the Himalaya, examine the major chemical weathering reactions in the tributaries of the Tsangpo-Brahmaputra, and determine the total weathering flux from carbonate and silicate weathering processes in this region. We show that high precipitation, rapid tectonic uplift, steep channel slopes, and high stream power generates high rates of chemical weathering in the eastern syntaxis. The total dissolved solids (TDS) flux from the this area is greater than 520 t km\textsuperscript{-2} yr\textsuperscript{-1} and the silicate cation flux more than 34 tons km\textsuperscript{-2} yr\textsuperscript{-1}. In total, chemical weathering in this area consumes 15.2 x 10\textsuperscript{5} mol CO\textsubscript{2} km\textsuperscript{-2} yr\textsuperscript{-1}, which is twice the Brahmaputra average. These data show that 15-20% of the total CO\textsubscript{2} consumption by silicate weathering in the Brahmaputra catchment is derived from only 4% of the total land area of the basin. Hot springs and evaporite weathering provide significant contributions to dissolved Na\textsuperscript{+} and Cl\textsuperscript{-} fluxes throughout southern Tibet, comprising more than 50% of all Na\textsuperscript{+} in some stream systems. Carbonate weathering generates 80 to 90% of all dissolved Ca\textsuperscript{2+} and Mg\textsuperscript{2+} cations in much of the Yarlung Tsangpo catchment.

Precipitation and aggregation of ZnS nanoparticles in the presence of low-molecular weight organic acids

HEILEEN HSU-KIM

Duke University, Civil & Environmental Engineering, Box 90287, Durham, NC 27708 (hsukim@duke.edu)

Introduction

ZnS and other metal-sulfide nanoparticles are known to exist as intermediates during precipitation and dissolution of their respective bulk mineral phases [1, 2]. However, the mechanisms that enable these nanoparticles to persist in surface waters and sediment porewaters are unknown. Humic substances and other hydrophilic organics can stabilize metal-oxide colloids in solution by adsorbing to particle surfaces and preventing aggregation [3]. This study seeks to identify whether similar processes occur for nanocolloidal ZnS.

Experimental Methods

The stability of aqueous ZnS nanoparticles was investigated by assessing the role of low-molecular weight organic ligands (oxalate, serine, cysteine, thioglycolate, and glycolate) during precipitation of ZnS. Zn(NO\textsubscript{3})\textsubscript{2} and Na\textsubscript{2}S were dissolved (2 μM each) in laboratory aqueous solutions buffered at pH 7.5 and containing one of the organic ligands. Particle formation and size was monitored over time by dynamic light scattering. Zn speciation was measured in filtered (<0.2 μm) ZnS solutions by anodic stripping voltammetry to confirm that Zn was coordinated to sulfide during the aggregation experiments and not in the form of dissolved Zn-organic complexes.

Results and Discussion

Observed growth rates of ZnS aggregates varied by orders of magnitude, depending on the type and concentration of organic ligand in solution. Growth rates were slowest in the presence of thiol-containing ligands: cysteine and mercaptoacetate. In contrast, ZnS aggregation rates were generally not affected by oxalate, serine and glycolate. These compounds contain hydroxyl, carboxylate, and/or amine functional groups. Thermodynamic stability constants for the Zn-thiol complexes are greater that those for the other Zn-organic complexes. Thus, slow aggregation of ZnS nanoparticles may be caused by specific attachment of the thiol on surface Zn sites. These results demonstrate a possible mechanism that stabilizes nanocolloidal metal-sulfides in the aquatic environment.

Distribution of Cesium sorption on micas and application on nuclear waste disposal

H. Hu1, R.C. Wang1, A.C. Zhang2 and S.J. Xu1

1State Key Laboratory of Mineral Deposit Research ,
Department of Earth Sciences, Nanjing University,
Nanjing 210093, China (huhuan@nju.edu.cn)
2Purple Mountain Observatory, Chinese academy of sciences,
Nanjing 210008, China (aczhang@pmo.ac.cn)

Introduction Cs is an important radionuclide in nuclear waste. It not only 135Cs is extremely long-lived (t1/2=2.0×106) and 137Cs is a major radioactive contaminant in high-level nuclear waste (HLW), but also exhibits almost unlimited solubility, so it is very necessary to find highly insoluble phases able to fix radionuclide Cs and to have a long-term stability in geological repositories.

Natural micas are important constituents of geological formations and they also contain elevated contents of Cs, therefore we tried to make cesium sorption experiments on micas and to evaluate the ability of micas to incorporate and retard radionuclide cesium.

Experiments Four different micas, such as muscovite, lepidolite, biotite and phlogopite were hand-picked from the pegmatite and granite samples. Micas that had not been exposed to CsCl solution were analyzed by EMPA, average Cs content of muscovite and lepidolite are very lower and respectively are 0.02wt% and 0.09wt%, Cs content of biotite and phlogopite all below detectable limit.

All minerals were processed by ultrasonically washing in deionized water before absorption experiments. Cesium-absorption experiments were performed by 0.1g samples of the reaction vessels with 20ml 0.1M CsCl solution for 7 days, 14day and 21days. No additional buffer was used. Treated slab samples was simply removed from the reaction vessels, then ultrasonically washing in deionized water and allow to air dry. Treated slabs were observed and analyzed by the EMPA method.

Conclusions 1) Cs content of all treated micas became higher than untreated samples, even in the treated biotite for 21days, Cs content up to 2.05wt%. These show that the four micas are able to fix radionuclide Cs in their interlayer structure and may be the possible stable waste disposal phases in the near field of geological barrier; 2) The distribution of Cs in micas was variable, Cs was preferentially sorbed where individual sheet boundaries were crude steps and abundant on these areas; 3) The ability of bonding of cesium is different. Ferriferous micas, such as biotite and phlogopite, are likely to be higher than muscovite and lepidolite. It indicates that biotite and phlogopite are good candidates for the storage of Cs.

Biogeochemical investigations of the Zunyi sedimentary Ni-Mo-PGE ores in the Lower Cambrian black shale formation, South China

K. Hu, S.P. Yao, J.Y. Pan, J. Cao and J. Zhou

Department of Earth Sciences, Nanjing University, Nanjing, 210093, China (kahu@nju.edu.cn)

The metalliferous black shales and their Ni-Mo-PGE ores can be traced across a broad region of South China, mainly south of the Yangtze River, extending a 1600 km belt of main provinces. The Lower Cambrian black shales that host the ores are approximately 60 to 150 m thick and include the Niutitang Formation of Guizhou and Hunan and stratigraphic equivalents elsewhere. The Ni-Mo ore bed itself varies in thickness from a featheredge to ~30 cm and consists largely of pyrite, apatite, vaesite, gersdorffite (NiAsS), and an amorphous Mo-S-C mixed-layer phase. Lots of organic matter, including algae and bacteria are abundant and constitute up to 10% of the ores, which may have played an important role in their formation.

Combined organic petrography, elemental and stable isotope (S) analyses of samples from the Lower Cambrian shale Ni-Mo-PGE ores of Zunyi provide insight into the relationship of organic matter-ores, biogeochemical alteration of hydrocarbons, microbial sulfate reduction, and mineral deposition. In the absence of vitrinite, relative thermal maturity were determined from the reflectance of bitumen, and marine kerogen like algal remains, Ro basically in range from 2.0 to 4.1%. Elemental analyses suggest that organic matter has been oxidized throughout the study area. The sulfur isotopic composition of the metal sulfides correlates with the degree of biodegradation of hydrocarbons, with the base-metal content and with the proportion of aromatics in the organic extracts. Sulfur isotopes study shows that micro-organism took active part in the re-enriching processes of metal sulfide, barite and witherite during digenesis. Variation of conventionally determined δ34S values are great, ranging from +25‰ to -12‰ for samples from the study area in Zunyi. Individual nodules also show large variations in the drilled sulfide data of up to 15.7‰ between rims and cores of sulfide ore nodules. The high variation in isotopic fractionation of the ores may reflect the varying proportions of different sulfide minerals. On the other hand, Extreme variation of δ34S values during the formation of the Ni-Mo sulfide ores could have been caused by the effects of both biogeochemical and hydrothermal activity during the formation of these unusual ores.

Funding for this investigation was provided by NSF of China grants 40638042 and 40572056.
Geological and geochemical constraints on the origin of the giant Lincang coal seam-hosted germanium deposit, Yunnan, SW China

RUIZHONG HU1, HUAWEN QI1, MEI-FU ZHOU2, WENCHAO SU1, XIANWU BI1 AND JIANTANG PENG1
1The State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China (huruizhong@vip.gyig.ac.cn)
2Department of Earth Sciences, the University of Hong Kong, HK, China

The Lincang germanium deposit in Yunnan, SW China, contains at least 1000 tones of Ge at an average grade of ~850 ppm Ge, being one of the largest germanium deposits in the world. The deposit is hosted in coal seams of the Miocene Bangmai Formation deposited on a Ge-rich granitic batholith. The Bangmai Formation is divided into eight units among which three units are coal-bearing. The Ge-bearing coal seams are inter-layered with siliceous rocks and siliceous limestones in the basal coal-bearing unit. The coal seams of the other two coal-bearing units are not inter-bedded with siliceous rocks and siliceous limestones, and are barren. Equant or elongated germanium ore-bodies are mainly distributed at fault intersections, and are located at the top and bottom of coal seams where they mainly contact with the layered siliceous rocks or siliceous limestones. Ge is mainly associated with organic matters of coal seams. The major and trace elements, O- and C-isotopes of the siliceous rocks and siliceous limestones, the major and trace elements, and O- and C-isotopes of the siliceous rocks and siliceous limestones are similar to those of hydrothermal sediments, indicating formation by hydrothermal sedimentation. Compared with barren coals, Ge-rich coals are notably rich in Nb, Li, Sh, W, Bi and U and show substantial enrichment of HREE which increase with Ge. Ge-rich coals have the vitrinite reflectance generally higher than barren coals. They contain disseminated pyrites with δ34S from 17.2‰ to 51.4‰, similar to the pyrites in barren coals, and thin vein-like pyrites with δ34S from 1.9‰ to -5.4‰, similar to the sulfides in granite-related quartz veins. We propose that circulating hydrothermal fluids leached abundant Ge and other elements from Ge-rich granite in the basement, and then discharged into the basin mainly along fault intersections to form layer-like siliceous rocks and siliceous limestones by depositing Si and Ca, and to form germanium deposit through interaction between germanium in the fluids and organic matters in coal seams.

Oxygen and carbon isotope composition and implication of Early Palaeozoic dolomites in Keping, Tarim Basin

WX HU, XM XIE, JT ZHANG AND XL WANG
Department of Earth Sciences, Nanjing University, Nanjing 210093, China (huwx@nju.edu.cn)

In order to approach to the formation environment and fluid condition, carbon and oxygen isotopes are analyzed of Early Palaeozoic dolomite sequences in Keping, northwest of Tarim Basin, for the dolomite sequences are important reservoir rocks in the basin.

104 field dolomite samples were collected from the outcrop of Early Palaeozoic in Keping. This outcrop is consisted of algal dolomite, bedding dolomite, calcareous dolomite, and some limestone. Evaporates and many siliceous aggregates were found in the middle Cambrian, which might be related to special environments. In order to figure out variations of the isotopes in the samples with different composition and texture, micro-area sampling was conducted by Hand Grinder with 1mm in diameter. The analysis was performed on CF-IRMS in Nanjing University.

The isotopic result is mainly consistent with ancient seawaters of that age. The δ13C of the samples ranges from -1.6‰ to 1.6‰, with an average of 0.515‰, and the δ18O from -12.7‰ to -5.7‰, with an average of -7.23‰. The δ18O varies larger in different samples than the δ13C, and the δ18O become depleted with increasing ages. The δ13C and δ18O have relatively lower values in middle Cambrian dolomites. But they rise to -1‰ and -7‰, respectively, and become relatively stable in upper Cambrian and Ordovician dolomites. In addition, the obvious variation of the isotopes can be found between different algal dolomite layers in middle Cambrian, but such a variation becomes small in the younger algal dolomites in upper Cambrian and Ordovician.

The depleted δ18O in middle Cambrian, most less than -10‰, is likely related to hydrothermal activity. On the other hand, evaporation process during middle Cambrian could make the δ13C and δ18O of the seawaters enriched, and the δ13C and δ18O rise in the related dolomites. Because the above two aspects had different constraints on the variation of the isotopes in the seawater, the δ13C and δ18O of middle Cambrian dolomites go up and down frequently. There was no effect of hydrothermal fluids and evaporation process in upper Cambrian and early Ordovician, and little variation of the δ13C and δ18O can be seen of the younger dolomites, just showing δ13C of about -1% and δ18O of about -7‰ consistent with the seawaters at that ages.

Effect of geologic and biologic cycling on Se variability in a soil ecosystem with high level of nonagenarians

BIAO HUANG, WEIXIA SUN AND YONGCUN ZHAO
State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, P.O. BOX 821, Nanjing, 210008, China (bhuang@issas.ac.cn)

Introduction
The spatial variability of Se in soils is affected by geologic and biologic cycling and has the potential to induce human health problems through food chains. The objectives of this study were to determine the effect of sedimentation and pedogenesis on the spatial variability of Se in an agriculturally soil ecosystem with high level of centenarians in Rugao County, Jiangsu province, China and discuss the Se bioavailability to rice and human longevity.

Materials and Methods
342 surface soil samples and 9 of soil profiles in the studied area with 1,450 km² of land area and 1.54 million populations were taken. Total and water soluble Se (H₂O-Se) in profile soil samples were determined using atomic fluorescence spectrometer (AFS). 97 of rice grain and drinking water samples were taken for Se determination using AFS. The ratio of population of nonagenarians over total population (90-rate) was calculated using the data of the national census in 2002.

Results and Discussion
The results showed that the total Se concentrations (0.127±0.021 mg kg⁻¹, n=203) had a narrow variation in topsoils derived from paleo-alluvium, lacustrine deposits or neo- alluvium, while H₂O-Se (2.42±1.09 µg kg⁻¹, n=342) had a wide variation among the soils derived from different parent materials. The concentrations of H₂O-Se in the soil series on lacustrine deposit with fine texture and long-term development were greater than those on paleo-alluvium with long-term development but coarse texture or neo-alluvium fine texture but short-term development. Increased H₂O-Se in the topsoil of soils was, in part, related to the changes of soil properties due to weathering, pedogenic processes, and human activities. Correlation analysis between Se in the soils and rice Se or 90-rate in the study area showed that H₂O-Se in topsoil had a significant relationship with rice Se or the 90-rate at village level (p<0.01), but total Se had no any relationship between them (p>0.05). Similar variation of Se in drinking water to H₂O-Se in soils was found as well.

Conclusions
In conclusion, the geologic and biologic cycling in the studied area didn’t cause the significant variation of total Se in soils, but significantly affected the variation of H₂O-Se in soils, and further Se uptake by crops, Se in ground water, and human health. It suggested that H₂O-Se in soils of the agricultural ecosystem might be one of the most important geochemical factors affecting human health or longevity.

Mg and Fe isotopes as tracers of temperature gradient driven diffusive differentiation

F. HUANG, C.C. LUNDESTROM AND A.J. IANNO
Dept. of Geology, University of Illinois, Urbana-Champaign, Urbana, IL 61801, United States (fhuang1@uiuc.edu, lundstro@uiuc.edu, and ianno@uiuc.edu)

The development of high precision MC-ICP-MS has led to breakthrough observations which have fundamentally called into question our current understanding of melt-mineral equilibrium and chemical differentiation processes. Although the mafic terrestrial igneous earth appears to have a near constant Fe isotopic composition with δ⁵⁶FeIRMM of ~ 0.07‰, a majority of granites and rhyolites with SiO₂ content > 71 wt.% have a significantly heavier Fe isotope signature than the mean mafic earth with δ⁵⁶FeIRMM up to 0.4% (e.g. [1]). This has generated vigorous debate [2], since the origin of Fe isotope variation with differentiation remains unclear.

A thermal migration experiment using wet andesite (AGV-1) along a temperature gradient from 950°C to 350°C over 2 cm in a 3/4” piston cylinder apparatus for 66 days at 0.5 GPa produces silicic solid, melt + solid, and more mafic melt from the cold bottom to the upper top of the charge, respectively. Major-trace elements and mineralogy vary with temperature due to temperature gradient driven chemical differentiation (thermal migration). Most importantly, Fe-Mg isotopes of the experiment vary consistently as a function of position. The bottom solid portion does not deviate significantly from the starting material, AGV-1. However, the heavy isotopes of Mg and Fe are depleted in melt at the hot end and enriched in the middle melt + solid portion. δ⁵⁶FeIRMM and δ⁵⁶MgIRMM vary by 2.8‰ and 9.9‰, respectively. These total variations in Fe-Mg isotopes are much greater than those observed in the terrestrial igneous Earth. These variations are not caused by kinetic diffusion or equilibrium isotope fractionations. Instead, they appear to result from Soret diffusion, in which light isotopes are known to be enriched in the melt + solid portion. These total variations in Fe-Mg isotopes are much greater than those observed in the terrestrial igneous Earth. These variations are not caused by kinetic diffusion or equilibrium isotope fractionations. Instead, they appear to result from Soret diffusion, in which light isotopes are known to be enriched in the melt + solid portion. These total variations in Fe-Mg isotopes are much greater than those observed in the terrestrial igneous Earth. These variations are not caused by kinetic diffusion or equilibrium isotope fractionations. C and S isotope records in Doushantuo Formation: Implication for Redox Fluctuation of the Ediacaran Ocean

J. HUANG AND X. CHU

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China
(jhuang@mail.iggcas.ac.cn; xchu@mail.iggcas.ac.cn)

Carbon and sulfur isotope evidence from Oman and iron speciation data from Newfoundland suggested a stepwise oxidation of the Ediacaran ocean from ca. 635 Ma to ca. 542 Ma (Fike et al., 2006; Canfield et al., 2007). New isotope data obtained from the Ediacaran Doushantuo Formation, however, reveal alternative oxidation events from ca. 653 Ma to ca. 551 Ma that suggest stepwise oxidation of the Ediacaran ocean, with significant ocean anoxia following each oxidation event. No Δδ34S values exceed 46‰ in the Doushantuo Formation, indicating the absence of sulfur disproportionation before 551 Ma and a complete oxidation of deep oceans did not occur until the latest Ediacaran or early Cambrian. Our data of δ13Corg, δ13Ccarb, δ34SCAS, and δ13S provide an alternative environmental interpretation for the evolution of early animal life and subsequent Cambrian explosion.

Increases of δ13Ccarb and Δδ34S, with occurrence and diversification of Doushantuo-Pertatataka acritarchs (DPA), in the lower and middle Doushantuo Formation after the Nantuo (or Marinoan) glaciation indicate the first oxidation event to cause oxic water column in the shelf. Constant δ13Ccarb values (down to –29‰) with variable δ13Corg (–6.93‰ ~ +6.17‰) are consistent with the existence of DOM (dissolved organic matter) rich deep-ocean. Following negative shifts in δ13Ccarb (down to –9.62‰) and δ34SCAS (down to +9.5‰), a temporary anoxia occurred between the middle and upper Doushantuo Formation that is concordant with DPA’s extinction. Another oxidation in the upper Doushantuo Formation, where multicellular, macroscopic algae (the Miaohu biota) were found. The prominent negative δ13Ccarb (down to –8.98‰) excursions and associated decline of δ34SCAS (from +43.5‰ to +10.2‰) imply both oxidations of DOM and sulfide from anoxic water column of deep-ocean. Unusually low δ13Corg values (down to –38‰) and increasing δ13Ccarb (from –8.16‰ to –2.00‰) in the uppermost Doushantuo Formation (ca. 551 Ma) suggest involvement of anaerobic methane oxidation, possibly associated with the upwelling of anoxic deep-ocean seawater. Eventually, another anoxia possibly occurred at the near Dengying-Doushantuo boundary.

Geochemical structure of the Hawaiian plume: Inferences from Mahukona volcano

S. HUANG1, W. ABOUCHAMI2, J. BLICHERT-TOFT3, D.A. CLAGUE4, B.L. COUSENS5 AND F.A. FREY6

1Florida State University, USA (huang@magnet.fsu.edu)

3Ecole Normale Supérieure de Lyon, France
4Monterey Bay Aquarium Research Institute, USA
5Carleton University, Canada
6Massachusetts Institute of Technology, USA

Young, <2Ma, Hawaiian volcanoes define two parallel spatial trends, Loa and Kea. Most Loa- and Kea-trend shield lavas are geochemically distinct in major and trace element compositions and radiogenic isotopic ratios. Lasiter et al. (1996), among others, proposed a radially concentrically zoned plume with Loa shields forming closer to the plume center than Kea shields. Abouchami et al. (2005) proposed that Pb isotopic ratios are the best Loa-Kea discriminant, e.g., Pb/206Pb* > 0.95 for Loa lavas; they proposed a bilaterally asymmetrically zoned plume with geochemical differences between the northeast and southwest halves of the plume. These models are oversimplified because they do not consider local (Ren et al., 2005) or vertical heterogeneities (Blichert-Toft et al., 2003) in the plume; nevertheless the alternative large-scale zonation models can be evaluated with geochemical data for shields formed at varying distances from the plume center; e.g., Bryce et al. (2005) suggested that when active the submarine Mahukona volcano was southwest of the current location of Mauna Loa, a Loa-trend volcano; hence Mahukona lavas should be Kea-like in the concentrically zoned model and Loa-like in the bilaterally zoned model.

We report major and trace element compositions, Pb and Hf isotopic ratios for 18 Mahukona lavas; these include three transitional to slightly alkaline basalts from the large 125–350 m cones that may represent preshield lavas based on their 3He/4He ratios of ~20 R/Ra (Garcia et al., 1990). Consistent with this inference, the cone samples overlap with the distinctive Pb isotopic field defined by preshield lavas from Loihi seamount. All other Mahukona lavas are tholeiitic basalt that define three groups based on CaO content at a given MgO content. The high CaO group, >12%, has unusually low 206Pb/204Pb (<18.0) and may be derived from a peridotite source (Herzberg, 2006). All other tholeiitic lavas straddle the Loa-Kea boundary in Pb isotopic space with 206Pb/204Pb* between 0.940 and 0.951 compared to the range of 0.947 to 0.956 for Mauna Loa lavas. In a 176Hf/177Hf vs 206Pb/204Pb* plot (Huang et al., 2005), the inverse trend of Mahukona lavas also straddles the Loa-Kea boundary. Their Zr/Nb ratios (12.1-14.8), another Loa-Kea discriminant, are also at the Loa-Kea boundary. Clearly, Mahukona tholeiitic basalt has a weaker Loa geochemical signature than Mauna Loa lavas. This result may require modification of the simple large-scale zonation models.
Inter-diffusion of Mg/Ca in synthetic polycrystalline carbonates at elevated temperature and pressure

WUU-LIANG HUANG

Department of Geosciences, National Taiwan University, Taiwan, R.O.C (wlhuang@ntu.edu.tw)

The transport rates of MgCO$_3$ from dolomite into calcite were measured within synthetic dry dolomite-calcite polycrystalline aggregate at 1.6 GPa and isothermally at 800, 850, and 900 °C over different run durations. Aragonite in the starting dolomite-aragonite aggregate was first transformed rapidly to calcite, which, then, reacted with dolomite to form Mg-calcite progressively rich in Mg at slower rates.

The average contents of Mg in calcites determined by XRD increase with run time, which can be described empirically by the first-order rate law. The temperature dependence of the overall transport rate of MgCO$_3$ from dolomite into calcite can be estimated by the kinetic parameters ($E = 231$ kJ and $A_0 = 22.7$ hr$^{-1}$). The extrapolation using the Arrhenius equation to the prograde metamorphic conditions reveals that the formation of Mg-calcite saturated with Mg from dolomite-calcite aggregate in the absence of metamorphic fluid may not completed at temperatures below 600 °C over different run durations. Aragonite in the starting dolomite-aragonite aggregate was first transformed rapidly to calcite, which, then, reacted with dolomite to form Mg-calcite progressively rich in Mg at slower rates.

The extrapolation of the rate to the conditions during exhumation of UHPM rocks, at which the P-T path entered calcite stability field from dolomite-aragonite field, indicates that the reaction of dolomite with calcite can be completed in a geologically short period (< 1 my).

The SEM-EDS analysis of individual calcite grains shows that the Mg contents in calcite grains progressively decrease with increasing the distance from dolomite-calcite grain boundary, suggesting a diffusion control of the reaction. The Mg/Ca inter-diffusion coefficient at 850 °C calculated using the diffusion equation is around 3 x 10$^{-16}$ m$^2$/sec. The calculated closure temperatures for Mg/Ca inter-diffusion as a function of cooling rate and grain size in calcite reveal that the Ca/Mg resetting in calcite in dry polycrystalline carbonate aggregate may not occur at temperatures below 600 °C at geological cooling rate (> 100 °C/my), unless other processes were involved.

Pressure dependence of viscosity of hydrous rhyolitic melts

HEJU HUI, ZHENGJU XU AND YOUXUE ZHANG

Department of Geological Sciences, The University of Michigan, Ann Arbor, MI 48109-1005, USA (huih@umich.edu; zhengjiu@umich.edu; youxue@umich.edu)

Knowledge of viscosity of silicate melts is critical to the understanding of igneous processes. Numerous viscosity measurements have been carried out on the natural and synthetic silicate melts under ambient pressure, but only a few investigations have examined the pressure dependence of viscosity of silicate melts. “Hydrous species reaction viscometer” (Zhang et al., 2003) based on the concentrations of two hydrous species in the melts after a known cooling history is applied to investigate pressure dependence of viscosity of hydrous rhyolitic melts at near glass-transition temperatures.

The samples used here are natural obsidian glass with about 0.85 wt% water and hydrated natural obsidian glasses with higher water contents (2 wt% and 4 wt%). The experiments were conducted in piston cylinder apparatus at 1, 2 and 3 GPa. A prerequisite for viscosity inference with this “viscometer” is to know the temperature dependence of the equilibrium constant $K$ of the interconversion reaction at a given pressure. Hence, pressure dependence of the speciation of dissolved water in these samples was investigated. Comparing with speciation model at ambient pressure (Ihinger et al., 1999), equilibrium constant changes with pressure nonlinearly, decreasing from 0.1 MPa to 1 GPa and then increasing from 1 GPa to 3 GPa.

Cooling rates varied from ~ 100 K/s to 0.1 K/s in the cooling-rate experiments. Viscosity (in Pa·s) at the apparent equilibrium temperature of the hydrous species reaction (i.e., glass transition temperature) is obtained as 10$^{11.45/q}$ where $q$ is cooling rate in K/s. So the total range of viscosity inferred from this method in this study is 3 orders of magnitude. Preliminary results show that viscosity of hydrous rhyolitic melts increases by about 1.4 log unit from 0.1 MPa to 3 GPa. The behavior of viscosity as a function of pressure for hydrous rhyolitic melts with water content of 0.8 wt% or more at low temperature range is similar to that of depolymerized melts.

Nucleation, growth, and phase transformation of titanium oxides in hydrothermal solution

D.R. Hummer1, P.J. Heaney1, J.D. Kubicki1 and J.E. Post2

1Department of Geosciences, The Pennsylvania State University (dhummer@geosc.psu.edu; heaney@geosc.psu.edu; kubicki@geosc.psu.edu)
2Department of Mineral Sciences, The Smithsonian Institution (postj@si.edu)

Fine grained titanium oxide minerals are environmentally important in soils, where they take part in a variety of geochemical processes. They are also industrially important as catalysts, pigments, food additives, and dielectrics. Recent research efforts have focused on an apparent reversal of thermodynamic stability between TiO2 phases at the nanoscale that may be caused by the increased contribution of a surface energy term to the total free energy. We have performed time-resolved X-ray diffraction experiments at the National Synchrotron Light Source (NSLS) at Brookhaven National Labs (BNL) in which titanium oxides crystallize from aqueous TiCl4 solutions between 100 and 200 °C, as diffraction patterns were collected at intervals of ~ 4 minutes. These experiments confirm that anatase is the first phase to nucleate from solution within the first ~ 20 minutes of heating, and then slowly begins converting to rutile. Whole pattern refinement of diffraction data reveals that lattice constants systematically change during particle growth for both phases throughout the crystallization process. The unit cell dimensions eventually converge to values close to those of the bulk phases.

Using the Vienna Ab-initio Package Simulation (VASP) with soft pseudopotentials, we modeled the energetics of bulk anatase and rutile using our refined structures of the evolving nanoparticles. The density functional theory (DFT) calculations indicate that the change in free energy between the incipient nanoparticles and bulk crystals was on the order of 0.5 kJ/mol for each phase, as compared to the 9 kJ/mol difference in free energy of formation between the two phases. To the extent that the structures of the nanoparticles that first nucleate in our experiments reflect the surface structures of bulk anatase and rutile, our results indicate that the energetics of the bare surface do not dictate the relative stabilities of nanoparticulate anatase and rutile.

Predicting Raman spectra of aqueous silica and alumina species in solution from first principles

J.D. Hunt, E.A. Schauble and C.E. Manning

Dept of Earth and Space Sciences, UCLA, Los Angeles, California (jhunt@ess.ucla.edu)

Dissolved silica and alumina play an important role in lithospheric fluid chemistry. Silica concentrations in aqueous fluids vary over the range of crustal temperatures and pressures enough to allow for significant mass transport of silica via fluid-rock interaction. The polymerization of silica and alumina could afford crystal-like or melt-like sites to otherwise insoluble elements such as titanium, leading to enhanced mobility. Raman spectroscopy in a hydrothermal diamond anvil cell has been used to study silica polymerization at elevated pressure and temperature [1, 2], but Raman spectra of expected solutes are not fully understood. We calculated Raman spectra of H4SiO4 monomers, H6Si2O7 dimers, and H6SiAlO7 dimers, from first principles using hybrid density functional theory (B3LYP). These spectra take the variation in Si-O-X bridging angle that the dimers will have at a given temperature into account, thereby broadening the main dimer peak. Solution effects are incorporated in two separate ways - by using a polarizable continuum model and adding explicit water molecules. Both methods are in excellent agreement with each other. However, the results are in contradiction with earlier results based on gas phase models, in which the bridging angle variation broadens the 630 cm⁻¹ silica dimer peak enough to explain the broad peak observed at high temperatures. In the solution phase, whether by a polarizable continuum model or adding explicit water molecules, the peak is not broadened enough to explain experimental results. The observed broadness, therefore, is most likely caused by additional, higher order polymers that have peaks within the broad observed peak. Ring polymers in particular may provide much of the observed broadness. The synthetic spectrum of the silica-alumina dimer suggests that there may be a higher ratio of complexed alumina to free alumina in solution at highly basic pH than previously estimated [3].

Paleoaltimetry from “clumped” $^{13}$C-$^{18}$O bonds in carbonates, Colorado Plateau

KATHARINE HUNTINGTON, BRIAN WERNICKE AND JOHN EILER

$^{1}$California Institute of Technology, Pasadena CA, 91125 (kateh@gps.caltech.edu; brian@gps.caltech.edu; eiler@gps.caltech.edu)

The elevation history of Earth’s surface is a key element linking tectonic, geodynamic, climatic, and surface processes, but remains difficult to reconstruct from the geologic record. In contrast to conventional stable isotope paleoaltimetry approaches, the new “clumped” $^{13}$C-$^{18}$O paleothermometer independently determines carbonate growth temperature and the $\delta^{18}$O of water from which the carbonate grew, potentially enabling the effects of altitude, climate, and seasonality to be distinguished. This approach has been successfully applied to paleosol nodules. Here, we examine what other materials may potentially access paleoelevation information using this technique, including gastropods, the bivalve anomia, oysters, barnacles, soil, marl, and limestone from Cretaceous to Pliocene deposits from and adjacent to the Colorado Plateau, southwestern USA.

The abundance of $^{13}$C-$^{18}$O bonds in diverse carbonate materials from related sediments records temperatures between 20-84°C and $\delta^{18}$O$_{\text{smow}}$ water values of -2 to 12‰. Temperature estimates for independent preparations of the same sample are reproducible to within ±0.55-2.2°C (2 s.e.), and average temperatures determined for different materials from the same deposit exhibit negligible variations (±0.05°C).

While samples at the lower end of the observed temperature range represent reasonable Earth surface conditions that may be interpreted in terms of paleoelevation, samples yielding temperatures in excess of ~33°C likely provide a record of carbonate recrystallization/replacement during burial metamorphism (“resetting”). Clear examples of resetting include gastropod fossils in which original aragonite is completely replaced by calcite (yielding apparent temperatures of 76.5±1.7°C) and a suite of more cryptically reset Pliocene molluscs from tidal flat facies that yield temperatures of >42°C. Most apparently unreset samples are fine-grained (impermeable) micrites, which consistently yield temperatures within the plausible Earth-surface range. This suggests that resistance to diageneis is grain size dependent – a promising result given the abundance of well preserved fine-grained lacustrine and marine carbonates found throughout the geologic record. Results for micritic carbonates from Middle Miocene to Pliocene age record reasonable spring to summer depositional temperatures and oxygen isotopic values relative to modern lake waters on the Colorado Plateau.

Simulations of dry-out and halite precipitation due to CO$_2$ injection

S. HURTER, D. LABREGERE AND J. BERGE

Schlumberger Carbon Services, La Defense, France (SHurter@slb.com, DLabregere@slb.com, JBerge@slb.com)

Although CO$_2$ is not very soluble in supercritical CO$_2$, a continuous stream of CO$_2$ being injected into a formation, will result in a region around the injection well to dry out. As the water of the formation brine is continuously extracted, the irreducible water saturation may attain practically zero. Enhanced injectivity is the result in a low salinity brine environment. In formations saturated with highly saline brine (e.g. Northern German Basin) the outcome is opposite: injectivity is impaired. In this case, the brine becomes supersaturated as continuously H$_2$O evaporates into the CO$_2$ phase and salt (halite) precipitates in the pores. The porosity and permeability diminish, which can lead to the loss of a injection well.

We present simulations of these processes as an example of pre-injection study for a CO$_2$ injection and storage site. The simulation tool consists of a commercial compositional code used extensively in the oil and gas industry to simulate the flow of multiple phases (oil, water, gas) in porous or fractured media. The mutual solubility of CO$_2$ and H$_2$O with a correction for salinity is implemented as described in Spycher and Pruess (2005). The brine salinity is adjusted accordingly until the saturation threshold is reached and halite is precipitated. The severity of this process can be evaluated for a specific site and also remediation strategies (injection of dilute fluids) tested.

Method measurement of Ar isotopes in He stream (conflo) for K/Ar geochronology

A.V. IGNAUTIEV, T.A. VELEVETSAYA and S.Y. BUDNITSKIY

Far East Geological institute, FEB RAS, Vladivostok, Russia (ignatiev@fegi.ru)

Mass-spectrometric methods of measurement of Ar isotopes for K/Ar geochronology after of some key development (Inghram et al., 1950, Standacher et al., 1978) are developed on a way of perfection low background equipments. Achievement low background conditions measurement of Ar isotopes is extremely a challenge, requires greater efforts and a lot of time. Here, we report a new laser GC-MS method that incorporates helium carrier gas and chromatography methods (conflo) that allow for rapid analyses for small samples. The Ar gas is swept into the mass spectrometer in a helium carrier gas, allowing for extremely small samples to be quantitatively transferred (<5 .10-13g). The laser GC-MS technique consists of six components: the overall high vacuum extraction line, the system of input tracer 38Ar, the sample chamber, the laser, the gas chromatograph, the interface to the mass spectrometer and the mass spectrometer via a split interface (Matthews, Hayes, 1978). To separate the Ar from any other gas, and admitted into the mass spectrometer, Extracted Ar together with tracer (38Ar – 0.5105g) passes through U-shaped a trap (T =196) and is adsorbed onto activated coal in a loop at temperature of liquid nitrogen. He is passed through the loop (He, 99.9999%) and the loop is heated up to 100°C. The Ar gas is entrained in a helium stream (1-2 mL He/min), passes through the gas chromatograph to separate the Ar from any other gas, and admitted into the mass spectrometer via a split interface (Matthews, Hayes, 1978). To separate the Ar from other gas we use the capillary chromatographic column (HP-MOLSIV). Samples are analyzed using a dynamically pumped mass spectrometer. In general, Ar extraction by laser can be made every 15-20 min. The laser GC-MS system has been used successfully to analyze samples containing <510-13 g. Ar. Smaller samples can be analyzed with the use electron multiplier for 38Ar. Laser GC-MS method may be used and for 40Ar/38Ar geochronology.

On the nebular origin of water in the Earth

MASAHIRO IKOMA1 AND HIDENORI GENDA2

1Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan (miikoma@geo.titech.ac.jp)
2Research Center for the Evolving Earth and Planets, Tokyo Institute of Technology, Tokyo, Japan (genda@geo.titech.ac.jp)

Although the chondritic or cometary origin of water in the Earth has been widely accepted, we explore another possibility that the Earth acquired water from the solar nebula. Several recent theories of the final assembly of the terrestrial planets in the solar system (e.g., Kominami and Ida 2002; Nagasawa et al. 2005) suggest that there existed the nebular gas until the formation of the terrestrial planets was completed. When that is the case, the planets collect large amounts of hydrogen from the solar nebula.

Our simulations of the structure of the atmosphere on terrestrial planets embedded in the solar nebula (Ikoma and Genda 2006) demonstrate that the planet’s surface temperature is rather insensitive to the parameters and almost always higher than the melting temperature of silicate. In that situation the atmospheric hydrogen efficiently reacts with oxides contained in the magma ocean to produce water on the planet. From the chemical equilibrium constants (Robie et al. 1978), we find it possible that the reaction yields water comparable in mass to hydrogen. Although the exact amount of hydrogen that the primitive Earth acquired is unable to be determined at present because of the uncertainties in the heat flux and the grain abundance in the primitive atmosphere, our simulations show that production of water comparable in mass to the Earth’s current sea water is possible for wide ranges of the values of the quantities.

We have also tackled the well-known problem of the discrepancy between the D/H ratios of the Earth’s current sea water and the nebular gas (e.g., Drake and Righter 2002). We have simulated the evolution of the D/H ratio of sea water in the case the Earth had a relatively massive hydrogen atmosphere, which was neglected by previous studies, and found that the D/H ratio of the sea water increases by a factor of 3 to 9, depending of the escape rate of the atmospheric hydrogen (Genda and Ikoma 2007); this is consistent with the current D/H ratio of the Earth’s sea water.

In the presentation we will discuss the advantages and disadvantages of the nebular hypothesis about the origin of water in the Earth.

Time-series analysis of Magnesium isotopes in speleothems

A. IMMENHAUSER, D. BUHL AND D. RICHTER
Ruhr-Universität Bochum, Institute for Geology, Mineralogy and Geophysics, Universitätsstrasse 150, D-44801 Bochum, Germany (adrian.immenhauser@rub.de)

Magnesium-isotope time series MC-ICP-MS analyses from NW Africa (Morocco) speleothems are reported. In addition, high-resolution C, O and Sr-isotope data, and Mg and Sr element abundances were compiled. The analytical results show clearly co-variant, systematic and cyclical fluctuations for all proxies collected along the growth axis and - with respect to the analytical error - invariant data within one growth increment. Magnesium-isotope ratios ($\delta^{26}\text{Mg}$) fluctuate between -4.39‰ ± 0.02σ and -4.17‰ ± 0.05σ. The difference of 0.22‰ is significantly beyond the error of the external reproducibility of ± 0.03‰ σ for $\delta^{26}\text{Mg}$. Considering the analytical error, neither a purely kinetic nor an equilibrium fractionation process explains the observed isotope pattern. Two external factors might drive the speleothem Mg-isotope cyclicity: (1) climate-driven (arid versus humid) variances in the precipitation rate of a carbonate phase from meteoric water; and (2) changing rates of silicate versus carbonate weathering. Both of these processes fractionate the Mg-isotopic composition of runoff/seepage water.

Fractionation of iron isotopes in shallow-marine ferromanganese concretions

J. INGRI1, I. RODUSHKIN1,2, D. MALINOVSKY1, U. HÄLENIUS3, D.C. BAXTER2 AND P.S ANDERSSON4
1Division of Applied Geology, Luleå University of Technology, SE-971 87 Luleå, Sweden
2ALS Analytica AB, Aurorum 10, SE-977 75 Luleå, Sweden
3Department of Mineralogy, Swedish Museum of Natural History, Box 50007, SE-104 05 Stockholm, Sweden
4Laboratory for Isotope Geology, Swedish Museum of Natural History, Box 50007, SE-104 05 Stockholm, Sweden

Fe-isotope data for ferromanganese concretions indicate a trend from positive to negative values going from the freshwater environment, via the Arctic Ocean to the Atlantic and Pacific Ocean nodules, possibly following the redox related separation pathway of Fe from Mn in the exogenic cycle. However, the database is still small and additional Fe-Mn concretion data is needed, especially from continental margins, to verify if such a trend exists.

Shallow marine Fe-Mn concretions from the Baltic Sea and the Barents Sea analysed in this study show large variations in $\delta^{56}\text{Fe}$, from -1.55 to +1.0, thus spanning the whole range of $\delta^{56}\text{Fe}$ values presented so far for ferromanganese concretions. There are also large variations in $\delta^{56}\text{Fe}$ in concretions from the same area. Large positive $\delta^{56}\text{Fe}$ values are obtained only close to the reduced-oxidised interface in the sediment. Samples taken at some distance from the reduced-oxidised interface with low Fe/Mn ratios generally show negative values. It can be concluded that the local redox conditions strongly influence the Fe-isotope signal in the concretions.

This study indicates that dissolved heavy Fe-isotopes preferentially are trapped close to the reduced-oxidised interface and any dissolved Fe that might escape from the sediment up into the bottom water during early diagenesis should have a clear negative $\delta^{56}\text{Fe}$ value. Hence, early diagenetic cycling of Fe-oxyhydroxides in shallow marine sediments acts as a sink for heavy Fe-isotopes and as a source of lighter ones.
A U-series study on groundwaters from southwestern France

C. INNOCENT AND PH. NEGREL

BRGM – MMA/ISO, 3 avenue Claude Guillemin, BP 6009, 45060 Orléans cedex 2, France (c.innocent@brgm.fr; p.negrel@brgm.fr)

U-series have been investigated in groundwaters from one demonstrative water body named the Eocene sands aquifer (Adour-Garonne district, southwestern France). This work was done in the framework of a research project (CARISMEAU, Négrel et al., 2007), related to the UE Water Framework Directive (WFD, 2000/60/EC). The Eocene sands aquifer extends north and south of the Garonne River. Groundwaters have been recovered both in spring and fall, in order to check for seasonal variations.

The $^{234}$U/$^{238}$U activity ratios are in any case higher than 1 (equilibrium value), some of them being very enriched in $^{234}$U (up to 11 in the northern part). Only slight isotopic variations of the $^{234}$U/$^{238}$U activity ratios have been evidenced between spring and fall waters. In the southern part, the highest $^{234}$U/$^{238}$U activity ratios correlate roughly with the oldest measured $^{14}$C ages (> 25 ka, André et al., 2005) while recharge areas have the lowest $^{234}$U/$^{238}$U activity ratios, closer to the equilibrium value. Hence it is not possible to apply a "simple" model featuring a decay of excess $^{234}$U through time during groundwater circulation to put chronological constraints on the residence time of waters in the aquifer.

Thorium isotopes have been measured successfully in some of these groundwaters, due to recent analytical improvements in Th isotopic analysis (Innocent et al., 2006). $^{230}$Th/$^{232}$Th activity ratios range between 0.4 ($^{230}$Th deficit) and 9.2 (large $^{230}$Th excess). $^{230}$Th/$^{234}$U activity ratios are very low ($\leq 0.01$), except for recharge areas (0.6). High $^{230}$Th/$^{232}$Th roughly correlate with $^{234}$U/$^{238}$U close to the equilibrium. A open-system model, combining these three activity ratios is presented, potentially constraining groundwater residence times in the aquifer.

Spatial and temporal variation of anthropogenic lead inputs to the western Pacific

MAYURI INOUE1 AND MASAHARU TANIMIZU2

1Ocean Research Institute, The University of Tokyo, 1-15-1 Minamidai Nakano-ku, Tokyo 164-8639, Japan (mayuri-inoue@ori.u-tokyo.ac.jp)

2Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, Monobe-B 200, Nankoku, Kochi 783-8502, Japan (tanimizum@jamstec.go.jp)

A continuous record of anthropogenic lead affecting on the western Pacific has been less studied compared to the North Atlantic. In this study, Pb contents and isotopic compositions in the annually banded coral (Porites sp.) from Ogasawara, Japan was used for reconstruction of Pb variation since the late 19th century. We also determined Pb in corals collected from several sites in the western Pacific to examine spatial distribution of Pb in sea surface. Determinations of Pb contents and isotope ratios were conducted using inductively coupled plasma mass spectrometer (ICP-MS) and multiple collector ICP-MS, respectively (Inoue et al., 2006; Tanimizu and Ishikawa, 2006). The spatial distribution of Pb showed a clear dilution pattern of Pb from Asian continent to the open ocean. In addition to the spatial distribution, Pb contents in Ogasawara coral have gradually increased during last 108 years. Although Pb emitted from Japan seems to be main source during the period of 1960 – 1980, that from China might be predominant source of Pb affecting on the western Pacific for the last 20 years based on the variation of Pb isotope ratios in the coral core.

Peridotite xenoliths from the andesitic Avacha volcano, Kamchatka – Any signatures of subduction metasomatism?

We report chemical data, Os- and Li-isotope ratios, PGE abundances and \( f_{O_2} \) estimates for peridotite xenoliths from the active Avacha volcano in southern Kamchatka peninsula, Russia. The rocks are large, fresh and homogeneous spinel harzburgites that contain accessory interstitial cpx and amphibole as well as highly variable amounts of fine-grained, second-generation orthopyroxene (opx). None of the samples have intrusive magmatic or metasomatic veins.

Major and trace element compositions were obtained for 17 peridotites. The whole-rocks contain 0.4-0.9% \( \text{Al}_2\text{O}_3 \), 0.5-0.9% \( \text{CaO} \), <0.03% \( \text{Na}_2\text{O} \), <0.01% \( \text{K}_2\text{O} \); Mg\# = 0.906-0.916. They are highly refractory rocks produced by high degrees of melt extraction, but their Mg\# are lower than in many other (Ca,Al)-poor mantle peridotites. The Avacha xenoliths have low HREE and are depleted in LREE and MREE relative to HREE. The rocks show minor enrichments in Rb, Ba, U and Sr relative to adjacent REE but no significant Zr, Nb or Ti anomalies. Overall, they show no enrichment patterns considered typical of “subduction” metasomatism.

The rocks have 2.7 to 9.6 ppb Os; \( ^{187}\text{Os}/^{188}\text{Os} \) range from 0.1235 to 0.1319 and are positively correlated to Al contents. This “alumichron” is not likely to be related to ancient melt extraction. Rather, it may reflect a correlation between the amounts of slab-derived radiogenic Os and those of late-stage amphibole and pyroxenes added by percolating fluids. Li abundances in whole-rocks, olivine and opx range from 0.8 to 1.8 ppm, i.e. match estimates for melting residues. \( \delta^7\text{Li} \) range from -2 to +4.7‰, with averages for olivine, opx and WR from +1.7 to +2.7‰, i.e. are within the range reported for oceanic basalts and “normal” mantle. \( \Delta \log f_{O_2} \) determined using measured \( \text{Fe}^{3+}/\text{Fe}^{2+} \) in spinels are FMQ +0.1 to +1.8.

Relatively high \( f_{O_2} \), Os abundances and \( ^{187}\text{Os}/^{188}\text{Os} \) in several Avacha peridotites might be related to enrichments by slab-derived fluids but these are decoupled from trace element and Li-isotope signatures, which show no or little evidence for metasomatism. The slab-derived fluids may be largely consumed by reaction with wall-rocks in the lower mantle wedge, with only small amounts of residual fluids occasionally reaching the shallow uppermost mantle sampled by the Avacha xenoliths.

Re-Os evidence for ancient mantle beneath the Ontong Java Plateau

A. ISHIKAWA, D.G. PEARSON and C.W. DALE

Department of Earth Sciences, Durham University, UK (akira.ishikawa@durham.ac.uk)

We have carried out a Re-Os isotope study of a suite of peridotite xenoliths from Malaita, Solomon Islands in order to better understand the nature and formation of oceanic lithosphere beneath the Early Cretaceous Ontong Java Plateau (OJP). Thermobarometric and petrochemical evidence reveal that the xenoliths represent virtually the entire section of subplateau lithospheric mantle (<120 km) which is stratified in compositional [1]. Os isotope data have been obtained for samples covering the whole range of \( P-T \) and depletion.

Whole-rock analyses of peridotites from the shallow part of the lithosphere (<95 km) yield an average \( ^{187}\text{Os}/^{188}\text{Os} \) ratio of 0.1247 (n=15) and a range from 0.1223 to 0.1272, illustrating an affinity with abyssal peridotites (whole-rock mean ~0.1246) [2]. This is consistent with previous Sm-Nd results indicating a recent (Jurassic) mid-oceanic ridge origin for the shallow lithosphere [3]. By contrast, the deep-seated peridotites (>95 km) show much greater variation in Os isotope composition that is correlated with differences in rock types: garnet lherzolites have limited \( ^{187}\text{Os}/^{188}\text{Os} \) variations (0.1244-0.1254); spinel harzburgites record unradiogenic \( ^{187}\text{Os}/^{188}\text{Os} \) ratios (0.1174-0.1196); Fe-rich garnet lherzolite from the deepest portion possesses the most unradiogenic ratio (0.1156). These unradiogenic ratios yield Proterozoic model \( T_{BD} \) ages of 1.2-1.8 Ga, demonstrating the existence of ancient mantle in the basal section of subplateau lithosphere.
